Preface

The field of Transplant Infectious Diseases has emerged over recent decades to meet the challenges of caring for immunocompromised solid organ and stem cell transplant recipients. Innovations in surgical and cellular therapies and changes in transplant immunosuppression have impacted the variety of bacterial, viral, fungal, and parasitic organisms that may cause disease in this population. Transplant programs worldwide now recognize the need for expertise in the management of infectious complications and consider infectious disease specialists an essential part of the transplant team. Clinical trials in post-transplant prophylaxis and treatment have optimized the understanding of common infections such as cytomegalovirus, facilitating the establishment of clinical guidelines. Such guidelines are constantly subject to modification as ongoing changes in antimicrobial susceptibility have altered historically validated approaches to infection management. New guidance has also been required to address unique presentations of infections previously rarely seen in transplant recipients. Current transplant protocols must reflect the impact of global human migration and expanded access to transplantation in patients with previous exposure to rare tropical diseases. Trials of new immunotherapeutic agents are essential as we improve management of transplant rejection or disease relapse, but may facilitate the emergence of latent or previously unrecognized microorganisms. Novel molecular diagnostics have led to the identification of new pathogens which may be observed first in this vulnerable patient population. For the transplant teams seeking to optimize management of these infections, a comprehensive textbook which can be regularly updated is most welcome.

This premier edition of the *Emerging Transplant Infections* textbook was prepared by an international team of experts to provide an authoritative and current resource for transplant specialists seeking up-to-date guidance in the diagnosis and treatment of infectious complications of transplant. Information can be accessed electronically via SpringerLink or through current and future editions of the printed textbook. Chapters will be added and updated to reflect the constantly changing nature of the field. This edition contains 69 chapters divided into seven parts. The introductory part provides an overview of the field and encompasses general topics including transplant immunosuppression, infection control and prevention, and pre-transplant screening. This is followed by four pathogen-based parts devoted to bacterial, viral, fungal, and parasitic diseases of major importance in transplant

candidates and recipients. Authors were asked to share information on disease epidemiology, diagnosis, and management with an emphasis on the clinical impact on both solid organ and stem cell transplantation. A part focused on emerging clinical challenges follows which addresses cardiac device infections and other new areas of focus in the transplant world. The final part provides invaluable information using a syndrome-based approach that will enhance the ability of all readers to identify emerging infectious diseases. Chapters include dermatologic and ophthalmologic presentations as well as a review of emerging diagnostics and a section devoted to pediatric diseases.

It has been over three years since three Transplant Infectious Disease physicians joined together to develop a clinical reference that would assist our colleagues in navigating the challenging and rapidly changing field of emerging infections in transplantation. This project would not have been possible without the outstanding work of an international team of authors who were willing to dedicate their time and expertise in support of this effort. Many thanks to all of the contributors for their invaluable assistance. Thanks also to the editorial staff at Springer Nature, including Nadina Persaud who conceived of the project in late 2017, Alexa Steele who guided us in development, and Sonal Nagpal who provided us consistent production support throughout the project. We hope this collection is not only a useful tool in clinical care but also reflects the passion and commitment of all of us to share our knowledge with the goal of improving outcomes for the transplant patients who entrust us with their care.

Contents

Volume 1

Part I General Introduction 1

1 Impact of Infection on Transplant Outcomes: Transplant Infectious Disease Expertise as an Essential Component of Transplant Programs 3
Michele I. Morris

2 Introduction to Immunosuppression, Tolerance, and Infection Risk 11
Cameron R. Wolfe

3 Changing Definition of Immunosuppression: Targeted Therapies and Resulting Emerging Infections and Their Prevention 25
Nicolas J. Mueller

4 Stem Cell Transplantation: Infection Risk by Transplant Type and Emerging Trends in Infection Management 43
Gowri Satyanarayana, Katie S. Gatwood, and Whitney J. Nesbitt

5 Evolving Epidemiology of Transplant Infections: Impact of Population Shifts and Climate Change 83
Tirdad T. Zangeneh and Mohanad Al-Obaidi

6 Hospital Epidemiology and Infection Control in the Transplant Center 99
Gopi Patel and Sarah Hochman

7 Antimicrobial Stewardship for Transplant Candidates and Recipients 131
Catherine Liu and Erica J. Stohs

8 Antimicrobial Prophylaxis in the Age of Emerging Transplant Infections 155
Jonathan Hand

9 **Pretransplant Screening for Infection Exposure: Approach to the Patients with Epidemiologic and Geographic Risk Factors** . . . 171
Deepa Nanayakkara and Joanna Schaenman

10 **Transplant Tourism and the Traveling Transplant Recipient: Infection Mitigation and Treatment Strategies** 201
C. Arianne Buchan

11 **Preventative Health in Solid Organ Transplant: Safe Living Post-transplant** 239
Barbra M. Blair

12 **Vaccination Strategies in Solid Organ and Stem Cell Transplant** 253
Shilpa R. Jain and Deepali Kumar

Part II Bacterial Infections Introduction 285

13 **Multidrug-Resistant Organisms: Pre-transplant Evaluation and Management** 287
Anoma Nellore and Rachael A. Lee

14 **Multidrug-Resistant Organisms: Posttransplant Management for Extended-Spectrum Beta-Lactamase Producers and Carbapenem-Resistant Enterobacterales** 313
Jessica Howard-Anderson and Stephanie M. Pouch

15 ***Pseudomonas aeruginosa* Infections in Transplant: Epidemiology and Emerging Treatment Options** 343
John I. Hogan, Brandon K. Hill, and Costi D. Sifri

16 **Management of Acinetobacter Infections in the Immunosuppressed Host** 371
Emily Baneman and Meenakshi M. Rana

17 ***Burkholderia* in Transplant: Important to Speciate and Important to Treat** 391
Gregory Snell, Olivia Smibert, and Elizabeth Tullis

18 ***Mycobacterium tuberculosis* in Transplantation** 409
Aruna K. Subramanian

19 **Rapidly Growing Mycobacterial Infections in Transplant: Evolving Epidemiology and Treatment Options** 425
Nicholas A. Turner and Arthur W. Baker

20 **Slow-Growing Nontuberculous Mycobacteria in Transplant** 459
Esther Benamu and Joanna Nelson

21 ***Nocardia* Infections in Transplantation: Diagnosis, Management, and Impact on Outcomes** 487
Reuben J. Arasaratnam and Alejandro Restrepo

22 ***Mycoplasma* and *Ureaplasma* Infections in Transplantation: A Big Impact Despite the Lack of a Cell Wall** 505
Peter W. Schreiber and Nicolas J. Mueller

23 **Clostridioides Difficile: Where Should the Management Strategies in Transplant Vary?** 519
Jennifer C. Pisano and Kathleen M. Mullane

Volume 2

Part III Viral Infections Introduction **545**

24 **Cytomegalovirus in Solid Organ Transplant Recipients: Prevention, Diagnosis, and Treatment** 547
Camille Nelson Kotton

25 **Cytomegalovirus in Hematopoietic Stem Cell Transplant Recipients: Prevention, Diagnosis, and Treatment** 573
Jose F. Camargo

26 **Herpes Simplex and Varicella Zoster in Transplant Candidates and Recipients** 617
Richard A. Zuckerman

27 **Epstein-Barr Virus and Posttransplant Lymphoproliferative Disorders** 655
Masaki Yamada, Andrew Nowalk, and Michael Green

28 **HHV-6, HHV-7, and HHV-8: Forgotten Viruses in Transplantation** 683
Ghady Haidar

29 **Influenza Infections in Solid Organ and Stem Cell Transplant Recipients** 709
Yoichiro Natori

30 **Respiratory Syncytial Virus in Transplant: Stopping the Short-Term Spread, Solving the Longer-Term Problems** 725
A. J. Wright and A. Mah

31 **Respiratory Viral Pathogens in Solid Organ and Hematopoietic Stem Cell Transplant Recipients** 743
Steven A. Pergam and Michael G. Ison

32 Transplant Adenovirus Infection: Clinical Syndromes, Diagnosis, and Management 781
Maricar Malinis and Marwan M. Azar

33 BK Polyomavirus After Solid Organ and Hematopoietic Cell Transplantation: One Virus – Three Diseases 807
Fabrice E. Graf and Hans H. Hirsch

34 Challenges of Human Papillomavirus Infection in Solid Organ and Hematopoietic Stem Cell Transplant Recipients 833
Cristina Brickman and Peter Chin-Hong

35 Solid Organ Transplantation in HIV Positive Patients 859
Elmi Muller and Peter Stock

36 Hepatitis A Infections in Transplant 877
Rebekah J. Lane

37 Hepatitis E Infections in Transplants 909
Olivier Marion and Nassim Kamar

38 Hepatitis B and Hepatitis D Infections in the Transplant Setting 927
Brian Kim and Norah A. Terrault

39 Emerging Management of Hepatitis C in Transplant 951
Lorena Puchades and Marina Berenguer

40 West Nile Virus and Transplantation 971
Marilyn E. Levi and Marian G. Michaels

41 Emerging Tropical Viral Infections: Dengue, Chikungunya, and Zika 987
Alexandre Machado de Sant' Anna Carvalho and Clarisse Martins Machado

42 Yellow Fever: Prevention in Transplant Candidates and Emerging Treatment Data for Liver Transplant 1011
Alice Tung Wan Song and Luiz Augusto Carneiro D'Albuquerque

43 Viral Encephalitides Including Rabies and Lymphocytic Choriomeningitis Virus: Impact in Transplant Donors and Recipients 1027
Aalok Khole and Nicole M. Theodoropoulos

Part IV Fungal Infections Introduction **1043**

44 *Candida* Infections in Solid Organ Transplantation 1045
Nicolas Barros and Michael K. Mansour

45 *Aspergillus* in Solid Organ and Stem Cell Transplant Patients: Emerging Options for Diagnosis and Management 1077
Armelle Pérez-Cortés Villalobos and Shahid Husain

46 Management of Mucorales Infections in Transplant Patients 1109
Sharon C.-A. Chen and Monica A. Slavin

47 Non-*Aspergillus* Fungal Infections in Transplant Patients 1139
Sanjay G. Revankar

48 Management of Cryptococcosis in Transplant Candidates and Recipients 1155
John W. Baddley and Graeme N. Forrest

49 *Pneumocystis jiroveci* in Transplant: Recognizing Risk, Understanding Prevention, and Implementing Treatment 1183
Shmuel Shoham and M. Veronica Dioverti Prono

50 Coccidioidomycosis in Transplantation 1207
Brandon T. Nokes and Janis E. Blair

51 Emerging Epidemics in Transplant: Histoplasmosis, Blastomycosis, and Paracoccidioidomycosis 1225
Jeremy Nel, Anne Lachiewicz, and David van Duin

Volume 3

Part V Parasitic Infections Introduction 1251

52 *Toxoplasma gondii* in Solid Organ and Stem Cell Transplant: Prevention and Treatment 1253
Hélène Guegan and Florence Robert-Gangneux

53 Strongyloides: Emerging Challenges and Prevention 1281
Ricardo M. La Hoz and Alfredo G. Puing

54 Chagas Disease: Coming to a Transplanted Patient Near You 1293
Lígia Camera Pierrotti and Karim Yaqub Ibrahim

55 Leishmaniasis in Transplant Candidates and Recipients: Diagnosis and Management 1341
Wanessa T. Clemente and Paulo H. O. Mourão

56 Malaria in Transplant Candidates and Recipients: Diagnosis and Management 1373
Pilar Martín-Dávila, Francesca F. Norman, and Rogelio López-Vélez

57 Pathogenic Intestinal Parasites in Transplant Recipients 1397
Joelle I. Rosser and Brian G. Blackburn

58 ***Acanthamoeba*, *Naegleria*, and *Balamuthia* in Transplant Patients: An Emerging Threat** 1451
Yoram A. Puius, Margaret L. Aldrich, and Jennifer R. Cope

Part VI Emerging Clinical Challenges **1473**

59 Ventricular Assist Devices, ECMO, and Cardiac Support Devices: Challenges in the Bridge to Transplant 1475
Hao Tran and Saima Aslam

60 Emerging Transplant Infections: Cystic Fibrosis 1495
Omar H. Mohamedaly and Carrie A. Johnson

61 Vascular Composite Allografts (VCA): New Transplants, New Infections 1513
Julie M. Steinbrink, Timothy L. Pruett, and Linda C. Cendales

Part VII Considering Emerging Infections in Differential Diagnosis **1533**

62 Emerging Diagnostics for Transplant Infectious Diseases 1535
Marwan M. Azar, David C. Gaston, and Maricar Malinis

63 Rashes to Recognize in the Immunocompromised Transplant Patient: Focus on the Solid Organ Transplant Recipient 1577
Melodi Javid Whitley, Adela R. Cardones, and Sarah A. Myers

64 Ophthalmic Infections in Transplant 1595
Jacob E. Lemieux, Lucia Sobrin, and Miriam B. Barshak

65 Pulmonary Syndromes in Transplantation 1615
Sonya Trinh and Alfred Luk

66 Diarrhea in Transplant: Diagnosis and Management 1639
Diana F. Florescu and Andrea Zimmer

67 Altered Mental Status in the Solid Organ Transplant Recipient . . . 1661
Dilek Ince

68 Transplant Infectious Disease Evaluation of Cytopenias 1673
Rachel Miller and Annette Schlueter

69 Common and Emerging Infections in Pediatric Transplant Recipients 1709
Jennifer E. Schuster, Hilary Miller-Handley, and Lara Danziger-Isakov

Index 1727

About the Editors

Michele I. Morris, M.D., FIDSA, FAST, is Professor of Clinical Medicine and Director of the Immunocompromised Host Service in the Division of Infectious Diseases at the University of Miami Miller School of Medicine. She has spent the last 17 years of her career focusing her clinical practice and research efforts on transplant infectious diseases, with special attention to the area of emerging infections in transplant. Dr. Morris is also Medical Director of Infection Control and Antimicrobial Stewardship at Sylvester Cancer Center, and Fellowship Director of the Transplant Infectious Diseases fellowship at the University of Miami/Jackson Memorial Hospital. She has published over 90 peer-reviewed articles and 8 book chapters. Dr. Morris has delivered numerous presentations at national and international meetings, including invited lectures on five continents. She is a past president of the Transplantation Society's Transplant Infectious Disease Section. She is an active member of the American Society of Transplantation's Infectious Diseases Community of Practice (ID-COP), and a previous executive board member.

Acknowledgments:
I am privileged to be a member of the international community of transplant infectious disease specialists whose outstanding teamwork is demonstrated in this textbook. An enormous thanks to Camille Kotton and Cameron Wolfe – your dedication and incredible collaboration made this project possible. Thanks also to my daughters Elana and Kayla, who somehow taught me more about life and love (and popular culture) than I could ever teach them. And to my husband, Joel Fishman, who has been there since the beginning,

thank you for sharing your life with me. Your unwavering love and support has shaped my growth as a physician and a person.

Finally, from all of us in the field of Transplant Infectious Diseases, thank you to our amazing patients for your resilience and optimism and to transplant donors everywhere for making it all possible.

Camille Nelson Kotton, M.D., FIDSA, FAST, is Clinical Director of the Transplant Infectious Disease and Immunocompromised Host Program at the Massachusetts General Hospital and Associate Professor of Medicine, Harvard Medical School, Boston, Massachusetts. She was chair of the Infectious Disease Community of Practice of the American Society of Transplantation (2012–2018). From 2007 to 2013, she was the president of the Transplant Infectious Disease Section of The Transplantation Society. Highlights of her time as president include the development of international guidelines on CMV management after solid organ transplant, published in *Transplantation* (2010, 2013, 2018). She is the first transplant infectious disease specialist to be a councilor of The Transplantation Society (2020). Her clinical interests include cytomegalovirus, donor-derived infections, zoonoses, and travel and tropical medicine in the transplant setting.

She would very much like to thank her family for their wonderful support over the years, including her sons Benjamin and David, and her husband Darrell, both for extensive homework projects like this one, and for strength during the COVID-19 pandemic.

Dr. Cameron R. Wolfe is an Associate Professor of Medicine in the Division of Infectious Disease at Duke University, specializing in transplant infectious diseases emerging pathogens, HIV, and viral hepatitis. He grew up and trained in Australia, and has research interests in the management of pandemic disease in the general community and especially respiratory viruses in the immunocompromised. He lectures at the University of North Carolina, School of Public Health, as well as the Duke University Medical School. More than anything, Cameron is proud of the grace shown by his two sons, Callum and Lachlan, and his wife, Sarah, as this project has come to fruition!

Introduction

As an introduction to this textbook focused on emerging transplant infections, it is appropriate to begin with the emergence of the burgeoning field of transplant infectious diseases. Outcomes for both solid organ and hematopoietic stem cell transplantation have improved with the development of safer and more effective immunosuppression. Techniques in organ procurement and preservation as well as methods for hematopoietic stem cell harvest and infusion have evolved, contributing to significant expansion in the availability and safety of transplant. As transplant procedures have become more routine and better standardized, improved access to transplantation services internationally has expanded the number of potential recipients and the variety of infectious complications. Most recently, recognition of the relative importance of infection prevention and treatment in overall transplant success has reinforced the essential role of transplant infectious diseases subspecialists in the management of solid organ and hematopoietic stem cell transplant candidates and recipients.

The Essential Role of Infectious Disease Specialists in the Care of Transplant Patients

Infectious complications are now a more frequent cause of hospitalization after solid organ transplant than allograft rejection, largely due to the use of more efficacious and potent immunosuppressive therapies [1]. In a review of 1414 hospital admissions of 531 solid organ transplant recipients at a tertiary transplant center, infectious disease complications were identified in 603 (43%) of the admissions impacting 306 (58%) of the patients studied with an associated 10% inhospital mortality [2]. The major cause of mortality in hematopoietic stem cell transplant recipients is relapse of the primary disease, but non-relapse mortality (NRM) is frequently attributed to infection. The Center for International Blood and Marrow Transplant Research (CIBMTR) reported mortality data for US stem cell transplant recipients undergoing transplant in 2015–2016. Overall mortality within the first 100 days of allogeneic transplant was attributed to infection in 19% of HLA-matched sibling donor recipients and 21% of unmatched donor recipients [3]. A study of over 15,000 adult and pediatric stem cell transplant recipients who survived at least 2 years post-allogeneic transplant found infection to be a primary or contributory cause of mortality in 30% [4].

In both solid organ and hematopoietic stem cell recipients, the net state of immunosuppression significantly influences the risk of infectious complications. In addition to immunosuppressive medications, the patient's immune status is altered by other therapeutic interventions including surgical procedures and postoperative complications, the presence of indwelling catheters and drains, antineoplastic chemotherapy, and antimicrobial treatment. The overall level of immune dysfunction is also impacted by concomitant diseases such as diabetes, cirrhosis, renal dysfunction, genetic immunodeficiencies, and autoimmune conditions, as well as the presence of infections including cytomegalovirus, HIV, and hepatitis B and C. Immune modulation inherent to the transplant process may cause cytopenias which predispose to infection. Finally, the presence of allograft rejection and/or graft versus host disease alters the immune response of the transplant recipient well in advance of the effects of immunomodulatory therapies used to control these conditions. In the face of this multilayered attack on the immune defenses, a variety of opportunistic pathogens often emerge that require the assistance of experts in infectious disease diagnosis and treatment.

The importance of general infectious disease (ID) expertise in the successful management of common bacterial infections is well recognized. Multiple published studies from throughout the world have reported a significantly lower mortality rate in patients with *Staphylococcus aureus* bacteremia who received ID consultative care [5–11]. All of these studies included a significant immunocompromised population, with a variety of solid organ transplant and hematologic malignancy patients as well as others receiving cancer chemotherapy. Reported improvements in outcome were so profound that many hospitals have implemented mandatory infectious disease consultation for patients with *Staphylococcus aureus* bacteremia [12]. Improved survival has also been seen with early infectious disease (ID) consultation

in patients with candidemia [13, 14]. The benefits of ID involvement have been observed in the treatment of sepsis as well. In a study of emergency department management of severe sepsis, early involvement of infectious disease consultants was associated with increased identification of an etiologic diagnosis for sepsis (9% vs. 42%, $p < 0.001$) and more appropriate empiric antibiotic therapy (30% vs. 79%, $p < 0.001$) [15]. A review of Medicare claims submitted on behalf of over 200,000 hospitalized beneficiaries with a diagnosis of infection evaluated the impact of ID consultation on patient mortality, utilization of resources, and overall costs of care. This study found that the patient cohort treated with ID consultation demonstrated lower mortality (odds ratio 0.87) and fewer readmissions to the hospital (odds ratio 0.96) with no increase in Medicare charges and a 3.7% decrease in ICU length of stay. ID involvement within the first 2 hospital days was associated with lower 30-day mortality, 3.8% shorter overall and 5.1% shorter ICU hospitalizations, decreased readmission, and lower Medicare costs [16]. A French study of 4188 patient hospitalizations using the French national database revealed that patients receiving care in the ID ward had significantly lower mortality, shorter length of stay, and lower hospitalization costs [17].

The influence of infectious disease specialists on patient outcomes extends beyond the bedside due to the crucial role ID experts play in infection prevention. Medical center antimicrobial stewardship and infection control programs are of particular benefit to immunocompromised transplant candidates and recipients who often experience prolonged or recurrent hospitalization and are most vulnerable to infection. Numerous studies demonstrate the value of ID intervention in controlling antimicrobial resistance by lowering inappropriate antimicrobial use and implementing appropriate infection control interventions [18]. Active participation of transplant infectious disease specialists as leaders in infection prevention activities may improve transplant physician engagement and significantly benefit transplant outcomes [19].

Solid organ transplant patients with bacteremic sepsis are noted to have lower associated mortality than non-transplant patients, a finding that was attributed to immunomodulation of the inflammatory response due to immunosuppressive therapy [20]. This interpretation of the study findings was disputed in a letter that cited the importance of ID consultants as an integral part of the multidisciplinary transplant team, which may have improved access to early subspecialty care and could potentially impact sepsis outcomes in this population [21]. A Canadian study of transplant center admissions showed that ID consultation provided to solid organ transplant recipients was associated with increased hospital stay and costs but decreased 28-day mortality (hazard ratio 0.33) and readmission rates (16.9% vs. 23.9%). In the same study, early ID referral (within 2 days of admission) was found to reduce median length of stay and hospitalization costs [2].

A review of the specific benefits provided by ID participation in patient care attributed the improvement to specific diagnostic and therapeutic areas of expertise. These include the achievement of a more rapid diagnosis through the performance of a detailed history and physical examination and targeted use of laboratory testing, followed by timely initiation of appropriate antimicrobial therapy. Cognitive specialties such as ID have frequently been utilized through curbside consultation

without face-to-face direct patient interaction. Although informal telephone consultations may facilitate access to ID expertise in medical centers with limited staffing, the benefits afforded by ID involvement in patient care may be reduced. In one Finnish study of patients with *Staphylococcus aureus* bacteremia, clinical management incorporating bedside ID specialty consultation was associated with shorter fever duration ($p = 0.003$) and decreased mortality at 7, 28, and 90 days ($p = 0.001$, 0.001, <0.001, respectively) when compared with care supported through telephone ID consultation [22]. In addition to providing expedited diagnosis and treatment, ongoing infectious disease management by ID specialists may ensure adherence to the treatment plan and facilitate monitoring for drug-drug interactions and treatment-related toxicities. ID faculty may also provide support for the delivery of outpatient parenteral antimicrobial therapy to transplant recipients, which can shorten hospital stays and reduce costs [23].

It remains to be seen whether remote consultation through the use of electronic medical records will be effective in extending access to transplant ID expertise in areas that lack such ID specialty support. A recent study of electronic ID consultation in the US Veterans Administration system found that electronic consultations actually generated an increase in overall consult volume, with more rapid access to ID specialists supporting the time-sensitive clinical decisions often required in infection management [24]. As healthcare systems increasingly seek to manage patient populations in an effort to improve patient care and lower costs, outcomes data is needed to define the appropriate role for electronic consultation [25]. A systematic review of the use of provider to provider electronic consultation including literature from five countries concluded that further research is required to define the correct methods for implementation and safety and efficacy monitoring when clinical management is delivered remotely [26]. The allocation of remote access to the electronic medical records of transplant recipients has the potential to extend transplant center specialty care to patients who live far from major centers while insuring more accurate communication and comprehensive data transfer.

Expansion of the reach of transplant ID care is an emerging topic of interest, as the benefit of ID specialty care is not confined to major transplant centers. Despite the limited availability of trained ID specialists in many countries, there is growing worldwide recognition of the value of such expertise, including a detailed justification for the expansion of ID services in Germany medical centers [27]. In the United States, the national certification for transplant center approval and reapproval includes a requirement for access to ID specialists as an essential member of the clinical team [28]. Subspecialty training in transplant ID is now available at over a dozen centers in North America [29] with a recommended curriculum that includes training in the care of infections in solid organ and hematopoietic stem cell transplant recipients and frequently incorporates instruction in the management of infectious complications of cancer chemotherapy and mechanical circulatory support devices [30].

ID specialists have been recognized for their contributions to cancer care, including patients with hematologic malignancies and hematopoietic stem cell transplant recipients. Infectious complications cause half of all deaths in patients with acute myeloid leukemia (AML) and are a significant consideration for the timing of

consolidative chemotherapy and hematopoietic stem cell transplant in this population. Ninety five percent of AML patients experience at least one episode of neutropenic fever [31]. Inexperienced management may delay future chemotherapy leading to fatal disease progression. Close collaboration between hematologists and ID specialists familiar with leukemia care is now a recognized standard for a successful leukemia service [32]. A single-center retrospective review of outpatient ID consultative practice in a comprehensive cancer center found that ID specialists identified alternative diagnoses in 53% of consult patients, with 46% found to have a different infectious disease. Nearly one-third of patients (29%) were noted to have a noninfectious etiology for their clinical presentation. ID involvement was determined to significantly contribute to patient care in 62% of the 598 patient charts evaluated [33]. A review of ID specialty impact that included both inpatient and outpatient oncology practice data noted benefits including up to 34% increase in adherence to clinical guidelines, up to 52% increase in prescription of appropriate antimicrobial therapy duration, and up to 17% decrease in mortality [34]. The value of ID consultants in supporting transition of care after hospital discharge was also highlighted, along with their role in the prevention of recurrent and future infections.

The reemergence of vaccine preventable viruses such as measles in previously low-risk populations has underscored the importance of pre-transplant screening and vaccination of transplant candidates. Vaccination status should be reviewed and updated whenever possible, particularly in solid organ transplant candidates likely to respond prior to initiation of immunosuppression. In a study of 393 patients awaiting kidney or kidney pancreas transplant, those receiving ID care were significantly more likely to receive appropriate pre-transplant immunization [35]. Pre-transplant consultation also provides an opportunity to engage patients and their families in future infection prevention and safe living techniques more generally, including targeted counseling for the avoidance of identified microbial threats [36]. Consultation can also include travel medicine advice directed specifically to immunocompromised patients.

Recognition of the value that transplant ID specialists provide to a program is crucial, particularly since many infection prevention initiatives such as protocol development and antimicrobial stewardship cannot be financed through direct patient billing. A study of institutional support of ID specialists in North America found great variation between transplant centers, with a trend toward increased support in larger programs. In centers performing over 250 transplants annually, 80% of programs provided some financial support not obtained through individual patient care charges. Transplant ID programs were in place at 36 of the 42 transplant centers that participated in the study. The inclusion of ID subspecialists as part of the interdisciplinary transplant team was recognized in this study as the standard of care [37]. In an era in which post-transplant infections are a major factor impacting reportable metrics such as allograft and patient survival after transplantation, ID expertise is instrumental to the success of any transplant program. In this rapidly changing area of medical practice, ID specialists possess unique skills required to update transplant teams on the infection risks associated with novel immunosuppressants and the emerging pathogens that may harm patients receiving such therapies.

Among the challenges of transplant ID practice is the paucity of randomized clinical trials of infection management in the immunocompromised transplant population. Much of clinical care is based on single-center observational studies, individual case reports, and expert opinion. This is especially true for newer surgical and immunosuppressive techniques and also emerging biothreats. Guidance documents such as the latest edition of the solid organ transplant infectious diseases guidelines endorsed by the American Society of Transplantation's ID Community of Practice and published in 2019 in a special issue of Clinical Transplantation are invaluable as information sources [38]. Transplant ID specialists are frequently tasked to develop center specific protocols for infection screening and management focused on local exposure risk and practice. Protocol development and standardization of practice can lower patient morbidity and mortality, but infectious disease practice is constantly changing [18]. The ongoing emergence of new and increasingly resistant infectious pathogens such as *Candida auris* and the worldwide spread of the SARS-CoV-2 virus and other treatment resistant viruses are good examples. Expansion of older threats like influenza and measles disproportionately impacts immunocompromised populations. Climate change and global warming accelerate vector expansion, thereby enhancing disease spread. Changing immigration patterns and worldwide travel have erased the borders that previously protected transplant recipients from exposure to exotic geographically restricted organisms. Recognition of the unique and sometimes atypical presentations of such rare infections in an immunosuppressed transplant patient is an essential part of modern transplant practice. All of these factors mandate the development of a textbook devoted to *Emerging Transplant Infections*.

Conclusion

This collection will highlight the cutting-edge information required to provide transplant care today. Each chapter is focused on a unique problem or pathogen-facing transplant professionals. The international team of experts have been tasked with creating a concise overview of the latest knowledge in the field of transplant infectious diseases. The outstanding work of these well-recognized professionals will be a contribution to this emerging subspecialty, but no textbook can ever replace the value of bedside consultation with transplant ID specialists. As clinical practice evolves and new microbiologic threats emerge, this living textbook can provide a roadmap to guide ID specialists in the care of their most challenging and vulnerable patients.

Introduction

The human immune system is arguably one of the most complex, multifaceted systems in the human body, comprising not only fixed, evolutionarily older components, known as the innate immune system, but also adaptable arms capable of learning and remembering pathogens. These are commonly referred to as the adaptive immune system. For both hematopoietic stem cell transplantation (HSCT) and solid organ transplantation (SOT), as our understanding has grown of the roles the immune system plays in graft rejection, tolerance, and infection, so too have our

techniques been refined to try to strike a balance with therapeutic immunosuppression. We now recognize that rejection can be broadly divided into acute versus chronic rejection, and cellular versus antibody mediated rejection, although there is both overlap and interaction between each. Understanding the evolution of our immune system, the different pathways by which stimulation and proliferation occur, and the different timelines at play, can help us ensure our patients get the most out of their transplant.

Almost 70 years ago, when deceased donor kidney transplant was first attempted, organ rejection was rapid, given limited understanding of rejection, and no therapeutic avenues to impede the alloimmune response [1, 2]. In fact, initially, the only transplants that were successful for any length of time were between genetically identical donor and recipient pairs, such as the transplant between the Herrick twin brothers in 1954 in Boston [3]. Not long after that T cells were recognized as the major effector cells engaging the graft directly, leading to rejection. T-cell knockout mouse models were able to demonstrate that fully mismatched solid organ allografts underwent little or no rejection. When T cells were reconstituted, rejected ensued.

There are three key elements to any immunological decision faced by the human immune system. Each of these is areas for potential control in SOT, to prevent organs being rejected, and to ultimately allow tolerance. Firstly, cellular "context," that is, how efficiently adhesion molecules bind immune cells to foreign material, and how much co-stimulation exists allowing the response to be cemented. Secondly, "specificity," that is, an antigen's affinity for immune recognition after which activation begins. Finally, the "magnitude," that is, how much cytokine enhancement is present and therefore the degree by which immune activation is amplified.

Regarding specificity, immune recognition of foreign antigen is incredibly broad, especially via T-cell receptors. It evolves early in our life and yet remarkably allows for self-recognition. This usually occurs in the thymus, where immature thymocytes from the bone marrow undergo random reassortment of their TCR genes, and then checking for self-recognition. Cells that do not interact with the MHC complex and thereby are ineffective for the purpose of surveillance are apoptosed. Subsequently, cells with high-affinity for self-recognition are also destroyed, thereby minimizing risk of auto-immunity and leaving only cells that are active, and primed to recognize anything else.

In regards to the "context" of an immune system interaction, binding of any foreign material – specifically donor tissue in the case of organ transplant – to the recipient's immune system should not be viewed as a static process. Binding can be enhanced or restricted by inflammation. It can also be pharmacologically blocked by co-stimulation blocking drugs, thereby altering the magnitude of any immune response, even when recognition of foreign material is underway.

Time and recipient age also impacts immune system responsiveness, and therefore likelihood of rejection. Over time, "immunosenescense" begins – this is characterized by reduced thymus activity and increased reliance on homeostatic proliferation, that is, the response to things seen before, rather than the ability to respond robustly to new foreign entities. This leaves the immune system both prone to greater infection, but also potentially more tolerant of the foreign antigen

challenge posed by transplantation [4]. In another way, the naïve (hard to activate) immune system of a patient's youth moves to the memory (easy to activate and strong effector) state of our adulthood, to the exhausted (easy to activate but largely impotent) immune state of our elder years. The impact on rejection and tolerance is therefore very different at different stages of our life.

Finally, the immune system and its responsiveness is impacted by many other variables, for example, loss of regenerative capacity as we age, infections and vaccines priming our memory, trauma to a solid organ graft itself, allowing inflammation and accelerated immunologic recognition to name a few.

T-Cell, B-Cells, and the Innate Immune System Involvement in Rejection

Alloimmunity is the process by which our adaptive immune system recognizes self, and also targets non-self-antigens. It is, therefore, the focus of the majority of antirejection efforts posttransplant. T-cell function plays the most significant role in alloimmunity, and therefore rejection, although B-cells and other adaptive antigen presenting cells (APC) also play a significant role in the identification and presentation of foreign material to the immune system. While there are two major alloantigens that we respond to, ABO blood group antigens and human leucocyte (HLA) antigens, this chapter will focus on the HLA interactions, as they appear the most significant for transplant [5].

Foreign antigen is usually recognized shortly after a solid organ transplant is reperfused. At that point, alloantigen is gathered and processed, typically by macrophages acting as an APC, but occasionally by other cells including dendritic cells and vascular endothelial cells [6, 7]. Presentation to the adaptive immune system occurs usually through 3 pathways: first, the CD3 complex on T-lymphocyte surfaces are engaged through T-cell receptor-major histocompatibility-allopeptide complex engagement (see Fig. 1). The second pathway occurs via cellular co-stimulation. Specifically, CD80/86 on an APC binds antigen to CD28 on a T-cell. Both pathway 1 and 2 result in positive signaling through the calcineurin-calcium pathway, in addition to upregulated NF-κβ and protein kinase signaling. These, in turn, lead to more interleukin-2 and other cytokines produced by the now activated T-cell. Negative feedback loops do exist to prevent overstimulation and ongoing ultimately damaging proliferation. For example, there are increased surface inhibitory molecules expressed on cytotoxic t-lymphocyte (specifically, "antigen 4," or CTLA-4) on an activated T-cell, which have a higher affinity to CD80 and 86, thereby reducing costimulation through CD28, and eventually bringing proliferation under control [8]. With the advent of many new "checkpoint inhibitors" that seek to take the harness off the immune system in cancer, we may see new avenues of immunomodulation enter the transplant space, although at this time, their role is unclear. A final pathway exists, whereby secreted IL-2 binds to the IL-2R on the surface of T-lymphocytes. This activates the mammalian target of rapamycin (mTOR), which in turn regulates cellular proliferation and amplification.

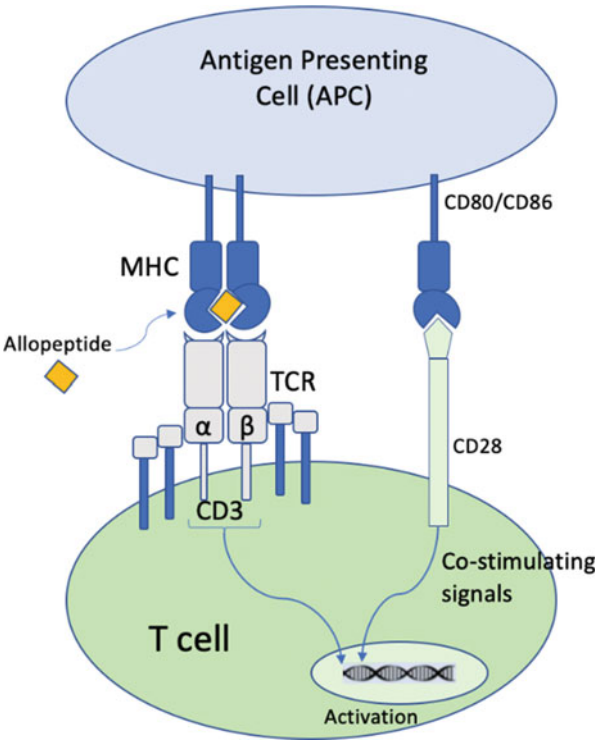

Fig. 1 T-cell receptor-major histocompatibility-allopeptide complex

Allorecognition also occurs via both donor and recipient APCs. Donor APCs within a graft can migrate out to present donor antigen to the recipient's immune system. This is sometimes referred to as "direct allo-recognition." Whereas when the recipient's antigen presenting cells penetrate the donor tissue, an MHC-II response occurs, with more intense reactivity resulting.

T-cell mediated rejection is most likely in the first year after transplant and diminishes thereafter, as graft tolerance develops. Risk factors for cellular rejection include presensitization (where the presence of donor-specific antibodies (DSAs) already exist, or where a recipient's propensity to react against a wide variety of human population tissue is already high (measured by "panel reactive antibody" or PRA). Additional factors include African-American ethnicity, prolonged cold ischemia time (see below), delayed graft function, and recipient age 18 years of age or younger. Finally, those with a previous episode of rejection, patients receiving their second transplant, and those who are noncompliant with medication are all at greater risk [9].

B cells also typically become upregulated in rejection. When a B-cell encounters antigen bound to complement, particularly in the presence of activated T-lymphocytes, the antigen can be internalized by the B-cell Receptor on the cell surface, fragmented, and returned to the surface via CD40 receptors. With the help of

T-lymphocytes (specifically the CD40-Ligand on their surface), B cells become activated, proliferate, and differentiate under the influence of IL-4, 5 and 6 [5]. B cell proliferation leads to direct differentiation into the relatively short-lived plasma cell, whose principal function is the amplified production of antibody. Ultimately therefore the end point of B-cell involvement in the immune response to transplant is to increase antibody-mediated rejection risk.

When acute antibody mediated rejection is occurring, antibodies typically bind to endothelium within the graft, thereby triggering further immune system activation through complement-dependent and independent mechanisms. Complement activation in turn recruits NK cells, neutrophils, and macrophages into graft tissue, leads to enhanced platelet aggregation, and ultimately generates capillaritis, thrombotic microangiopathy, and tissue destruction with a reduction in function of the graft. Although the clinical appearance of antibody-mediated rejection may appear different in different tissues, the immunologic pathway is the same. In kidney transplant, for example, glomerulitis is the most visible endpoint. In a lung transplant, acute capillaritis is also seen, although diffuse alveolar damage or organizing pneumonitis can also be present, mimicking infection [10]. Although there are acute and chronic forms of antibody mediated rejection, they present differently across the spectrum of SOT tissue types and are beyond the scope of this chapter.

Ultimately, more so than B-cells, T-lymphocytes are both sufficient and necessary for rejection of allogenic tissues, both solid organ and HSCT. Patients that are at high risk for T cell-mediated rejection (TCMR) are also at high risk for antibody-mediated rejection (ABMR).

Consequently, most antirejection focus is appropriately directed towards their control (refer to later in this chapter, and also to ▶ Chap. 3, "Changing Definition of Immunosuppression: Targeted Therapies and Resulting Emerging Infections and Their Prevention," by Nicolas J. Mueller for further details). However, the innate immune system does play a role, in fact one that can present earlier than the T cell response. In reality, the innate and adaptive immune systems are involved in a complex multifaceted interaction that is beyond the focus of this chapter.

One area where the innate immune system is particularly important for SOT is the injury and rejection associated with cold-time ischemia and reperfusion damage. Procurement injury and ischemia-reperfusion injury occur to varying degrees in all grafts, more for those with longer "cold-times" out of the body or with inadequate tissue perfusion during a donor's terminal illness. As a result of these antigen-independent insults and the consequent cellular damage in the grafted organ, a number of chemicals signaling "danger" to the primitive elements of the immune system are released. These include heparan sulfate, hyaluronan, heat-shock proteins, and the HMGB1 (high mobility group box 1) protein from within the nucleus. Such danger signals activate toll-like receptors (TLRs) and the pro-inflammatory RAGE (Receptor for Advanced Glycation End-products) that are found on donor dendritic cells (which act as APCs) thereby enhancing the subsequent adaptive immune response previously described. Expanding the discussion of Toll-like receptors (TLRs), these are in fact seen in multiple innate cells including macrophages,

epithelial cells and neutrophils, as well as dendritic cells. They recognize a variety of pathogen-associated molecular proteins, many common in transplant (viral hepatitis, cytomegalovirus (CMV), respiratory syncytial virus, herpes simplex virus, etc.) but can also help regulate rejection [11]. As more has been learned about the role of TLR's in graft regulation, especially when combined with clinical data about longer term sequelae, it became clear that the response to injury sustained during the transplant process was directly tied to subsequent allograft rejection and therefore should be minimized if at all possible [12, 13].

Other Elements of the Immune System Involved in Transplantation

We have a more nascent understanding of a number of the elements of the immune system, as they pertain to rejection and tissue tolerance. NK cells are one of the cellular arms of the innate immune system involved in rejection of transplanted tissue. Although technically lymphocytes, they lack the adaptive elements associated with the thymically nurtured T cell receptor. After a transplant, NK-cells are rapidly activated and contain KIR (killer cell immunoglobulin-like receptors) on their surface which regulate the killing activity of the cell; with more binding to self-aligned receptors on the graft tissue, KIR cannot activate the killing function of the NK cell. With less binding, that is, through a missing-self strategy, activation of cell occurs leading to tissue destruction [14]. NK cells typically act indirectly on their target cells, inducing apoptosis via granzyme and perforin release. Furthermore, NK secrete proinflammatory cytokines – specifically IFN-γ and TNF- α to increase expression of APC MHC molecules and costimulation receptors. This has the effect of promoting APC maturation and thereby amplification of T cell alloreactivity.

However, the precise role of NK cells in solid organ rejection is not as clear as their T cell cousins [15]. Firstly, there is some data to support the ability of NK cells to tilt the balance of overall Th1 (proinflammatory) and Th2 (regulatory) response, thereby actually promoting tolerance under certain circumstances. They can do this by focusing their toxic cytokine response on APCs themselves, thereby decreasing drive to alloreactivity [16]. Interestingly, standard immunosuppression appears not to have as much impact on NK cell activity as it does on T cells; we do not have enough understanding of the impact of novel therapeutics on NK function and number to consider directed therapy at this time.

Technically, the human microbiome is also part of innate immunity, providing host defense through the breadth and magnitude of microbial flora. It also helps modulate the balance between inflammation and immune homeostasis in both the nontransplanted and allografted patient [17]. Frequently during HSCT and SOT, the microbiome is damaged, either through the direct impact of antimicrobials, or as a result of surgical techniques and immunosuppression. Current research efforts designed to improve understanding of the role of the microbiome in regulating rejection and tolerance are ongoing.

Therapeutics Impacting Immunosuppression

Perhaps the easiest way to think about therapeutic immunosuppression as it pertains to SOT is to break up interventions into those occurring at the time of transplant, typically known as "induction therapies," and those occurring under more chronic situations, known as "maintenance therapy." In the sphere of HSCT, typically maintenance therapy is instituted with an aim of reducing the transplanted bone marrow's recognition of the host. Many new therapeutics and biologic agents are being developed that act on very focused sections of the immune system. Some of these are discussed in ► Chap. 3, "Changing Definition of Immunosuppression: Targeted Therapies and Resulting Emerging Infections and Their Prevention."

Induction agents are generally used to overwhelm the immune system for a short period of time; they are usually administered immediately prior to and just after transplantation. Their goal is to reduce acute rejection, typically in "high-risk" patients, as described earlier.

Cellular rejection therapy most commonly also mimics induction agents, with high-dose steroids followed by antibody therapy being the mainstay of most programs.

Common induction agents include corticosteroids (methylprednisone), polyclonal antibodies (antithymocyte globulin, antilymphocyte globulin), and monoclonal antibodies (alemtuzumab, basixilimab).

Maintenance agents typically begin shortly after transplant, are typically tapered steadily over the first 6–12 months after SOT, and try to strike a long term balance between rejection risk, infection risk, and side effect profile. Precise dosing is often required to achieve that balance, and therapeutic drug monitoring is often employed, often with the help of transplant pharmacists (Fig. 2). Common induction agents also include corticosteroids (prednisone), but additionally calcineurin inhibitors (tacrolimus, cyclosporine), antiproliferative agents (mycophenolate mofetil, azathioprine), mTOR inhibitors (sirolimus, everolimus) and co-stimulation blockers (belatacept).

Calcineurin Inhibitors

Long the backbone of most antirejection regimens across the world, calcineurin inhibitors work to block intracellular amplification of "nuclear factor of amplified T-cells" (NFAT), which subsequently blocks production of IL2, a major cytokine that stimulates T-cell activation and proliferation. Tacrolimus and cyclosporine are the two drugs in this class, both available in oral and IV formulations, with sublingual tacrolimus an option, and extended and short release versions of tacrolimus also available. Both are metabolized by both liver and kidney and excreted primarily in bile [18].

Common issues that ID physicians run into with calcineurin inhibitors include drug interactions, with azole antifungals, protease inhibitors, direct acting hepatitis C antivirals, and a number of antibiotics all having substantial impact on calcineurin metabolism. Common side effects of long term use include increased infection risk,

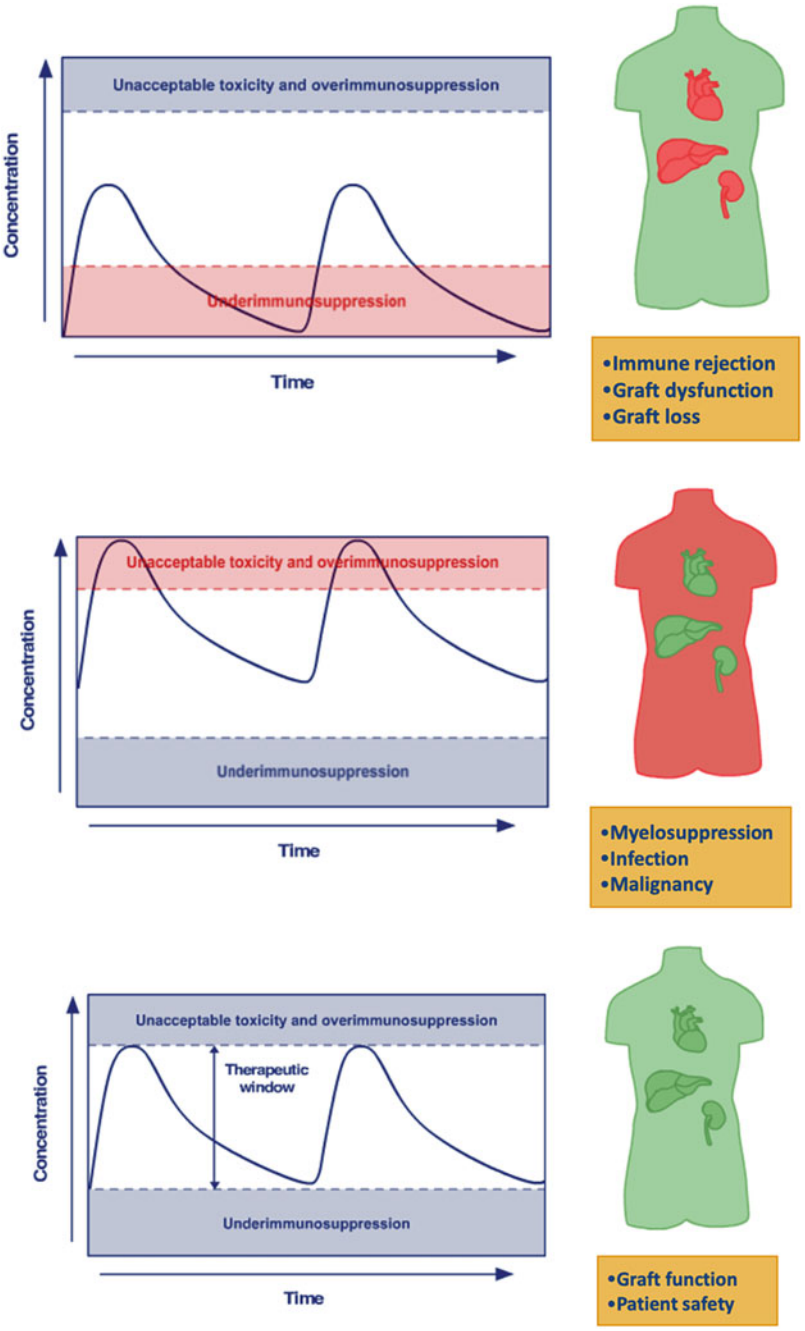

Fig. 2 Therapeutic drug monitoring for immunosuppression

especially in the viral, fungal, and mycobacterial realms, chronic renal dysfunction, hypertension, gum hyperplasia, tremors, and electrolyte disturbances.

Antiproliferative Agents

The two most common antiproliferative agents, azathioprine and mycophenolate mofetil, both act on intracellular components of lymphocyte division by decreasing the metabolism of purines and they may inhibit DNA and RNA synthesis. Azathioprine is used less commonly now, given long term risks with skin cancer development and the sense that mycophenolate seemed more efficacious in the long term. While both drugs lead commonly to dose-dependent cytopenias, mycophenolate is often associated with oral ulceration and chronic gastrointestinal side effects, especially diarrhea. The combination of oral ulceration, cytopenias, and diarrhea should make people consider mycophenolate toxicity, although often exclusion of infection is also required, especially CMV. Drug levels are available, specifically mycophenolic acid (MPA). Again, like the calcineurin inhibitors, the long term goal is to reduce antiproliferative dose to a minimum over the first year, thereby balancing risks and benefits [19, 20].

mTOR Inhibitors

Sirolimus and Everolimus are the two most widely available mammalian targets of rapamycin (mTOR) inhibitors, and work by blocking the signaling molecule that propagates the cell cycle and causes proliferation of T cells. Sirolimus was originally developed as an antifungal, although subsequently its immunosuppressive effects were noted. They are typically given in replacement of a calcineurin inhibitor, although can be given in addition to, or to supplement an antiproliferative agent in certain situations. Cytopenia and hyperlipidemia are commonly seen side effects, as well as impaired wound healing, something that has limited their wider use. Less common side effects include interstitial pneumonitis, which can be difficult to clinically separate from infectious pneumonia. Like the calcineurin inhibitors, they are extensively metabolized by the cyp450 system, and therapeutic drug monitoring is important [21].

Corticosteroids

Corticosteroids come in a variety of strengths and can be administered in a variety of ways, although they all fundamentally act to inhibit cytokine production and expression, thereby working as an anti-inflammatory. They suppress humoral responses also. At the cellular level, steroids passively diffuse through the outer membrane,

binding to intracellular receptors to form a complex that can move into the nucleus and interact with glucocorticoid-responsive elements (GREs). The interactions with GREs negate various proinflammatory genes, such as interleukin (IL)-1-alpha and IL-1-beta, as well as promoting the synthesis of numerous anti-inflammatory cytokines [22].

Prednisone is the most commonly used corticosteroid in the maintenance phase. Like most immunosuppressants, doses are tapered quickly over the first year of a transplant, often down to a chronic level of 5 mg/day, or discontinued altogether if a satisfactory level of tolerance is achieved. Side effects can be acute and long term. Acute issues include hyperglycemia, delirium, and insomnia. Longer term impacts include thinning of the skin, acne, Cushingoid body habitus changes, growth suppression, bone metabolic complications, glaucoma and cataracts, hyperlipidemia, and accelerated atherosclerosis. There is a dose-dependent infection risk and also suppression of endogenous adrenal function that results in a need to wean chronic steroids carefully.

Co-stimulation Blockade

Belatacept is a comparatively new form of immunosuppression, which binds to the CD80/86 on antigen presenting cells blocking T cell activation promoting anergy and apoptosis. Unlike other immunosuppressants, it is given as an IV infusion, typically monthly, although it may be used more frequently as an adjunct to induction therapy. Infection issues are uncommon but possible, with unique issues being seen in the EBV-naïve population who are at a markedly increased risk of EBV-associated posttransplant lymphoproliferative disorder (PTLD) should they acquire EBV through the transplanted graft or afterwards [23]. Furthermore, post-marketing surveillance has resulted in confirmed cases of aspergillosis, cryptococcal meningitis, and progressive multifocal leukoencephalopathy (PML) in $<1\%$ of patients treated with belatacept therapy [24].

Induction Therapies

A number of induction drugs can be used for transplant. Each of these also has a role to play in treatment of acute and sometimes chronic rejection. High dose corticosteroids are commonly used and have the same acute side effects as noted above. Additional agents include:

Anti-CD25 Monoclonal Antibodies

Basiliximab is the most commonly used of the monoclonal antibodies targeting CD25. It is a nondepleting chimeric/humanized monoclonal antibody, targeted against IL-2 receptors on activated T cells. As a result of its action, it blocks IL-2

mediated responses, thereby direction limiting T cell proliferation. The drug is typically administered intraoperatively [25].

Anti-CD52 Monoclonal Antibodies

Alemtuzumab is used frequently as an induction agent because of its profound and prolonged impact on lymphocyte function. As a humanized monoclonal, it results in antibody dependent lysis of T cells, B cells, NK cells, monocytes, and macrophages. CD4 cell counts have become a standard way of measuring the impact of alemtuzumab and often reflect substantial immunosuppression. Infection is the most significant side effect, particularly those impacted by impaired T-cell function (fungal infections, latent viruses, and mycobacteria). Given the impact can often last 6–12 months, most centers would combine the use of alemtuzumab induction with prophylactic antiviral and/or antifungal agents [26].

Polyclonal Antibodies

Two types of polyclonal antibody therapies exist: antithymocyte globulin, derived from rabbits, and antilymphocyte globulin, derived from horses. Both are produced by immunizing the animals with human cells and harvesting subsequent antibodies. Consequently, antibodies are produced against multiple targets within the human cell. This leads to the broad action of the drug, but also the multiple side effects. Some of the more immediate effects are infusional, and the products should be administered slowly, typically over 4–6 h, with premedication. Longer term side effects again stem from lymphocyte mediated infection risk [27].

Conclusion

Through continual advances in our understanding of the human immune system, we have been able to drive the fields of solid organ and bone marrow transplant forward. We now have far better ways to control and prevent rejection of solid organ transplants. Our recognition of the various ways our innate and adaptive immune systems interact to seek out and control infection and rejection has helped us control them. Although organ allograft rejection, and subsequent loss of graft function, remains one of the most challenging problems facing solid organ allotransplantation, countless developments in therapeutic immunosuppression have occurred in the years since the first solid organ transplants took place. They have enabled us to minimize rejection risk and improve the life expectancy and graft survival for many of our patients, albeit with the cost of greater infection risk. Ultimately, the field continues to work toward ways of measuring and achieving organ tolerance, whereby both rejection risk and the threat of infection are minimized.

Key Points

- Absent control, solid organ transplant rejection remains one of the most common causes of transplant graft failure. It can be acute or chronic, and predominantly cellular or antibody mediated.
- The human immune system regulates rejection and tolerance through interactions with both innate and adaptive immune mechanisms that are not static, rather they evolve and diminish again over time as we age.
- Balancing therapeutic immunosuppression with infection and malignancy risk is crucial to long-term graft survival. Often more significant immunosuppression is required at the time of transplant, or shortly thereafter, for bone marrow engraftment to prevent rejection and encourage tolerance.
- Triggers of graft rejection can be associated with different forms of rejection and also need to be controlled in different ways with cellular and humoral rejection.
- Thanks to multiple different therapeutic agents now available, immunosuppression can be tailored more precisely for everyone, and altered over time to continually adjust to rejection in ways that are more precise than were historically available to transplant clinicians.

Introduction

Biologics are therapeutic biological products manufactured in and/or isolated from natural resources. In a broader sense cells, blood, and components of blood, such as immunoglobulins, are sometimes included in the definition, whereas some prefer a more narrow definition emphasizing the active genetic manipulation involved in the manufacturing process. The introduction of these therapies has had a major impact in many fields of medicine. Indeed, in transplantation, the use of polyclonal antibodies against T cells (i.e., antithymocyte globulin) was one of the first clinical uses of a biologic product. A number of newer targeted therapies have more recently found their way into the field of transplantation. Biologic agents can be grouped by the target, the intended use, or the mechanisms of action. This chapter will concentrate on newer agents used in solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT), even if used for non-approved indications. The emphasis will be on the potential for infection, whereas indications (often overlapping) and mode of action will not be covered in detail. The note of caveat expressed in an earlier review still holds true: It remains very challenging attributing a specific infection to a specific immunosuppressive agent, given the complex interplay of many factors contributing to the "net state" of immunosuppression [1] as well as the common use of multiple drugs at the same time in the transplant setting. The rapid introduction of many biologics into clinical practice with few studies and less than optimal monitoring of infectious events has further complicated a solid assessment of risks. Also, rates of infections are never absolute rates but compared between interventions, highlighting the importance of the comparator arms in the respective trials.

Contrary to other patient groups treated with biologics, such as patients with neurologic or rheumatologic diseases, recipients of a solid organ or hematopoietic stem cells are usually screened for both active and latent infections, and appropriate prevention strategies are routinely implemented [2]. Standard prevention measures (updated vaccination status, screening for infections pretransplant, antiviral, and anti-*Pneumocystis* prophylaxis as per local guidelines, hepatitis B prevention if indicated, treatment of latent tuberculosis if required) are only mentioned in the specific chapters if warranted by an unusual pattern but are otherwise assumed. The recommendations are derived from expert statements, published trials, and personal opinion, and they are intended to help guide prevention measures but must be adapted to the individual patient.

Belatacept

The selective co-stimulatory blocking agent belatacept is used in induction and maintenance immunosuppression therapy after kidney transplantation. Both de novo and conversion protocols have been studied [3]. In liver transplant patients, an early study demonstrated decreased patient and allograft survival and higher rates of rejection, leading to the recommendation not to use belatacept in these patients [4].

A number of later smaller studies did however not replicate these findings [5, 6]. In thoracic transplantation, data are very limited, and belatacept is rarely used [3].

Infectious risks. Initial findings indicated that patients on belatacept experienced a small but reproducible increase in the rate of posttransplant lymphoproliferative disorders (PTLD). This increase was predominantly observed in Epstein Barr virus (EBV)-seronegative patients experiencing a primary infection [7]. This led to an FDA boxed warning not to use it in EBV-seronegative recipients.

In two large long-term randomized studies comparing belatacept with cyclosporine for maintenance immunosuppression (BENEFIT and BENEFIT-EXT), rates of serious infections did not differ between the two belatacept arms and the cyclosporine comparator [8, 9]. A Cochrane systematic review did not detect a PTLD signal, neither overall nor in subgroups such as EBV-negative recipients or patients receiving higher belatacept doses [10]. With the exception of EBV-associated PTLD in the initial studies, the remaining infections were those expected in an immunosuppressed population and did not differ, despite the concern that belatacept may specifically hamper de novo immune responses such as in a CMV high-risk constellation [11, 12].

Key Findings and Suggestions

- The main concern is the increased rate of EBV-associated PTLD, limiting its use to patients who are EBV-seropositive.
- Overall, infection rates were similar between belatacept and standard immunosuppression (usually a CNI-based regimen).
- Standard posttransplant infection prevention measures apply.

Basiliximab

Basiliximab is an anti-CD25 directed nondepleting antibody (interleukin-2 receptor antagonist) mainly used as part of an induction regimen in SOT. Occasionally, it serves as replacement immunosuppression for relevant calcineurin inhibitor toxicity and has been successfully used as treatment in refractory graft-versus-host disease after HSCT in small case series.

Infectious risks. The initial landmark trial comparing induction therapy with antithymocyte globulin versus basiliximab in recipients of a kidney graft showed a lower incidence of infection with basiliximab; however a recent meta-analysis including this trial did not report a difference in infection rates [13, 14]. In a large study on induction therapy from Brazil, a lower rate of CMV infection and disease was observed in the group receiving basiliximab, reduced dose tacrolimus and everolimus as compared to antithymocyte globulin [15]. A pediatric study using the ISHLT database did show a small but not significant increase in infections in the antithymocyte cohort as compared to basiliximab [16]. No excess infectious risk was

observed in a recent meta-analysis of basiliximab in liver transplant recipients [17]. A hypersensitivity reaction is very rare but can be mistaken for an infectious event.

Key Findings and Suggestions

- Overall, infection rates were similar or lower between basiliximab and comparator induction immunosuppression (usually an antithymocyte globulin regimen).
- Rarely, a hypersensitivity reaction can mimic an infectious event.
- Standard posttransplant infection prevention measures apply.

Rituximab and Obinutuzumab

Both anti-CD20-directed antibodies are mainly used in hematological malignancies, leading to a rapid elimination of most human B cells. Obinutuzumab is a member of a new generation of anti-CD20 humanized monoclonal antibodies; *in vitro* studies demonstrated an enhanced potency. Experience with rituximab in SOT is limited. It is part of desensitization protocols for highly sensitized patients or in ABO-incompatible kidney transplantation and used for some glomerular disease and antibody-mediated rejection [18]. Across the different organs, it is a cornerstone in the treatment of posttransplant lymphoproliferative disorder (PTLD). Obinutuzumab has occasionally been used in the context of allogeneic HSCT performed for chronic lymphocytic leukemia [19].

Infectious risk. Rituximab has rarely been used in controlled trials in both SOT and HSCT, rendering an estimation of the infectious risk difficult. Some papers describe a moderate increase of infectious complications with rituximab [20, 21]. In studies in patients without antiviral (anti cytomegalovirus) prophylaxis, rates of cytomegalovirus infections were high in the rituximab group [22]. Kamar et al. reported a higher infectious-related mortality in SOT recipients receiving rituximab for various indications; the only independent predictor was the concomitant use of antithymocyte globulin [23]. In pediatric kidney transplantation, use of rituximab was associated with a higher risk of infection, in particular if used in conjunction with additional immunosuppressive interventions, such as plasmapheresis [24]. Not Rituximab all studies did see a difference: In a case-control comparing highly sensitized patients with and without rituximab, no difference in severe infections was noted [25]. A systematic review of randomized trials of rituximab as induction therapy in non-sensitized patients did not reveal an additional infectious risk [26]. The data on overall infections highlight a number of inherent challenges: few of these trials were controlled, and the concomitant medication including immunosuppression differed considerably, as did the enrolled population (ABO incompatible and highly sensitized patients). Therefore, the risk attributed to rituximab varied from none to high.

Some specific concerns need mentioning. Fatal cases of reactivation of hepatitis B (mainly in the non-transplant population) lead to an FDA-issued black box warning

in 2013. When used in SOT patients, antiviral prophylaxis should be considered in patients at higher risk (HBsAg-positive or HBsAg-negative/anti-HBc-positive seroconstellation) [27, 28]. Of two recent reports in kidney transplantation, one reported an increased reactivation of hepatitis B under a standard, but not on a low-dose regimen [29, 30]. Occasional case reports describe the association with progressive multifocal leukoencephalopathy due to JC virus; there is concern that this may be a more significant risk with the newer anti-CD20 agents [31].

Whether the increased potency of obinutuzumab will result in more serious infectious complications remains to be seen; a similar pattern of infectious complications can be expected as seen for rituximab. Two cases of disseminated enteroviral infections were published in 2015 [32]. An FDA-issued black box warning includes hepatitis B reactivation and danger of progressive multifocal leukoencephalopathy.

An interesting concept was described in a pilot study by Schachtner et al., where rituximab was given to EBV-seronegative recipients of a living EBV-positive donor to prevent EBV primary infection. Three out of five remained EBV-negative, and none showed EBV viremia, favorably comparing to a Rituximab cohort of deceased kidney donation from an EBV-positive donor to an EBV-negative recipient [33].

Key Findings and Suggestions

- Overall, infection rates may be increased, especially with the use of higher doses and when given with additional immunosuppressive agents.
- A preventive strategy for cytomegalovirus should be initiated, if not already in place.
- In all patients with a diagnosis of either active or latent hepatitis B, prophylaxis should be evaluated, depending on seroconstellation/activity (as measured by HBV DNA) [27].
- Standard posttransplant infection prevention measures apply.

Alemtuzumab

The hallmark of alemtuzumab is its long-lasting depletion of lymphocytes and its subsets, e.g., CD4 helper T cells, which can last as long as 1 year after transplantation [34]. The main indication is induction therapy.

Infectious risk. One would expect that this profound and lasting effect on lymphocytes should translate in a higher rate of infections, but in most studies, a clear signal is missing. Contrary to the personal experience, a similar rate of infections between the alemtuzumab arm and the comparator was reported in the majority of studies in SOT [35, 36]. Whether this is due to the study setting with careful evaluation and strict prevention measures in place is unknown, as data from larger registries are missing. Looking more at specific pathogen groups, fungal and bacterial infections did not differ, whereas in some settings, specific viral infections were slightly increased (BK viremia), whereas, interestingly, some even reduced

(cytomegalovirus), nicely summarized in [37]. Similar rates between alemtuzumab and comparators were reported after induction therapy in HSCT, also in a pediatric population [38–40]. The few studies that have analyzed the repeated use, e.g., for rejection treatment, did however find an increased rate of infection (4.5% vs. 21% in the alemtuzumab group [41]).

Key Findings and Suggestions

- Overall, infection rates were similar when used as induction therapy, but data is limited to patients in a study setting, with antimicrobial preventive measures in place.
- SOT and HSCT populations do not differ in risk of infection.
- Infections rates were higher if given repeatedly, e.g., as part of a rejection treatment. In this setting, a prevention strategy for cytomegalovirus and a *Pneumocystis* prophylaxis should be initiated, if not in place.
- Standard posttransplant infection prevention measures apply.

Eculizumab

The mechanism of action of eculizumab, blocking the cleavage and activity of complement factor 5, explains the increased risk of infection for encapsulated bacteria and, in particular, with *Neisseria* spp. Its main use is in patients with paroxysmal nocturnal hemoglobinuria [42, 43] and atypical hemolytic uremic syndrome-associated thrombotic microangiopathy [44]. For these two FDA-approved indications, eculizumab is used prior and after transplantation [45]. HSCT-associated thrombotic microangiopathy has been successfully treated with eculizumab [46, 47]. Small studies have tested eculizumab in desensitization protocols or as treatment of antibody-mediated rejection, with mixed results [48–51]; nonetheless its use has been increasing after solid organ transplant.

Infectious risk. The risk is directly related to the inhibition of the terminal cleavage of complement and specifically infections with *Neisseria* spp. Interestingly, invasive infections with other capsulated organisms like *Streptococcus pneumoniae* are rare, likely due to alternative mechanisms such as opsonization [52]. For *Neisseria gonorrhoeae*, disseminated courses have been associated with use of eculizumab [53, 54], the largest being a recent case series [55]. Unusual *Neisseria* species have been reported as well [56]. Several severe cases of meningococcal disease were reported, also in vaccinated individuals [57–59]. It remains unknown if infections other than due to *Neisseria* spp. are increased, but so far, no robust signal was observed [52]. In an open-label, randomized study in pediatric kidney recipients on the role of eculizumab in ischemia-reperfusion injury, four participants in the eculizumab arm did lose their graft to a flu-like infection (none were vaccinated against influenza), but the infection was not characterized further, and significance is unclear [60].

Prevention strategies are therefore primarily directed against gonococcal and meningococcal disease. For gonococcal disease prevention, active screening of patients and partners who are sexually active and at risk for acquisition of new infections is recommended. The cornerstone of prevention of meningococcal disease is vaccination in combination with antibacterial prophylaxis. Conjugate quadrivalent meningococcal vaccines should be used against serotypes ACWY, in conjunction with a serotype B vaccine, where available. For the ACWY vaccines, most will recommend two initial doses separated by at least 4 weeks, the initial dose 2 weeks before first dose of eculizumab, and a booster every 5 years [61]. A systemic antibacterial prophylaxis with meningococcal coverage such as penicillin, amoxicillin, azithromycin, or ciprofloxacin is initiated at the same time. The main unresolved question in prevention is whether longer concomitant antibacterial prophylaxis is warranted for the duration of eculizumab therapy in properly vaccinated individuals. Most statements advocate for prolonged chemoprophylaxis for the duration of eculizumab therapy in immunocompromised patients [62]. Monitoring antibody titers against meningococci is not widely available.

Key Findings and Suggestions

- Due to its mechanisms, eculizumab predisposes to invasive infection with *Neisseria* spp.
- Gonococcal disease prevention consists of screening of at-risk sexually active patients and their partners, by PCR.
- Vaccination with a conjugated quadrivalent serotype ACWY vaccine together with a recombinant serotype B vaccine is strongly recommended, ideally at least 2 weeks prior to first dose of eculizumab. A second dose after 4 weeks (or later) and a booster every 5 years are recommended for the quadrivalent vaccine, whereas for the serotype B vaccine, best practice is unknown, although its immunogenicity is less durable.
- Additional systemic antibacterial prophylaxis is recommended for at least 4 weeks after last vaccine dose. Most expert statements favor continuous chemoprophylaxis for the duration of eculizumab therapy in immunocompromised individuals due to reports of breakthrough infections. Penicillin V is preferred over ciprofloxacin for ecological reasons.
- Vaccine failures have been reported. It might be prudent to include meningococcal vaccination as required immunization upon listing, especially in highly sensitized patients, which may result in better vaccine responses prior to the onset of immunosuppression.
- Standard posttransplant infection prevention measures apply, in particular a documented vaccination against pneumococci.

Ruxolitinib

Ruxolitinib is a Janus kinase inhibitor approved for the treatment in myelofibrosis and polycythemia vera [63–65]. More recently, it has been studied in steroid-refractory graft-versus-host disease (GvHD) including bronchiolitis obliterans syndrome in adult and pediatric recipients of an allogeneic HSCT [66–68]. Randomized trials are planned, but the literature on infectious risk in this very vulnerable population is very limited [69]. It is not being used after SOT.

Infectious risk. Most of the knowledge comes from its use in myelofibrosis and polycythemia vera [70]. These initial studies did report a higher rate of infection in the ruxolitinib groups, but in later trials, only a mild to moderate effect was seen [71]. In the transplant setting, prior use of a Janus kinase inhibitor did not adversely affect the outcomes of allogeneic HSCT, including the rate of infections [72]. In patients treated for refractory GvHD, the type of infections reported included viral, fungal, and bacterial infections, affecting over 50% of patients, but it was not possible to discern the role of ruxolitinib [66]. Cytomegalovirus reactivation was observed in 25–30% of all patients [73]. Antimicrobial prophylaxis was specified in one pediatric series and consisted of antifungal prophylaxis, cotrimoxazole against *Pneumocystis jirovecii*, and antiviral prophylaxis if GvHD was acute [68]. Lussana et al. have summarized the infectious risk in randomized trials in myelofibrosis and polycythemia vera [74]. The only infection significantly associated with ruxolitinib was herpes zoster. In a long-term follow-up study of patients taking ruxolitinib for myelofibrosis, infection risk correlated with disease severity and a history of a previous infection: infections were observed in 28% of all analyzed patients (23%, bacterial; 5%, viral; only three patients with a fungal infection) [75]. Rare (opportunistic) infections were seen early on, including reactivation hepatitis B, toxoplasmosis, and cryptococcosis, prompting the question of appropriate antimicrobial prophylaxis [76–80]. Biologic drugs do not always enhance the risk for infections and can be used to help treat infections: ruxolitinib was successfully used as treatment in a case of chronic mucocutaneous candidiasis caused by STAT1 mutation, an effect believed to be mediated by the induction of interleukin 17 [81], and was used to treat a patient with relapsed refractory chronic active Epstein–Barr virus infection [82].

Key Findings and Suggestions

- The share of ruxolitinib on the burden of infectious complications in patients with GvHD does not seem higher than current standard of care, although comparison is challenging given the already intense immunosuppression of patients with treatment-refractory GvHD.
- Often, these patients are on antiviral, antifungal, and *Pneumocystis* prophylaxis. It is prudent to continue or put patients on broad antimicrobial prophylaxis if ruxolitinib is used as a therapeutic option for GvHD.

- Herpes zoster was the only infection significantly increased in the ruxolitinib patients when given for myeloproliferative neoplasms, such that antiviral prophylaxis would be recommended. Use of a zoster vaccine should be evaluated before start of ruxolitinib.
- Standard posttransplant infection prevention measures apply.

Ibrutinib

Ibrutinib is approved for a number of B cell-derived hematological malignancies, such as chronic lymphocytic leukemia, Waldenstrom's macroglobulinemia, mantle-cell lymphoma, and marginal zone lymphoma [83, 84]. If judged from the literature on primary immunodeficiency where the X-linked agammaglobulinemia mimicking the predicted effect of ibrutinib results in severe, life-threatening bacterial infections, one would expect a similar increased risk with ibrutinib use [85]. However, the therapeutic effects on the hematological malignancies seem to offset these risks, and the data on the infectious risks has shown only a moderate increase. Bacterial infections (pneumonia, urinary tract infection) predominate [84, 86]. The main data comes from studies in patients with chronic lymphocytic leukemia, but smaller studies for the other indications yielded similar results [87]. A steady but small number of cases of invasive fungal infections have been reported, prompting a call to action to improve the knowledge and data collection on the use of this and similar compounds [88]. Indeed, the authors state the same challenges: often, the risk is not defined through one factor alone, but is a complex interplay between various risk factors. Much less is known about the added infectious risk when ibrutinib is used in the treatment of chronic GvHD. The largest observational trial did include 42 patients, of whom 69% had an infection (any grade) and 36% (15 patients) a grade $\geq$3 infection [89]. In agreement with the previous experience, pneumonia was the lead infection.

Key Findings and Suggestions

- Ibrutinib is used in patients with chronic GvHD. The small studies so far do not allow a concise infection risk stratification.
- The main infections seen are pneumonia, skin/soft tissue, and urinary tract infections.
- Reports of invasive fungal infections are increasing, so while still low, it has led to a heightened awareness and a call to improve our knowledge.
- Most patients with chronic GvHD are on antiviral, antifungal, and anti-*Pneumocystis* prophylaxis. It is prudent to continue or put patients on a broad antimicrobial prophylaxis if ibrutinib is used as a therapeutic option for GvHD.

Bortezomib

Besides its indication for multiple myeloma and relapsed or refractory mantle cell lymphoma, bortezomib has been tested as part of a preventive combination treatment for GvHD [90–92]. Occasionally, it has been used for the treatment of humoral rejection after SOT. Owing to the key effect of this drug, depletion of T cells, a higher risk of viral infections is expected and confirmed by the literature [93]. Indeed, a higher risk of herpes zoster described in the initial studies prompted many centers to adopt a specific antiviral prevention strategy [94]. An Australian study did see a higher rate of severe influenza courses in patients treated with bortezomib [95]. Fungal infections and other opportunistic infections, such as *Pneumocystis*, were not found to be increased or related to underlying disease progression [96]. Bortezomib did not increase the infection risk when it was tested in a three-arm GvHD prevention study [92].

Key Findings and Suggestions

- Antiviral prophylaxis is strongly recommended in VZV-seropositive individuals for the duration of bortezomib use, given the augmented rates of herpes zoster (patients on acyclovir, famvir, or valacyclovir or on cytomegalovirus prophylaxis with (val)ganciclovir are protected, but not on maribavir or letermovir).
- Herpes zoster recombinant vaccine should be considered in patients with planned bortezomib use, where possible.
- Bortezomib per se did not increase the infectious risk when used in a large three-arm study as prevention for GvHD.
- Most patients with chronic GvHD are on an antiviral, antifungal, and anti-*Pneumocystis* prophylaxis. It is prudent to continue or put patients on a broad antimicrobial prophylaxis if ibrutinib is used as a therapeutic.
- Standard posttransplant infection prevention measures apply.

Brentuximab

Brentuximab vedotin is an anti-CD30 monoclonal antibody-drug conjugate approved for the treatment of relapsed/refractory Hodgkin lymphoma and anaplastic large T-cell lymphoma. In the context of transplantation, it is used for recurrent Hodgkin lymphoma after allogeneic HSCT [97]. In the initial studies including as part of a consolidation therapy after autologous HSCT, no excess risk was noted, but patients were on a prophylactic regimen for herpesviruses and *Pneumocystis* [98–100]. In the study by Gopal et al. after allogeneic HSCT, severe infections were reported in 24% of patients, including *Pneumocystis*, *Pseudomonas*, and *Aspergillus* pneumonias. Dissecting the role of brentuximab is not possible [97]. In addition, a small series and single cases of progressive multifocal

leukoencephalopathy were reported, some occurring rather early after the end of treatment, leading to a specific FDA warning [101].

Key Findings and Suggestions

- An excess infection risk attributable to brentuximab was not seen in the larger initial studies, nor when used as salvage therapy for recurrent disease after allogeneic HSCT. Most patients however were on *Pneumocystis* and herpesviral prophylaxis.
- Herpesviral and *Pneumocystis* prophylaxis should be considered when on brentuximab.
- Rare cases of PML were observed, resulting in an FDA warning to stop therapy in case of clinical suspicion and initiate a diagnostic work-up.
- Standard posttransplant infection prevention measures apply.

Conclusions

The advent of biologic therapies has rendered the estimation of the infectious risk even more challenging. Not all pathways targeted result in an enhanced infection risk, and for some molecules, the spectrum of expected infections can be quite narrow. In transplant recipients, these agents are never used alone but are part of a combination of measures resulting in an overall "net state" of immunosuppression, which is difficult to quantify. The importance of well-maintained cohorts and registries, as well as post-marketing reporting to regulatory agencies, to detect rare signals in real-life patients cannot be overestimated.

Introduction

Since its inception in the 1960s, HSCT has revolutionized the management of malignant and nonmalignant diseases. With the development of protocols using reduced intensity conditioning regimens and alternate donor sources, such as cord blood and haploidentical donors, an increasing number of patients are eligible for allogeneic HSCT.

Infections after HSCT can result from chemotherapy-related neutropenia in addition to immunosuppression caused by medications used for prophylaxis and treatment of graft-versus-host disease (GVHD) and GVHD itself [1]. A large prospective multicenter study of infections after HSCT reported an infection in 93% of transplant patients in their cohort, with 21% infection-attributable mortality [2]. Bacterial infections such as bacteremia and *Clostridioides difficile* infection were the most common infectious complications, followed by viral infections and fungal diseases. Another large study evaluating infections in patients undergoing non-matched related donor HSCT for treatment of acute leukemia reported bacterial or viral infections in over 50% of patients and fewer with fungal diseases [3].

This chapter will highlight the risk of infectious complications based on the type of HSCT and discuss new trends in management of specific infections in this patient population.

Risk of Infection Post-HSCT

General Immune Reconstitution After Hematopoietic Stem Cell Transplantation

A major determinant of risk of infection after HSCT is immune reconstitution of the different compartments of the immune system. Deficiencies in natural killer (NK) cells, T-cells, B-cells, or immunoglobulins can predispose patients to infection within and beyond 1 year post-HSCT (Fig. 1) and are highly dependent on multiple patient- and transplant-related factors, which will determine the kinetics and extent of recovery of each component (Table 1).

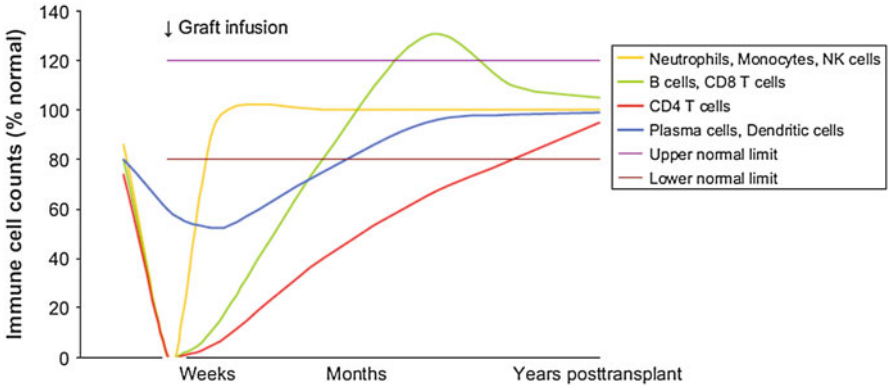

Fig. 1 Timeline of immune reconstitution post-allo HCT. (**License**: 4657680706894. PMID 19747629)

Table 1 Factors impacting post-allogeneic HCT immune reconstitution

Pretransplant factors	Transplant factors	Posttransplant factors
Age	Graft source	Thymic function
Comorbidities	Donor-recipient matching	GVHD
Underlying disease	CD34+ cell dose	Immunosuppressive agents for GVHD treatment
Prior treatment	Conditioning regimen intensity	Infection
	Ex vivo T-cell depletion	Nutritional status
	T-cell depletion (serotherapy)	Disease relapse

Aplastic Period

The initial phase after autologous and allogeneic HSCT is an aplastic phase produced by the conditioning regimen. The major determinant of infection risk during this time period is the depth and duration of neutropenia. Time to neutrophil recovery can be variable and is influenced by the source of hematopoietic cells. On average, recovery can be seen within 14 days after peripheral blood, 21 days after bone marrow, and 30 days after umbilical cord blood transplants [4]. CD34+ cell dose is directly correlated with time to engraftment and risk of infection during this period, with higher doses shortening the duration of neutropenia [4]. Infections occurring during this timeframe are commonly caused by bacterial and fungal pathogens. The extent of myelosuppression tends to be less severe with the use of reduced intensity conditioning regimens, as compared to myeloablative regimens [5]. Additionally, patients with prolonged periods of pretransplant neutropenia, such as patients with aplastic anemia or recent chemotherapy administration, are at an increased risk for infection during the posttransplant aplastic period, particularly with regard to fungal pathogens [5].

NK Cells and T-Cells

Natural killer (NK) cell recovery is dependent on the generation of donor-derived lymphoid progenitor cells [5]. NK cell numbers may be deficient up to 1 year post-allogeneic HSCT but are typically the first lymphoid cell line to fully recover [5]. T-cell reconstitution following allogeneic HSCT occurs via two distinct pathways. First, in the early posttransplant period, CD8+ memory T-cells preferentially expand, leading to an inverted CD4+/CD8+ ratio during this timeframe [4]. These are largely donor-derived T-cells although recipient cells which have survived conditioning chemotherapy may also be present. These T-cells are not especially responsive to central tolerance and will be more likely to cause GVHD [6]. Mature naïve CD4+ T-cell generation, comparatively, occurs in the thymus via donor-derived lymphoid progenitors and, therefore, is slower than CD8+ T-cell formation [4, 5]. It typically takes at least 100 days to reach a CD4+ T-cell count of 200/μL, which is one of the most reliable surrogate markers for estimating immune reconstitution in the HSCT population [4, 7]. However, many factors can impact thymic function and activity posttransplant and further delay reconstitution of the full T-cell repertoire [6]. The thymus is particularly sensitive to the high-dose chemotherapy used in HSCT conditioning regimens with damage occurring to both thymic epithelial cells and the thymic stroma [6]. Lymphodepleting agents, such as antithymocyte globulin and alemtuzumab, used to prevent GVHD and graft rejection or occasionally given pretransplant, as in the case of aplastic anemia, also lead to significant thymocyte depletion [6]. Age is another key factor impacting immune reconstitution due to age-related thymic involution resulting in decreased naïve T-cell generation [8]. This is particularly relevant as the upper age limit among patients receiving transplants has steadily increased over the last decade with improvements in transplant approaches,

such as the use of reduced intensity and nonmyeloablative conditioning regimens. Studies have shown markers of thymic-derived naïve T-cells remain low for 3–6 months after HSCT [9]. Therefore, sufficient T-cell reconstitution may not occur until 6–12 months post-allogeneic HSCT, at the earliest. Deficiencies in these cytotoxic lymphocyte cells predispose patients to viral infections and fungal diseases in particular.

B-Cells and Immunoglobulins

B-cell recovery after allogeneic HSCT can range from 1 to 5 years post-HSCT and is impacted by antigen exposure, interactions with CD4+ T-cells, and degree of GVHD [4, 7, 10]. Naïve B-cells often reconstitute before memory B-cells [4, 10]. Within 3–6 months after allogeneic HSCT, normal levels of serum IgM can be measured, followed by IgG and IgA [4]. Administration of antithymocyte globulin significantly impacts naïve and memory B-cell regeneration, delaying recovery by approximately 5 months [4]. Impaired B-cell and immunoglobulin recovery can predispose patients to infections due to encapsulated bacteria and viruses. Additionally, even once full recovery of B-cell numbers occurs, impaired responses to vaccines have been documented, and it is generally recommended to obtain titers following vaccination to ensure adequate protection [4].

Graft-Versus-Host Disease

GVHD occurs post-HSCT when donor T-cells respond to genetically defined proteins on host cells encoded by the major histocompatibility complex (MHC), minor histocompatibility antigens, or both [11, 12]. A sequence of steps including activation and proliferation of donor immune cells followed by target tissue destruction leads to acute GVHD (aGVHD) [11, 12], which most commonly occurs within the first 100 days post-HSCT and involves the skin, gastrointestinal tract, and liver [11, 12]. The pathophysiology of chronic GVHD (cGVHD) is more complex and is thought to involve thymic dysregulation leading to alloreactivity of T-cells, B-cells, and innate immune cells [13]. Chronic GVHD typically occurs later in the transplant course and can affect nearly all organ systems of the body [13]. Additionally, GVHD can cause direct damage to thymic epithelial cells due to their high levels of MHC expression which can lead to decreased thymic output of naïve CD4+ T-cells and further disruption of the T-cell repertoire [6]. It also inhibits appropriate negative selection and regulatory T-cell development, which contributes to the development of cGVHD [6].

Prevention of GVHD includes the use of medications such as T-cell-depleting agents (antithymocyte globulin, alemtuzumab), calcineurin inhibitors (tacrolimus, cyclosporine), inhibitors of cellular proliferation (mycophenolate mofetil, methotrexate), and mammalian target of rapamycin (mTOR) inhibitors (sirolimus). The standard first-line treatment for patients with GVHD is corticosteroid therapy [14].

Glucocorticoids are also known to cause thymic damage and atrophy and can therefore further impede the ability to reconstitute the immune system when used post-HSCT by leading to decreased production of naïve CD4+ T-cells [6]. There is no preferred second-line treatment regimen for GVHD that is unresponsive to steroids [11]. Immunosuppressive therapies most commonly utilized include extracorporeal photopheresis, rituximab, infliximab, etanercept, basiliximab, alemtuzumab, tocilizumab, pentostatin, low-dose interleukin-2, alpha-1 anti-trypsin, and imatinib [12, 15]. Recently, two agents have gained the first-ever FDA approvals for steroid-refractory GVHD. The Bruton's tyrosine kinase inhibitor, ibrutinib, was approved in 2017 for steroid-refractory cGVHD, and the Janus kinase JAK1/JAK2 inhibitor, ruxolitinib, was approved in 2019 for steroid-refractory aGVHD [16, 17]. Both agents are increasingly being utilized in practice. Therefore, both the immune mechanisms underlying GVHD and the treatment modalities for GVHD predispose post-HSCT patients to infections. Many of the agents used for treatment of GVHD increase the susceptibility to infections due to viruses and opportunistic pathogens.

Special Donor Populations

Due to delays in finding suitable donors and the limited donor pool for non-Caucasian and mixed ethnicity patients, alternate donor strategies have been developed and studied. These include allogeneic HSCT using umbilical cord blood units and HLA haplotype mismatched or haploidentical donors. Each strategy is associated with distinct patterns of immune reconstitution post-HSCT and, therefore, patient susceptibility to infection.

Umbilical Cord Blood Transplantation

Umbilical cord blood transplantation (UCBT) utilizes preserved umbilical cord blood (UCB) as the source of hematopoietic cells. Initial studies were performed in pediatric patients using a single UCB unit. Later studies found using a single UCB unit for adult allogeneic HSCT provided insufficient numbers of hematopoietic cells to achieve engraftment, so techniques such as ex vivo UCB expansion and use of double UCB units were developed to afford adequate amounts of hematopoietic cells for adults [18, 19].

Adult recipients of UCB transplants have been found to have longer median days to neutrophil engraftment, ranging from 27 to 29 days post-HSCT [20, 21]. Also noted are slow thymic T-cell recovery extending beyond 1 year post-HSCT [21, 22] and B-cell immune reconstitution starting at approximately 6 months post-HSCT [23]. UCB also contains regulatory T-cells which are potent suppressors of the immune response [24, 25].

Patients who have undergone UCB transplant are considered immunologically naïve and are susceptible for prolonged periods to both bacterial infections as a result of longer durations to neutrophil recovery and viral infections due to delays in T-cell immune reconstitution [3, 20].

Haploidentical Transplantation

Haploidentical donors are available for the majority of patients without significant delays in donor identification and therefore are a highly convenient donor source. Due to HLA haplotype mismatches, patients undergoing haploidentical HSCT are at an increased risk of T-cell-mediated processes such as rejection and GVHD [26]. Transplantation strategies have focused on modulating the T-cell content and activity of haploidentical grafts, specifically, with the use of T-cell-depleted grafts or unmanipulated grafts with post-HSCT alteration of T-cells using the administration of medications such as cyclophosphamide [26, 27].

In both strategies, NK and B-cell immune reconstitution demonstrate similar durations compared to traditional allogeneic HSCT. T-cell reconstitution is slower for T-cell-depleted haploidentical HSCT compared to unmanipulated haploidentical HSCT, with published reports of low to normal numbers of CD4+ T-cells being detected 180 days post-T-cell-depleted haploidentical HSCT [28]. This effect is attributed to the permissive effects cyclophosphamide has on naïve and memory T-cells which are able to reconstitute the immune system more efficiently as compared to T-cell-depleted grafts which rely solely on T-cell reconstitution through de novo generation of bone marrow lymphoid progenitors [29]. Consequently, while significant increases in both fungal diseases and viral infections have been found in patients receiving T-cell-depleted HSCT [28], only an increase in viral infections until day 100 post-HSCT has been noted in patients undergoing T-cell-replete haploidentical HSCT [30]. Additionally, time to neutrophil engraftment has been found to be significantly longer in haploidentical HSCT as compared to matched related and matched unrelated donor allogeneic HSCT, though shorter as compared to UCB transplantation [31, 32].

Pre-HSCT Recipient Infectious Disease Evaluation

The pre-HSCT recipient should be evaluated for evidence of protective antibody and exposure to several infections outlined in Table 2 [5, 33]. The results of these laboratory tests enable clinicians to risk stratify the recipient for development of specific infections post-HSCT. Current guidelines recommend pretransplant hepatitis B immunization for HSCT recipients from donors who are anti-hepatitis B core antibody positive. Revaccination is recommended starting at 6 months post-HSCT for recipients who lost detectable pre-HSCT hepatitis B surface antibody and for those who had no evidence of pre-HSCT hepatitis B surface antibody (please see section "Post-HSCT Vaccinations") [5, 34].

Table 2 Recipient pretransplant infection assessment

Infection	Pretransplant assessment
Cytomegalovirus (CMV)	CMV IGG[a]
Epstein-Barr virus (EBV)	EBV IGG

Prophylaxis and Management of Infection Post-HSCT

Bacterial Infections

Bloodstream Infections

Bacterial infection is a common and life-threatening complication of HSCT, particularly in the pre-engraftment phase. General risk factors for development of bacterial infections after HSCT include the source of stem cells, use of myeloablative conditioning regimens, duration of neutropenia, underlying medical comorbidities, presence of central venous catheters (CVCs), and the presence of GVHD. Compared to autologous HSCT, pre-engraftment neutropenia lasts significantly longer among allogeneic HSCT recipients who receive myeloablative conditioning regimens, thus placing this group at higher risk of bacterial infections with reports of twice the cumulative risk for gram-negative bacteremia in allogeneic HSCT compared to autologous HSCT recipients (17.3% vs. 9.0%) [35]. Patients who receive UCB transplantation and haploidentical HSCT experience longer pre-engraftment neutropenia compared to those who receive peripheral blood grafts, so are at higher risk of bacterial infections. CVCs have considerably improved the management of patients undergoing HSCT by facilitating the administration of chemotherapy, stem cell infusion, intravenous medications, electrolyte supplementation, nutritional support, and blood products [36]. The incidence of CVC-related infections in this patient population is particularly high, ranging as high as 21%, and is associated with significant morbidity [37].

Bloodstream infections are the most commonly documented types of bacterial infection after HSCT (20–30%), followed by pneumonia, skin and soft tissue infections, and enterocolitis [35]. The epidemiology of bacterial pathogen etiology

has changed over time. In the 1960s–1970s, infections due to gram-negative bacteria were most common; however, beginning in the 1980s, gram-positive bacteria have predominated. Within the last decade, many institutions have reported a shift back toward gram-negative bacteria, particularly with multidrug-resistant isolates [38–40]. Increased severity of underlying pre-HSCT hematologic malignancy with prolonged durations of neutropenia, use of antibiotic prophylaxis, and protracted use of broad-spectrum antibiotics have contributed to this shift.

The use of prophylactic antibiotics, fluoroquinolones most commonly, during periods of neutropenia in HSCT patients remains the standard of care for prevention of bacterial infections and is endorsed by multiple guidelines [5, 33, 41]. Routine prophylaxis has been shown to decrease the incidence of febrile neutropenia and all-cause mortality [41]. However, data continues to emerge regarding adverse effects, increased antimicrobial resistance, and disruptions of the gut microbiome associated with fluoroquinolone prophylaxis, and efforts have been made to limit their use whenever possible [42]. In particular, there has been a recent focus in the literature on loss of diversity of the gut microbiome in HSCT patients as a result of fluoroquinolone prophylaxis and broad-spectrum antibiotic treatment. Outside of periods of neutropenia, bacterial prophylaxis with penicillins is also recommended in patients with cGVHD, as they are at an increased risk for *Streptococcus pneumoniae* infection [5, 43]. This loss of diversity has been correlated with increased rates of *Clostridioides difficile* infection, intestinal inflammation, and gastrointestinal GVHD [42].

Diagnosis

Obtaining blood cultures is a crucial determinant of detecting a bloodstream infection. It is recommended that an evaluation of fever in neutropenic patients with cancer should consist of blood culture sets from all CVC lumens (if present) and one set from a peripheral vein [44]. Multiple blood culture sets from different sites are recommended based on studies which found that two blood culture sets detect 80–90% of bloodstream infections in critically ill patients, whereas three or more sets of blood cultures are required to increase detection to greater than 96% [45, 46]. Positive blood cultures drawn from CVCs and a peripheral vein can aid in the determination of source of the infection based on differential time to positivity. A time difference for blood culture positivity of greater than 120 min between peripheral vein and CVC blood cultures, with CVC blood culture turning positive first, is suggestive of a central line-associated bloodstream infection [44].

The implementation of rapid diagnostic tests (RDTs) for bloodstream infections, particularly when paired with antimicrobial stewardship practices, has demonstrated significant decreases in mortality and time to effective antibiotic therapy, even among patients with cancer [47, 48]. Available RDTs for bloodstream infections may detect both bacterial and fungal pathogens from blood cultures within 20–150 min after blood cultures turn positive [49]. Additionally, some RDTs may also detect the genetic presence of certain resistance mechanisms among bacteria, such as

mecA, *vanA/B*, CTX-M, or even NDM, which often aids in the appropriateness of antibiotic therapy and resultant decreases in the time to effective therapy and risk of mortality.

Management

Given the inter-institutional variability in the incidence and epidemiology of bacterial infections, HSCT centers should emphasize the importance of infection control measures and antimicrobial stewardship practices. Hand hygiene, environmental cleaning, screening for colonization with resistant bacteria (e.g., MRSA, VRE, or ESBL-producing gram-negative bacteria), and isolation or cohorting of patients with evidence of colonization, active infection, or a history of resistant bacteria are important infection control measures. Antimicrobial stewardship should be a collaborative effort between hematology physicians and pharmacists, infectious disease providers, nursing staff, and members of the antimicrobial stewardship team to provide optimal empiric therapy for patients with febrile neutropenia. Current therapy generally consists of antibiotics active against most gram-negatives, including *P. aeruginosa*, as well as MRSA in patients who meet defined risk factors. However, an individualized approach to defining an optimal empiric antibiotic regimen may be implemented which accounts for local epidemiology including bacterial resistance patterns, individual patient risk factors, and severity of infection.

Gram-Positive Bacterial Infections

In addition to vancomycin or teicoplanin, antibiotics effective in the treatment of methicillin-resistant *Staphylococcus aureus* (MRSA) infection are outlined in Table 3.

Fewer treatment options exist for infections due to vancomycin-resistant *Enterococcus* (VRE) (Table 3). Doses of daptomycin in the range of 8–12 mg/kg are recommended for the treatment of VRE bacteremia when exhibiting higher daptomycin MICs, particularly those defined as susceptible dose-dependent per

Table 3 Gram-positive infection treatment

Etiology and site of infection	Treatment
MRSA bacteremia	Vancomycin, teicoplanin, daptomycin, telavancin, ceftaroline
Persistent MRSA bacteremia salvage therapy	Ceftaroline +/− daptomycin
MRSA pneumonia and skin and soft tissue	Linezolid, tedizolid, oritavancin, dalbavancin
VRE bacteremia	Daptomycin, linezolid, quinupristin-dalfopristin[a], tigecycline, oritavancin[b], dalbavancin[c], and fosfomycin IV

[a] *E. faecium* only
[b] VanA phenotype
[c] VanB phenotype

updated CLSI breakpoints. Linezolid has been extensively studied for the treatment of VRE, including bacteremia; however, bacteriostatic activity, drug-drug interactions, thrombocytopenia, and leukopenia may limit its use in HSCT patients. Data regarding the use of lipoglycopeptides, oritavancin and dalbavancin, have demonstrated variable efficacy. Synergistic combinations, such as daptomycin plus ampicillin or daptomycin plus ceftaroline, have been effective against persistent VRE bacteremia and for VRE with decreased susceptibility to daptomycin and/or linezolid [50, 51].

Multidrug-Resistant Gram-Negative Bacterial Infections

Carbapenems remain the drugs of choice for systemic extended spectrum beta-lactamase (ESBL)-producing gram-negative bacteria [52]. Piperacillin-tazobactam, nitrofurantoin, and oral fosfomycin are therapeutic options for treatment of ESBL cystitis. Tigecycline may be a useful carbapenem-sparing option for the treatment of complicated intra-abdominal infections due to ESBL-producing pathogens. New carbapenem-sparing beta-lactam-beta-lactamase inhibitors (BL-BLIs) ceftolozane-tazobactam and ceftazidime-avibactam, and carbapenem BL-BLIs such as meropenem-vaborbactam and imipenem-relebactam, have in vitro activity against ESBL-producing organisms. The novel siderophore cephalosporin, cefiderocol, currently in the development pipeline has a similar chemical structure to both ceftazidime and cefepime but with increased stability against ESBL production.

Carbapenem-resistant gram-negative bacteria pose a growing challenge. Combinations of antibiotics often including aminoglycosides, polymyxins, and/or tigecycline are frequently used empirically in order to increase the probability of adequate therapy. Depending on the mechanism of carbapenem resistance, treatment with a single agent such as ceftazidime-avibactam, meropenem-vaborbactam, and imipenem-relebactam has efficacy against carbapenem-resistant gram-negative organisms. Cefiderocol has also demonstrated in vitro activity. Additionally, tigecycline possesses activity against carbapenem-resistant gram-negative bacteria with the exception of *P. aeruginosa.* Additionally, this antibiotic should not be used for the treatment of bacteremia or urinary tract infections due to limited drug concentrations achieved in these areas.

Multidrug-resistant *P. aeruginosa* has limited treatment options. Empiric regimens often include combinations of a carbapenem plus polymyxin or aminoglycosides. Fosfomycin has also demonstrated activity and may be a treatment option. Among the new BL-BLIs, ceftolozane-tazobactam has demonstrated the most potent activity.

Bacterial Pneumonia

The incidence of bacterial pneumonia after autologous and allogeneic HSCT has been reported to range between 15 and 25% in retrospective studies [53, 54]. One large prospective study of 427 allogeneic HSCT patients reported bacteria being the most common etiology of pneumonia in their cohort, with 44% of all pneumonias

attributed to bacterial pathogens [55]. *Escherichia coli* and *Pseudomonas aeruginosa* were the most frequently isolated bacteria in this multicenter study. Factors that may influence the bacterial etiology include prior bacterial colonization of the recipient, post-HSCT neutropenia, administration of post-HSCT antibacterial prophylaxis, and receipt of vaccinations post-HSCT. This leads to some variability post-HSCT regarding which bacteria may be causing pneumonia, but bacteria such as *E. coli*, *P. aeruginosa*, *Streptococcus* species, and *Staphylococcus aureus* remain significant pathogens.

Clostridioides Difficile

The incidence of *C. difficile* infection (CDI) in HSCT patients is reported to be up to ninefold higher than for hospitalized patients without cancer [56] and twofold higher in allogeneic versus autologous HSCT patients [57, 58]. The severity of CDI in HSCT patients is generally mild to moderate, occurring most frequently in the early posttransplant period, with conflicting mortality data [59, 60]. Due to myeloablative conditioning regimens and slow immune reconstitution, HSCT patients have lower levels of protective antibodies, and CDI in this patient population has been associated with decreased antibody responses to *C. difficile* toxins A and B [61, 62].

Risk factors for CDI such as age $>$ 65 years and proton pump inhibitor use also apply to HSCT patients; however, risk factors such as immunosuppression, antibiotic exposure, and healthcare contact are more frequent in this patient population. Other reported risk factors for CDI in HSCT patients include aGVHD, mucositis, CMV reactivation, HSV or VZV reactivation, and intestinal dysbiosis [60, 63, 64]. Intestinal microbiome diversity is a protective host factor against *C. difficile* and other invasive bacteria. Receipt of antibiotics early in the posttransplant period is associated with decreased microbial diversity and increased transplant-related mortality [65]. In the setting of intestinal dysbiosis, there is loss of gastrointestinal microbial diversity, leading to alterations in intestinal metabolism, allowing for colonization by pathogenic bacteria such as *C. difficile*.

Diagnosis

Current guidelines recommend *C. difficile* testing within 24 h for patients who have greater than or equal to three unformed stools new in onset and no attributable etiology.

The most frequently used laboratory methods for detection of CDI include enzyme-linked immunosorbent assays (EIA) which target glutamate dehydrogenase (GDH) or toxins A and B or nucleic acid amplification tests (NAAT) which are most often polymerase-based reaction (PCR) tests. The EIA for GDH is highly sensitive but not specific, and the NAAT is highly sensitive and moderately specific. Given the high rate of NAAT sensitivity, detection of *C. difficile* colonization is common. Diagnosis of *C. difficile* post-HSCT can be complicated by other causes of diarrhea in this setting, including conditioning regimen-related toxicity, dietary supplementation, and gastrointestinal GVHD.

Table 4 *Clostridioides difficile* testing algorithm for HCT patients

Glutamate dehydrogenase + toxin A and B OR
Glutamate dehydrogenase + nucleic acid amplification test OR
Nucleic acid amplification test + toxin A and B

Table 5 *Clostridioides difficile* management

Initial episode	Vancomycin 125 mg PO or Fidaxomicin 200 mg PO BID
First and subsequent recurrence	Vancomycin 125 mg PO q6h or Vancomycin taper or Fidaxomicin 200 mg PO BID
Second and subsequent recurrence	Fecal microbiota transplant
Fulminant infection	Vancomycin 500 mg PO q6h + intravenous metronidazole 500 mg q8h +/− vancomycin 500 mg q6h per rectum or Surgical intervention
Infection complicated by ileus	Rectal vancomycin instillation 500 mg q6h
Secondary prophylaxis	Vancomycin 125 mg PO daily or Fidaxomicin 200 mg PO daily

Due to data suggesting poor performance of toxin assays in immunocompromised patients [66], guideline-recommended methods for detection of CDI include the use of a stool toxin test as part of a multistep algorithm for HSCT patients (Table 4) [67].

Management

In the United States, management of patients with CDI involves discontinuation of the inciting antibiotic(s) when possible, and treatment modalities are outlined in Table 5.

Oral vancomycin and fidaxomicin are recommended preferentially over metronidazole for initial non-severe and severe episodes due to superior efficacy [67, 68]. Although one small retrospective review of patients with hematologic malignancies who received oral vancomycin or metronidazole for the treatment of CDI showed no difference in treatment outcomes between the two groups [69], subsequent studies have demonstrated superior efficacy of oral vancomycin over metronidazole and reductions in mortality [70, 71].

Initial treatment responses to oral vancomycin and fidaxomicin have been shown to be equivalent [72, 73]. In a post hoc analysis, lower overall treatment responses (79% vs. 87%), prolonged durations of diarrhea, and overall cure rates did not differ among patients with cancer compared to the general study population (89% vs. 89%,

respectively). Although not statistically significant, fidaxomicin demonstrated higher cure rates compared to oral vancomycin in patients with cancer (85% vs. 74%, respectively), and the odds of a sustained response were 2.6-fold higher in the fidaxomicin group ($P = 0.003$) [74]. Other treatment modalities for clinical presentations associated with CDI are shown in Table 5 [67].

Recurrent CDI

Rates of recurrent CDI are similar among immunocompetent patients and those post-HSCT [67, 75]. As outlined in Table 5, several strategies may be considered for the treatment of recurrent CDI. In a retrospective, propensity-matched study of patients with first or second CDI recurrences, there was no difference in the combined outcome of clinical failure or 90-day recurrence between fidaxomicin and oral vancomycin [76]. Of note, only 18% of the population in this study had a hematologic malignancy. Fidaxomicin has been studied as an extended-pulsed dosing regimen compared to standard doses of oral vancomycin as treatment for initial episodes of CDI. The extended-pulsed fidaxomicin regimen significantly improved sustained clinical cure in patients over age 60 years and reduced CDI recurrence rates up to 90 days after treatment initiation versus standard dose oral vancomycin [77].

Fecal microbiota transplantation (FMT) is a guideline-recommended option for the treatment of second and subsequent recurrences of CDI. FMT in HSCT patients has been associated with restoration of gastrointestinal microbiome diversity [78]. Clinically, FMT following HSCT has been reported to be a successful treatment option for recurrent CDI without FMT-related adverse events in several retrospective studies [79].

Bezlotoxumab, an intravenous monoclonal antibody directed against toxin B *C. difficile*, may be a treatment option to prevent cases of recurrent CDI. In pooled data from two large randomized trials, the addition of bezlotoxumab to antibiotic treatment for CDI reduced recurrent CDI rates from 27% in the antibiotic treatment plus placebo arm to 17% in the adjunctive bezlotoxumab arm ($P < 0.0001$) but did not affect clinical cure. The benefits of bezlotoxumab were most pronounced in patients most at risk for recurrence, including those who were immunocompromised, with a 36% rate of recurrence in patients who received antibiotic treatment plus placebo compared to 19% in patients treated with adjunctive bezlotoxumab [80].

Secondary Prophylaxis

The receipt of antibiotics after an episode of CDI is a significant risk factor for recurrent CDI and one that is oftentimes unavoidable early post-HSCT. Therefore, recommendations for the use of prophylaxis are outlined in Table 5. Prophylaxis with oral vancomycin or fidaxomicin versus placebo for HSCT patients has been associated with significantly lower rates of CDI recurrence [81, 82]. Oral vancomycin prophylaxis has also been studied in the setting of multiple CDI recurrences compared to placebo. These studies have raised concern that oral vancomycin prophylaxis may not be as effective for multiple CDI recurrences (> 1 prior episode) versus its use following one episode of CDI [83, 84].

Fungal Infections

Medical advances in the treatment of cancer, notably new chemotherapeutic agents and HSCT, have increased the number of patients susceptible to invasive fungal disease (IFD). The use of broad-spectrum antibiotics and antifungals in this population is common and has led to changes at the patient level as well as the global microbiome, leading to the emergence of drug-resistant fungal pathogens. In parallel, advances in technologies used to identify fungi have led to earlier detection of fungal infections as well as recognition of new species of fungi and novel susceptibility patterns.

The gold standard diagnosis of invasive fungal disease relies on identification of the fungus by histopathology, cytopathology, or direct microscopy or fungal growth in culture of specimen obtained by sterile needle aspiration or biopsy of an abnormal site [85]. Several limitations prohibit obtaining sterile material in the HSCT population, including risk of bleeding due to coagulopathy or thrombocytopenia, pneumothorax in cases of isolated pulmonary disease, and potentially death in critically ill patients. Therefore, clinicians sometimes rely on indirect tests for diagnosis.

Yeasts

Disease Epidemiology

Candida species have been the most common cause of IFD in patients who have undergone HSCT. Colonization of the gastrointestinal tract with *Candida* followed by administration of cytotoxic chemotherapy leading to injury of the gastrointestinal mucosal barrier is one of the most important risk factors for invasive candidiasis during neutropenia [86, 87]. Ninety percent (90%) of invasive human disease is caused by *Candida albicans*, *C. glabrata*, *C. tropicalis*, *C. parapsilosis*, and *C. krusei. C. albicans*, which is generally susceptible to fluconazole, has long been the most prevalent species implicated in invasive candidiasis. Widespread use of antifungal prophylaxis targeting *Candida* has led to a decrease in overall rates of *Candida albicans* infections, with an increase in infections caused by more fluconazole-resistant species such as *C. glabrata* and *C. krusei* [88, 89]. The TRANSNET surveillance system, which performed prospective surveillance of 22 HSCT centers, found *Candida glabrata* to be the most common cause of invasive candidiasis (33%), followed by *Candida albicans* (20%) [90]. While *Cryptococcus* remains a significant fungal infection after solid-organ transplant, its impact post-HSCT is not as considerable, with the TRANSNET surveillance system reporting only a 0.4% incidence of *Cryptococcus* in their HSCT cohort [90].

Candida auris

One of the most alarming changes in the epidemiology of invasive candidiasis has been the global emergence of the multidrug-resistant healthcare-associated fungal pathogen *Candida auris*. Since initial isolation in 2009 from the external ear canal of

a patient in Japan, *C. auris* has been reported from 35 countries from 6 continents, and 685 confirmed cases of *C. auris* have been reported in the United States [91]. *C. auris* infections have been associated with nosocomial outbreaks within intensive care units in patients with serious underlying medical conditions such as those with underlying hematologic malignancy and immunocompromised, requiring invasive procedures and receipt of prior antifungal therapy [92–94].

C. auris most commonly causes candidemia, with mortality rates over 50% reported in the United States, but has also been isolated from other sites in the body [92, 93, 95]. *C. auris* infection poses many challenges including difficulties in identification, unknown population prevalence, propensity for environmental spread, virulence factors, and inherent antifungal resistance.

Diagnosis

Blood Cultures

A large multinational prospective cohort study reported a 1.6% incidence of fungemia in HSCT recipients [96]. In many cases, initial fungal blood cultures may be negative, with reports of sensitivity as low as 30% for the diagnosis of invasive candidiasis in neutropenic patients and missed diagnoses of disseminated candidiasis in more than 50% of patients [97–99].

Fungal Antigen Testing: Serum 1,3-Beta-D-Glucan

1,3-Beta-D-glucan (BG) is a polysaccharide in the cell wall of most fungi with the exception of *Mucorales* and *Cryptococcus* [100]. Commercially available tests rely on activation of the coagulation cascade of the horseshoe crab in the presence of BG, with a positive test detecting concentrations of BG in the picogram per milliliter (pg/mL) range. The Fungitell assay, which is FDA approved, reports a positive result as a concentration greater than 80 pg/mL [101].

The reported pooled sensitivity and specificity of one positive BG test in the setting of proven or probable IFD are 76.8% and 85.3%, respectively [100], while two consecutive positive BG tests had a sensitivity of 49.6% and specificity of 98.9% in a cohort of hematology-oncology patients with proven or probable IFD [102].

Invasive fungal infections due to *Candida* or *Aspergillus* species, two of the most common fungal pathogens which cause invasive infection during febrile neutropenia, as well as with *Pneumocystis*, can produce a positive glucan, so a positive result does not help identify the exact species of fungus causing infection. False-positive test results can occur in patients who have been treated with IV albumin, IV immunoglobulin, and hemodialysis with a cellulose-containing membrane [103].

Nanodiagnostics

Magnetic resonance technology has been used to create a panel that detects the DNA of five different species of *Candida*, including *Candida albicans*, *Candida tropicalis*, *Candida parapsilosis*, *Candida krusei*, and *Candida glabrata*, in the blood. The FDA-approved T2Candida panel has a sensitivity of 90% and specificity

of 98% for candidemia [104]. A 98% negative predictive value of the T2Candida panel for candidemia in neutropenic patients has been reported [104]. The T2Candida panel may be more useful than standard blood cultures when de-escalating empiric antifungal therapy, with reports of patients receiving fewer days of antifungal therapy when using the T2Candida panel [105–107]. Further studies utilizing this technology in the neutropenic and HSCT patient population are needed.

Candida auris-Specific Diagnostics

C. auris is most phylogenetically related to the *C. haemulonii* species complex. Using conventional phenotypic and biochemical diagnostic methods, *C. auris* has often been misidentified as *C. haemulonii* or other fungal species such as *C. famata*, *C. sake*, *Rhodotorula glutinis*, or *R. mucilaginosa* [93, 95, 108, 109]. The CDC recommends reporting *Candida* isolates from sterile site cultures to the species level. The use of chromogenic agar to differentiate between *C. auris* and *C. haemulonii* isolates has been suggested as a low-cost method for identification [109]. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) is a potentially accurate and rapid method for identification; however, *C. auris* has only been added to libraries for research use thus far [110]. PCR assays have been developed and show promise for rapid and accurate identification of *C. auris* [111].

Management

Candida Species

An echinocandin is recommended as the first-line therapeutic agent to treat candidemia in neutropenic patients and as initial treatment for *Candida krusei* and *glabrata*, until susceptibilities are known. Fluconazole is an acceptable alternative treatment for those patients who are not critically ill or do not have suspected azole-resistant *Candida* infection (i.e., no prior prophylaxis or other major fluconazole exposures). Liposomal amphotericin B is an alternative agent but has more potential for toxicity, and risks versus benefits of administration should be considered [112]. Removing central lines is essential. Ophthalmologic exams for endophthalmitis are also recommended, optimally when not neutropenic [44].

Candida auris

The treatment of *C. auris* is complicated by the lack of species-specific antifungal breakpoints and the organism's ability to harbor and develop multidrug resistance. To date, most isolates have displayed elevated fluconazole MICs ($\geq$ 16 μg/mL) and variable susceptibilities to other azoles. Resistance rates to voriconazole have ranged between 3 and 73%. Among the triazoles, posaconazole, isavuconazole, and itraconazole are generally considered the most potent in vitro. Although less common, elevated MICs have also been demonstrated for amphotericin and echinocandins [94, 113–115]. According to the CDC, the majority of *C. auris*

isolates are susceptible to echinocandins, and treatment with an antifungal from this class, along with infectious diseases consultation, is recommended. Liposomal amphotericin B could be considered for patients clinically unresponsive to echinocandin therapy or who have persistent *C. auris* fungemia for greater than 5 days [116].

Of concern, about 40% of isolates have been resistant to ≥2 antifungal drug classes, and a smaller percentage (4–10%) have been resistant to most antifungals [114]. The novel oral 1,3-β-D-glucan synthesis inhibitor ibrexafungerp (formerly SCY-078) has demonstrated potent in vitro activity against *C. auris* [115]; ibrexafungerp has been an effective treatment for *C. auris* candidemia, even in the setting of high-level echinocandin resistance [113].

Cryptococcus

HSCT patients who have mild to moderate pulmonary cryptococcal infection may be treated with 6–12 months of fluconazole therapy, depending on their level of immunosuppression and clinical course. Cryptococcus infections involving the central nervous system (CNS), causing severe pulmonary disease, or involving sites outside of the CNS or lungs should be treated with at least 2 weeks of liposomal or lipid complex amphotericin B and flucytosine, followed by fluconazole consolidation and maintenance [117]. Lumbar punctures are often recommended so as to help with planning of treatment. The duration of fluconazole therapy may be at least 6 months or more, with longer durations of treatment for those HSCT patients who remain on immunosuppressive therapy for GVHD.

Molds

Disease Epidemiology

Over the last two decades, invasive fungal disease (IFD) secondary to opportunistic molds has become more prevalent than *Candida* in HSCT recipients. The incidence of IFD after allogeneic HSCT has been reported to range from 6 to 8% [90, 118]. Infection secondary to *Aspergillus* species is the most common, followed by *Mucorales* and *Fusarium* species [1, 36, 118, 119].

Clinical Impact

Receipt of a T-cell-depleted allogeneic HSCT, degree and duration of neutropenia after HSCT, and development and treatment of acute and chronic GVHD with corticosteroids are important risk factors for the development of opportunistic mold infection [120]. Invasive mold infections have varied symptoms depending

upon the site/s of infection, with the lungs being the most common site. Symptoms of invasive pulmonary mold infection can range from isolated fever with no respiratory symptoms to pleuritic chest pain with or without cough. Once the diagnosis of IFD is made, careful examination of the patient for other foci of infection (i.e., brain, skin, other organs) is important since dissemination of mold infections can occur, especially during neutropenia. Extrapulmonary sites of IFD should be assessed for feasibility for surgical debridement in an attempt to control the infection.

Diagnosis

Culture

Diagnosis of IFD using standard culture methods may be challenging due to the risks of obtaining specimen from affected sterile sites in critically ill patients and a delay in IFD diagnosis due to slow growth of mold in culture [121]. Current guidelines provide detailed microbiologic criteria for IFD diagnosis [85].

Galactomannan

Galactomannan (GM) is a polysaccharide found in the cell walls of *Aspergillus* and *Penicillium* species and is released into the blood during fungal growth. The detection of GM in serum and/or BAL is a diagnostic tool for invasive aspergillosis.

The Platelia assay, an enzyme immunoassay, can be used to measure GM in serum and bronchoalveolar lavage fluid (BAL). A large meta-analysis found an overall sensitivity of 71% and specificity of 89% when using serum GM in cases of proven invasive aspergillosis [122]. Biweekly GM testing has been found to increase the diagnostic sensitivity for invasive aspergillosis (IA) in high-risk HSCT patients but may be associated with higher costs and fewer additional diagnoses of IA [123–125]. Two large meta-analyses evaluating BAL GM reported a pooled sensitivity of 86–87% and specificity of 89% in cases of proven or probable IA [126, 127].

The sensitivity of the test decreases in patients receiving anti-mold therapy. Several published reports described false-positive GM results in patients receiving piperacillin-tazobactam [128–131], though this problem has been attributed to contamination of the drug lot [131, 132]. False-positive serum GM test results have also been reported in patients with underlying *Histoplasma* infection due to cross-reactivity in the assay [133].

Aspergillus PCR

Several commercial *Aspergillus* PCR tests which target the 18S rDNA and/or the 28S rDNA are available, with reported sensitivity and specificity in bronchoalveolar lavage fluid greater than 70% and 80%, respectively [134]. The *Aspergillus* PCR in conjunction with the *Aspergillus* galactomannan may be a useful combination test for earlier diagnosis of pulmonary aspergillosis [134].

Radiographic Studies

Computed tomography (CT) of the chest may be useful in diagnosing IFD in neutropenic patients due to molds such as *Aspergillus* species or *Mucorales*. The radiographic morphology of a pulmonary opacity on a CT scan of the chest can be suggestive of a potential fungal etiology.

Invasive pulmonary aspergillosis classically manifests radiographically as a "halo sign" (Fig. 2), which is a mass-like infiltrate with a surrounding halo of ground-glass attenuation [135–137]. Other radiographic findings in the setting of invasive pulmonary aspergillosis at various stages of evolution include cavitary lesions, infarct-shaped nodules or consolidations, and air-crescent signs [138].

Invasive pulmonary mucormycosis has been linked to a different radiographic sign, the "reversed halo sign" (Fig. 3), which is a central ground-glass opacity surrounded by a denser airspace consolidation [139].

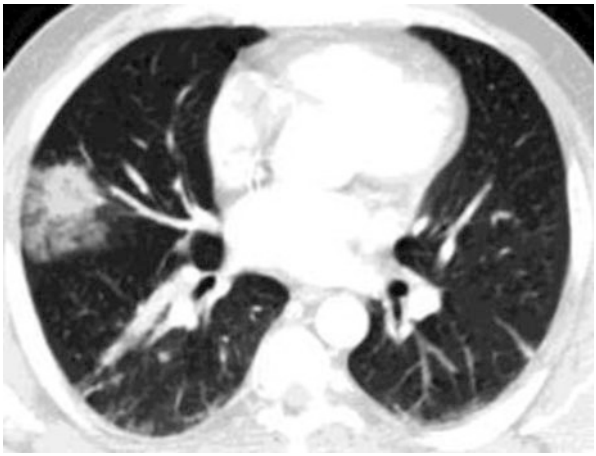

Fig. 2 Halo sign on chest computerized tomography. (Raveendran, S and Lu Zhiyan. *Radiology of Infectious Diseases*. Volume 5, Issue 1, March 2018, pp. 14–25, Fig. 3. Creative common license. Open access)

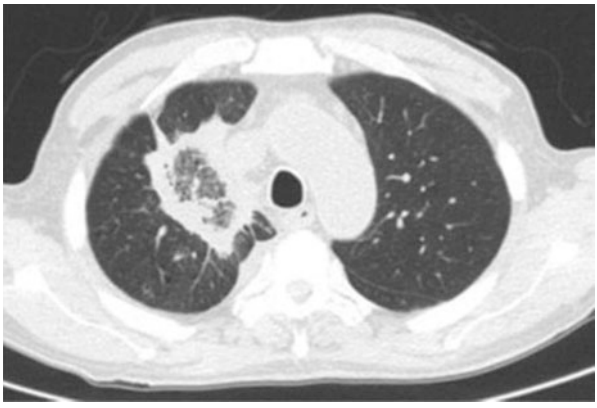

Fig. 3 Reversed halo sign. (Cornely et al. 2004 [150]. License: 4647870816622)

Fungal Metabolite Testing

Thermal desorption gas chromatography/mass spectrometry technology to detect fungal volatile metabolites found in breath specimens is a noninvasive diagnostic tool currently in development for detection of mold disease in HSCT patients [140, 141]. This technology may eventually be a rapid tool to diagnose fungal disease.

Management

Prophylaxis

Prevention of invasive fungal disease using antifungal prophylaxis has been studied in a subset of HSCT recipients [142]. This clinical trial found posaconazole to be non-inferior to fluconazole in prevention of invasive fungal disease in patients with GVHD, with the most significant impact in patients with Grade III–IV GVHD. The incidence of proven or probable IA was lower in patients who received posaconazole and mortality due to IFD was less in the posaconazole arm; however, there was no difference in overall mortality between the two groups.

Treatment

Historically, for cases of suspected or proven invasive *Aspergillus* infection, voriconazole has been recommended as first-line therapy and liposomal amphotericin as alternate therapy for patients who cannot receive voriconazole [120, 143]. A phase III double-blind non-inferiority study found a novel triazole, isavuconazole, to be non-inferior to voriconazole for the treatment of proven or probable IA [144] and led to the addition of isavuconazole as a first-line therapeutic option for *Aspergillus* infection [120]. Of note, there have been reports of breakthrough fungal infections due to *Candida* species, *Aspergillus* species, mucormycosis, and *Fusarium*, in patients on isavuconazole treatment [145, 146].

Of note, with the use of azoles in pesticides and agricultural demethylase inhibitors, there are reports of voriconazole-resistant *Aspergillus fumigatus* in Europe and azole-resistant *Aspergillus fumigatus* in the United States [147–149].

Use of amphotericin B deoxycholate and the more recent, less toxic lipid formulations and surgical debridement remain the mainstays of treatment for mucormycosis [150]. Posaconazole has been used as salvage therapy in patients who could not receive liposomal amphotericin B, with a reported success rate of 61–70% [151, 152], and remains a potential treatment option. In 2016, data were published showing isavuconazole had activity against several species of mucormycosis with comparable treatment outcomes to a matched historical group of patients who received amphotericin B for treatment of mucormycosis [153]. This study led to the approval of isavuconazole for the treatment of mucormycosis. In some cases of mucormycoses, isavuconazole might be an efficacious treatment option. An important consideration is variable susceptibility of the agents of mucormycosis to posaconazole and isavuconazole [154].

There are no recommendations for the optimal antifungal therapy for *Fusarium* infection, but initial treatment with voriconazole or lipid formulations of

amphotericin B has been suggested. In many cases, successful treatment has required varying combinations of antifungal medications while awaiting antifungal susceptibility testing results [155].

Pneumocystis Jiroveci

Pneumocystis jiroveci (PJP) is a fungal pathogen that can cause acute or subacute pulmonary infection in HSCT patients. Current guidelines recommend administration of prophylaxis directed again *Pneumocystis jiroveci* for 3–6 months in those autologous HSCT patients who have received intensive chemotherapy treatment or conditioning regimens or treatment with high-dose steroids post autologous HSCT and for a minimum of 6 months after allogeneic HSCT. The duration of prophylaxis post-allogeneic HSCT should be extended if the patient is receiving immunosuppressive therapy. Trimethoprim-sulfamethoxazole (TMP-SMX) is the preferred agent, but dapsone, aerosolized pentamidine, and oral atovaquone are alternative options.

Viral Infections

Herpes Simplex Virus

Given the ubiquity of herpes simplex virus 1/2 (HSV) seropositivity in the general population, there is an approximately 80% reactivation rate in the early post-HSCT period, particularly in the setting of mucositis [33]. All patients should be tested for serum anti-HSV IgG prior to transplant. Acyclovir prophylaxis for HSV seropositive (IgG) patients is recommended for a minimum of 30 days post-HSCT and is frequently extended to at least 1 year or longer post-HSCT to prevent HSV or VZV infection, especially in those patients who remain on intensive immunosuppression [5, 33]. Valacyclovir is presumed to be an equivalent substitute for acyclovir for HSV prophylaxis; however, data regarding safety and efficacy in the HSCT population is limited [5, 33, 156].

Varicella Zoster

All patients should be tested for serum anti-VZV IgG prior to transplant. Reactivation of VZV typically occurs within 3–12 months of transplantation, and a high proportion of patients will experience reactivation without adequate prophylaxis [5, 33, 157]. Therefore, long-term prophylaxis against VZV is recommended for all autologous and allogeneic HSCT recipients through the first year following transplantation or longer for patients with cGVHD remaining on immunosuppressive therapy [5, 21, 33]. Acyclovir and valacyclovir are the preferred agents for VZV prophylaxis, with valacyclovir having superior bioavailability over acyclovir [5, 33]. Due to the high morbidity associated with VZV disease, it is imperative that HSCT recipients avoid VZV exposure and that

seronegative caregivers and other household contacts receive VZV vaccination at least 4–6 weeks prior to HSCT [5, 33].

Cytomegalovirus

Although patients are at risk for many viral infections post-allogeneic HSCT, cytomegalovirus (CMV) infection remains the most clinically significant. CMV serologic status (IgG) of the recipient and donor is the most important risk factor for development of CMV reactivation, with CMV seropositive recipients of allogeneic HSCT from seronegative donors being at highest risk [158, 159]. Other risk factors for development of CMV infection include undergoing non-matched related donor HSCT, treatment with corticosteroids, and receipt of T-cell-depleting therapy. CMV reactivation occurs in 80% of seropositive recipients who do not receive prophylaxis [159], and mortality as high as 60% has been reported in patients who develop CMV disease [158]. Use of ruxolitinib for treatment of steroid-refractory acute GVHD has also recently emerged as a new risk factor for CMV reactivation post-HSCT [14]. The initial trial describing ruxolitinib's activity in the management of GVHD reported a CMV reactivation rate of 33% in aGVHD patients and 15% in cGVHD patients [160].

CMV reactivation post-allogeneic HSCT can result in detectable virus in the blood, CMV infection, and progression to end-organ disease. The majority of organs can be involved in CMV disease, with published definitions of specific end-organ diseases [161]. CMV has also been associated with indirect effects, specifically an increased risk of bacterial infections such as CDI and fungal diseases post-HSCT [161].

Diagnosis

Initial tests used CMV antigen testing (CMV pp65), with the majority of transplant centers now using quantitative CMV DNA polymerase chain reaction (PCR) and fewer using mRNA nucleic acid sequence-based amplification. International guidelines recommend use of real-time quantitative PCR for the diagnosis and monitoring of CMV viremia [162].

Assessment of CMV-specific immune reconstitution using CMV-specific enzyme-linked immunospot (ELISPOT) assay may help identify those patients at risk for developing CMV infection and disease after allogeneic HSCT, allowing clinicians to administer targeted antiviral prophylaxis and treatment [163].

Preemptive Management

The traditional approach post-HSCT was to monitor patients at risk for CMV reactivation and end-organ disease with weekly CMV DNA PCR until at least day 100 for evidence of CMV virus replication. An institution would determine the threshold viral load above which initiation of CMV treatment was started and patients

were initiated on anti-CMV therapy with an agent such as ganciclovir, valganciclovir, or foscarnet. Patients were generally treated until resolution of CMV viremia and possibly longer in cases of end-organ disease. Uses of preemptive screening and treatment strategies have reduced the risk of death from CMV to less than 10% [164].

Prophylaxis: Shift in Management

Over the last three decades, studies have attempted to identify a safe and effective CMV prophylactic strategy in allogeneic HSCT recipients [165]. Limitations to finding a suitable prophylactic agent included non-efficacious compounds and significant drug side effects. In 2017, an antiviral which inhibits the CMV viral terminase complex, letermovir, was approved for CMV prophylaxis in allogeneic HSCT recipients. Data from a phase III, randomized, double-blind, placebo-controlled study showed that CMV seropositive recipients who received letermovir prophylaxis by day 28 post-allogeneic HSCT had significantly less CMV infection than those receiving placebo or standard of care therapy with no significant differences in side effects between the two groups [166]. The identification of an effective and well-tolerated prophylactic agent has changed the landscape of HSCT, leading to a shift in management from a preemptive to prophylaxis strategy in many centers (Table 6).

Letermovir is an effective prophylaxis only against CMV and lacks prophylactic activity against other human herpes viruses. Therefore, additional prophylaxis for herpes simplex virus (HSV) and varicella zoster virus (VZV) with acyclovir or valacyclovir is recommended for HSCT patients. Mutations in the UL56 terminase gene has been shown to lead to letermovir resistance [167] with numerous such reports in clinical practice [168, 169].

Drug-Resistant CMV Infection

Foscarnet and cidofovir remain potential therapeutic options for HSCT patients who develop ganciclovir-resistant CMV infection. Abnormal renal function, significant electrolyte depletion, and inability to administer long-term intravenous antiviral therapy limit the use of these antivirals. Several phase II clinical trials have shown safety and efficacy of maribavir, an inhibitor of the pUL97 viral kinase, for treatment of patients with CMV viremia and drug-resistant CMV disease [170–172]. Currently, there are two phase III clinical trials evaluating maribavir treatment for CMV infections in HSCT patients and drug-resistant CMV infection in transplant patients.

Table 6 Cytomegalovirus management post-HCT

Preemptive therapy	Letermovir prophylaxis
Weekly cytomegalovirus viral load	Initiate prophylaxis post-HCT Initiate HSV/VZV prophylaxis post-HCT
Institution viral load threshold	Continue until at least day +100
Start antiviral therapy directed at CMV	Stop letermovir and start antiviral therapy directed at CMV for patients with infection

The only method to assure sustained control of CMV infection is to achieve immune reconstitution with CMV-specific CD4+ and CD8+ T-cells [130]. However, this is often delayed in the HSCT population for reasons highlighted throughout this chapter. Therefore, adoptive T-cell therapy is currently an active area of investigation for management of refractory CMV infection [173]. This can be done through initial HSCT donor-derived or third-party donor-derived T-cell engineering, with the former generally proving to be more successful [173].

Epstein-Barr Virus

Epstein-Barr virus (EBV) in the HSCT population most commonly arises from reactivation from the patient or donor, but primary infection can also occur [5, 40]. The primary concern associated with EBV reactivation and infection following HSCT is the development of posttransplant lymphoproliferative disorder (PTLD) which is associated with significant morbidity and mortality [174]. Therefore, serial monitoring of EBV DNA via PCR testing is recommended to allow for preemptive management of reactivation and is particularly important in high-risk patients [33, 174, 175]. Patients at highest risk of EBV reactivation or primary infection are those who received a T-cell-depleted graft or T-cell-depleting serotherapy as well as haploidentical HSCT and UCB HSCT recipients due to profound lymphopenia [5, 33, 174]. No standard threshold exists for initiation of treatment of EBV viremia, and currently available antiviral agents do not have significant activity against EBV, so prophylaxis or treatment with antivirals is not recommended [5, 33, 174]. Preemptive treatment approaches include reduction in immunosuppression, when possible, and B-cell depletion with rituximab, as these have been shown to prevent progression to PTLD, particularly in high-risk patients [5, 33, 176]. Adoptive T-cell therapy using donor or third-party-derived EBV-specific T-cells also has demonstrated efficacy in controlling EBV viremia but is currently only available in clinical trial settings [177, 178].

Adenovirus

In HSCT patients, adenovirus (AdV) reactivation or primary infection can cause pneumonitis, colitis, and hepatitis associated with significant morbidity and mortality. Rates of AdV infection are approximately two times higher in pediatric HSCT patients than adult patients due to persistent viral circulation and therefore is of particular concern in that population [179]. Control of AdV reactivation and infection is highly dependent on cellular immunity following T-cell immune reconstitution, and therefore recipients of UCB, haploidentical, or T-cell-depleted HSCT or patients receiving T-cell-depleting serotherapy, such as ATG, or on intensive immunosuppression for GVHD are at highest risk for disease [5]. A preemptive management approach using weekly AdV viral PCR monitoring for high-risk patients can be considered and has been shown to prevent progression to end-organ disease [179, 180]. However, the majority of data supporting preemptive management is in the

pediatric HSCT population, and the toxic effects of AdV treatment can limit the utility of this approach in adults [179, 181]. Therefore, AdV viral PCR screening can also be restricted to symptom-triggered testing as an alternative [179]. Recommended treatment of AdV reactivation or disease is cidofovir 5 mg/kg IV weekly and should be given with hyperhydration and probenecid to limit nephrotoxicity [179, 181]. Cidofovir 1 mg/kg three times weekly can be used as an alternative dosing strategy for preemptive therapy only and is associated with lower rates of nephrotoxicity [179, 181]. Brincidofovir, an oral lipid conjugate of cidofovir with decreased myelosuppressive and nephrotoxic effects, has a growing body of literature supporting its efficacy in AdV reactivation management and may eventually become more useful as a preemptive therapeutic agent [179]. Adoptive T-cell therapy is another management approach that is an area of active investigation and has documented success in treatment of resistant or refractory AdV disease in early trials [173, 179, 182].

BK Virus

Human polyomavirus type I (BK virus) seropositivity has a high prevalence of up to 90% [183]. Therefore, asymptomatic urinary shedding occurs in up to 80% HSCT recipients in the early posttransplant period and is more common in allogeneic HSCT recipients, particularly those receiving myeloablative conditioning regimens and in MUD, UCB, and haploidentical transplants [183, 184]. However, 5–15% of patients will develop BK virus-associated hemorrhagic cystitis (BKV-HC), typically occurring after engraftment [5]. PCR testing for BK virus in urine or blood can be performed to assess for reactivation. Fluoroquinolones are known to inhibit BK virus replication; however, no preemptive or prophylactic strategies have demonstrated efficacy in preventing the occurrence of BKV-HC [5, 183]. Cidofovir has been reported in several retrospective studies to be effective in treatment of BKV-HC with complete response rates ranging from 60 to 100% [183]. It has been used both IV and intravesicularly and at a variety of dosing schedules ranging from 0.5 to 5 mg/kg one to three times per week with and without probenecid [183]. Nephrotoxicity is a major limitation associated with cidofovir therapy and can be mitigated with intravesicular administration and concomitant probenecid [183]. There is no consensus on when to initiate treatment of BKV-HC versus continuation of supportive care alone, but general consideration can be made for high-grade HC or any grade HC with concomitant BK viremia [183].

Parasitic Infections

Toxoplasmosis

The risk of *Toxoplasma gondii* reactivation is 2–6% in patients who are seropositive prior to HCT, with recipients of UCB, or those on extensive immunosuppression being at higher risk for reactivation [185]. Routine PCR screening of blood can be

considered to allow for early detection prior to onset of clinical symptoms of disease. Alternatively, symptom-triggered testing is also a reasonable approach, particularly in patients receiving appropriate prophylaxis, as reactivation in this setting is rare [5, 186]. Patients receiving TMP-SMX for PJP prophylaxis will be appropriately protected against *T. gondii* as well, so no additional preventative therapy is needed [5, 33]. In patients who cannot tolerate TMP-SMX, prophylaxis with agents active against *T. gondii* can be given (such as clindamycin or pyrimethamine plus leucovorin), or no specific prophylaxis can be administered, and PCR monitoring can be performed to allow for preemptive treatment [5, 186].

Strongyloides

Strongyloidiasis is a rare infection after HSCT, with case reports in the literature. Patients from endemic areas and those with gastrointestinal symptoms or unexplained eosinophilia pre-HSCT should be screened with *Strongyloides* species immunoglobulin G enzyme-linked immunosorbent assay or stool screening if serologic testing is unavailable and treated with anti-parasitic therapy before HSCT. The diagnosis of strongyloidiasis post-HSCT can be challenging, as gastrointestinal symptoms may mimic those of GVHD, and a detailed exposure history may be the only significant factor to initiate evaluation for this infection [5, 187].

Post-HSCT Vaccinations

An essential aspect of infection prevention following both autologous and allogeneic HSCT is the administration of immunizations [5, 33, 188, 189]. Vaccinations should be administered starting between 3 and 6 months posttransplant; however, delays may be warranted in patients who remain on significant immunosuppression for GVHD treatment or those who have received rituximab within the past 6 months [188–190]. Due to the many factors that have been outlined throughout this chapter related to the variability in immune reconstitution following HSCT, it is recommended to obtain antibody titers following diphtheria-tetanus-pertussis, VZV, and hepatitis B vaccination administration to ensure adequate response and have been correlated with vaccine efficacy in studies [188, 189, 191]. Revaccination should be performed if titers are insufficient. Table 7 outlines the typical recommended immunization schedule for HSCT patients.

Conclusions

The risk of developing an infection after HSCT is determined by a complex interplay of a variety of factors. These include cumulative pretransplant cytotoxic chemotherapy, depth and duration of posttransplant neutropenia, receipt of a transplant from an umbilical cord blood or haploidentical donor, and development of acute and/or

chronic GVHD requiring treatment. Distinguishing immune reconstitution pattern between different modalities of HSCT allows for risk stratification of specific infections over time. Improvements in diagnostic technology have enabled earlier detection and identification of new infections in HSCT recipients. Additionally, drug development and clinical trials have led to new prophylactic and therapeutic options for infections which have historically been associated with significant HSCT patient morbidity and mortality.

Key Points

- Risk of infection after hematopoietic cell transplantation is dependent on multiple factors including extent of pretransplant chemotherapy exposure, duration of posttransplant neutropenia, source of allograft, and severity of graft-versus-host disease.
- Understanding the kinetics of posttransplant immune reconstitution allows for infection risk stratification and development of a timeline of infections after allogeneic hematopoietic cell transplantation.
- Patients who have undergone hematopoietic cell transplant are at risk for bacterial, viral, fungal, and parasitic infections.
- Patients who have undergone HSCT are among those at the highest risk for the development of drug-resistant pathogens, often requiring medications with increased toxicities for treatment.
- Special considerations should be made for prophylaxis and treatment of infections in the HSCT population based on risk factor assessment.

Introduction

The emergence and spread of infectious diseases is related to weather and seasonal variability, from the amount of rainfall, flooding, and drought to the rise in local temperatures. Climate change and global warming will impact worldwide temperatures and seasonal variability with different amounts of moisture and heat [1]. Selected infectious diseases affected by climate change including viral, bacterial, parasitic, and fungal infections are expected to rise in frequency [2]. The incidence of emerging infectious diseases is likely to increase in relation to changes in human

activity through commercial globalization, population movement, and global environmental changes [3]. Profoundly immunosuppressed patients are at a greater risk of mortality and morbidity secondary to infections related to population shift and climate change. This is due to this population's underlying suppressed immunity, lack of effective and appropriate response to immunizations, and the absence of unified proper initiatives to face the problem of infectious diseases in the setting of epidemiological shifts. In addition, SOT and HSCT recipients are at risk of donor-derived infections and debilitating infectious diseases through the acquisition of new or reactivation of old infections that they acquired through the environment. Predicting infectious diseases patterns due to epidemiological shifts resulting from climate change will guide the prevention of infectious diseases in transplant recipients [4].

Migration and Population Shift

Geographic shifts in population and global demographic changes have become the norm, as it is estimated that 150 million people lived somewhere outside their country of origin by the end of the twentieth century [3]. In 2015 there were reported 244 million international migrants from Europe, Asia, Africa, and the Middle East [5]. In the same year, close to 65 million people were displaced globally due to wars and natural disasters, generally relocating from regions with limited healthcare systems [6]. In addition, international travel has become more popular. According to the United Nations World Tourism Organization (UNWTO), international tourist arrivals grew by 7.0% in 2017, the greatest increase since 2009. A total of 1,326,000 tourist arrivals were recorded in destinations around the world, 8.5% more than in 2016. It is expected that by the year 2050 close to 70% of the world population will inhabit urban areas with limited resources [7]. There are well-established historical accounts of how colonialism, human migration, and religious conquests led to outbreaks of new infections in susceptible populations. The "Black Death" or the Great Plague pandemic, caused by the bacterium *Yersinia pestis* transmitted by flea-infested rodents, originated in China and spread along the great trade routes to Europe via Italy. The Plague killed between 25 and 30 million people worldwide and, from 1347 to 1352 CE, destroyed 60% of the European population [8, 9]. Today, a rise in the incidence of emerging infectious diseases may be linked to changes in human activity through commercial globalization, population movement, and environmental changes [3]. The increased movement of humans, animals, and food products resulting from changes in global commerce practices has led to infectious disease outbreaks [3]. Transportation used for human migration and travel including the use of ships has led to the spread of influenza, legionellosis, and diarrheal illnesses due to *Vibrio cholerae*. In addition, transportation of goods for human use has introduced diseases and led to the introduction of vectors into new geographic regions as documented by outbreaks of West Nile virus (WNV) transmitted by *Culex* mosquitoes and Chikungunya fever by *Aedes* mosquitoes. The emergence of outbreaks of Zika virus (ZKV) in South America, Central America,

and Florida highlights the link between human movement and emergence of new infectious diseases. This movement of people has intensified in the twenty-first century with the rise in globalization, poverty, environmental disasters, and political unrest resulting in the spread of infections [3]. The devastating 2010 earthquake in Haiti resulted in the death of over 200,000 people and the displacement of over a million people. Ten months following the earthquake, an outbreak of toxigenic *Vibrio cholerae* O1, serotype Ogawa, biotype El Tor, linked to a distant geographic source caused 8,183 deaths [10]. Civil unrest in the Democratic Republic of the Congo (DRC) resulted in 1152 Ebola-related deaths by July 2019. The armed militia hindered the efforts of Ebola response teams and containment efforts resulting in the displacement of at-risk populations [11]. Natural disasters have contributed to outbreaks of fungal infections as well. The displacement of fungi into new environments by the disruption of their habitats has led to clusters of respiratory and cutaneous infections. Coccidioidomycosis, mucormycosis, aspergillosis, and other pathogenic fungal infections have been implicated in such disasters. During the recovery phase, population displacement, lack of access to healthcare, and conditions of poor sanitation and hygiene may result in the rise of infections [12].

Diseases can either emerge in new environments independent of certain climate requirements or adapt specifically to tropical and subtropical regions where certain vectors are present. In addition, non-zoonotic means of transmission such as person-to-person transmission are linked to population density, sexual practices, and lack of immunity to vaccine-preventable diseases [3]. Political instability in Venezuela has resulted in the breakdown of its public health system. Much of the population has limited access to food and healthcare. This has resulted in new cases of measles, diphtheria, and malaria [13]. According to the World Health Organization (WHO), immigration and forced displacement have led to an increase in imported and autochthonously transmitted cases of leishmaniasis in Europe and other non-endemic regions where there is a limited healthcare provider experience in the control and management of this disease [14]. Global cholera epidemics most recently in Yemen have resulted from international spread of the infection due to mass migration, war, famine, and lack of infrastructure with limited access to medical care [15].

Modern Patterns of Human Migration and Infection

Modern patterns of human migration are complex and linked to changes in global trade and travel, advancements in communication technology, socioeconomic inequality, wars and other interpersonal conflicts, and lack of access to jobs and education. These factors coupled with changes in climate result in rising migration and immigration in order to avoid rising sea levels, extreme weather changes, droughts, and resulting decreased access to food [16]. Human migration due to weather-related disasters leads to forced displacement, often resulting in disease outbreaks. Slower migration patterns due to a gradual decline in environmental conditions force communities to move into crowded and poverty-stricken urban

areas with increased exposure to infectious diseases. Finally, planned resettlement and labor-related migration may increase infectious disease exposure risk [16].

As military, business, and pleasure travel increase in the twenty-first century, travel-associated illnesses are reported in regions where healthcare providers may be unfamiliar with these illnesses [17]. For example, patients who have visited the southwestern United States may experience significant delays in the diagnosis of coccidioidomycosis after returning home. International adoption practices must include early screening of children on arrival for latent or active infections and provide appropriate immunization for diseases such as polio, varicella, and measles [17]. Recent outbreaks of Ebola have raised international awareness of infection control measures. Infection control may be compromised in settings where access to hand sanitizers, soap, masks, gowns, isolation rooms, and other hygiene practices and education are limited or even nonexistent [17].

As increased tourism and global commercial exchanges have contributed to the emergence of some infectious diseases, institutions such as the Centers for Disease Control and Prevention (CDC) have been focusing on affected travelers, immigrants, and refugees who may become transplant donors or recipients. In a study of local international travelers attending a travel and migration center for travel counseling and immunization in Southern Italy between 2015 and 2017, at least 15% had specific antibodies to one or more vector-borne diseases including dengue, WNV, chikungunya, and ZKV [18]. In another study investigating imported malaria cases through the use of social networks in Swaziland, 73% of imported cases included laborers and self-employed contractors who traveled frequently to Mozambique to visit their families and conduct business while working in Swaziland. Interviews revealed common congregation points, such as urban markets and bus stations, where people with similar travel patterns and malaria risk behaviors could be located and tested. The study highlighted the use of social networking methods to provide interventions in the prevention of vector-borne infections including malaria among at-risk populations [19]. An increase in reported cases of endemic mycoses including histoplasmosis, coccidioidomycosis, and paracoccidioidomycosis has recently been reported in Spain, where infections are not endemic. The study documented an increase in imported endemic mycoses between 1997 and 2014 due to migration. Of the total cases, 65% with histoplasmosis, 25% with coccidioidomycosis, and 32% with paracoccidioidomycosis occurred in immunocompromised patients. Many diseases encountered outside endemic areas are also underdiagnosed due to the unfamiliarity of healthcare providers and the lack of mandatory reporting [20]. This raises the risk for unrecognized infectious diseases in the pool of transplant donors and recipients with a history of migration or relocation.

Shifting Populations and the Changing Epidemiology of Infectious Diseases

Organ, cell, and tissue transplant donors and recipients are exposed to tropical diseases through receipt of blood products, infected grafts, de novo infections,

reactivation of latent infections, and functionally healthy grafts that are reinfected posttransplant. Although most acquired parasitic infections resolve in 3–5 years, infections such as strongyloidiasis and Chagas disease can endure for decades and may result in catastrophic infections after transplantation. Additionally, commercial and transplant tourism may further fuel this process [21]. The transmission of *Trypanosoma cruzi* through blood and blood products and organ and bone marrow transplantation has been well documented in the literature. The changing epidemiology of Chagas disease with increased migration from endemic regions to Europe, the United States, and Australia has been recognized [22]. The CDC has estimated that 1.31% of Latin American immigrants in the United States have been exposed to Chagas disease. However, these estimates are based on test results from blood donors [23]. In a large-scale study, Meymandi et al. sought to assess the prevalence of Chagas disease in a US population of Latin American immigrants through *T. cruzi* antibody testing and reported a prevalence of 1.24%, implying that greater than 30,000 individuals were infected in Los Angeles County [23]. In Europe, most patients with Chagas disease have been diagnosed in Spain, Italy, France, the United Kingdom, and Switzerland where pooled seroprevalence studies report an overall prevalence of 4.2%. Efforts are underway to improve screening programs and raise physician awareness in order to recognize the serious complications of chronic Chagas disease. In addition, the risk of autochthonous transmission of *T. cruzi* and other infectious diseases is of concern for the transplant community [22]. Changes in the policies for blood donor screening in Europe and North America have been implemented for *T. cruzi* and *Plasmodium* species to prevent cases of transfusion-transmitted infections [24]. The first reported case of transfusion-associated babesiosis was reported in 1979; in 2010 blood donation centers in the United States began screening blood in endemic regions. In July 2018, the FDA issued a draft guidance to help reduce the risk of transfusion-transmitted babesiosis [25]. In 2016, in response to the Zika epidemic, the US Food and Drug Administration (FDA) required universal ID-NAT testing in the 50 states and Washington, DC [26]. Simkins et al. have since reported a low prevalence of ZIKV among their deceased donors in Florida despite local ZIKV transmission; infections were associated with donors who traveled to ZIKV-endemic countries [27]. By 2018, 23 transplant recipients had received organs from WNV-positive donors. US blood banks provide year-round screening for WNV, and living donor screening is recommended by Organ Procurement and Transplantation Network (OPTN) in endemic areas. However, for deceased donors there are no formal recommendations, and practices differ by organ procurement organizations (OPO) [28].

It is estimated that one-third of the world's population is infected with *Mycobacterium tuberculosis* (TB) and transplant recipients have a higher risk of developing life-threatening complications with TB. International travel and immigration have changed the epidemiology and donor populations; currently TB has become one of the common donor-derived bacterial infections in the United States and Europe where a reported 0.35–6.6% of recipients develop TB [29]. The diagnosis of donor-derived and reactivated latent tuberculosis (TB) in transplant recipients is challenging in low TB prevalence regions despite the availability of sensitive imaging modalities and improved diagnostic assays [29].

The global public health threat of antimicrobial resistance is linked directly to travel and/or immigration. This may have a significant negative impact for patients undergoing HSCT or SOT [3]. Numerous studies have linked the acquisition of multidrug-resistant organisms (MDROs) including multidrug-resistant *Enterobacteriaceae* (MRE) with international travel. The CDC has issued warnings concerning infections with nontuberculosis mycobacteria related to cosmetic surgery in countries such as the Dominican Republic. Most studies note that acquisition occurs through contact with local food, water, colonized individuals, antimicrobial use during travel, and nosocomial transmission during medical care. Many travelers and migrants are asymptomatic carriers of MDROs, and studies have documented that 6–24% continue to harbor MRE 6 months post travel [30]. Increased travel coupled with a global increase in the number of transplant procedures facilitates the emergence and transmission of infectious diseases in previously unaffected populations [7]. Transplant tourism places recipients at risk for medical and surgical complications. There is also a reported threefold increase in the risk of acquiring infections, including antibiotic-resistant bacteria such as New Delhi metallo-beta-lactamase-1 (NDM-1)-producing *Enterobacter cloacae* and extended-spectrum beta-lactamase (ESBL)-producing *Escherichia coli* [31, 32]. Infections are not limited to drug-resistant bacteria; at certain centers invasive fungal infections (IFIs) have been reported in up to 8% of commercial transplant recipients [33].

Preventative Strategies and Global Demographic Changes

Prevention of infectious diseases related to geographic shifts in population requires a multidisciplinary approach. Efforts are needed in the development of surveillance systems, vector control programs, educational initiatives, access to healthcare and immunizations, and humane political systems that do not demonize travelers, immigrants, and refugees [3]. In order to prevent the spread of infectious diseases, it is important to intervene early and provide appropriate public health measures and preventative services for immigrants and travelers. Awareness of travel history is key for evaluating infectious disease exposure and critical when addressing infectious disease risk for organ donors and recipients. Screening for communicable diseases such as tuberculosis, foodborne illness, and vaccine-preventable diseases encountered during prolonged travel or during residence in refugee camps is important. The testing and management of HIV, hepatitis B, hepatitis C, malaria, and chronic helminthiasis such as strongyloidiasis are a crucial component of the transplant screening process. Appropriate access to care is critical in this time of high human mobility and is an important factor in the prevention of infectious diseases. Access to such services should be independent of one's legal status [5]. Immigrants and refugees have faced discrimination through unfounded claims of infection transmission to new populations such as the baseless polio threat posed by Syrian refugees into Europe after a 2013–2014 outbreak [6, 34]. With the rise in human migration, infectious disease specialists and other healthcare providers have the additional task

of encouraging and educating society on the importance of humane and compassionate care for our fellow human beings who are fleeing unfavorable conditions [6].

Healthcare provider awareness of certain infectious diseases is also limited in developed countries. For example, the differential diagnosis for conditions associated with splenomegaly may be different than when encountered in developing countries where malaria, leishmaniasis, and schistosomiasis are more common [35]. Various studies have stressed the importance of research and public health policy in the development of surveillance systems for vector-borne diseases. In addition, calls have been made to the scientific community and policy makers to provide strategies that promote sharing of experience and data, pooling resources in order to respond promptly to the threat of vector-borne diseases [7].

Transplant screening guidelines, including those from the American Society for Transplantation (AST), the CDC, the Infectious Diseases Society of America, and the American Society for Blood and Marrow Transplantation, have addressed the prevention of infection in transplant recipients [21]. Screening and selection protocols can assist transplant care providers with the early detection of infections in donors and recipients from tropical and other geographic regions, which are usually not encountered at a transplant center [21]. In addition, recently published guidelines from the Infectious Disease Community of Practice of the AST have updated recommendations for prevention and management of travel-related infection in solid organ transplant (SOT) recipients and transplant tourists. The guidelines recommend counseling regarding travel, evaluation by travel medicine specialists, advice on vaccine-preventable illnesses, and antimicrobial prophylaxis. These guidelines and a chapter in the current book address the risks associated with transplant tourism [36].

Climate Change and Infectious Diseases

Over the past 3.5 billion years, the earth's climate went through a multitude of changes that led to environmental pressure on living organisms, species selection, and extinction. Most of the changes were naturally driven by the earth's geological activity, which resulted in the rise of new species while others perished [37]. The current planetary period during which humans have manipulated their surrounding natural habitats and affected species evolution is referred to as Anthropocene. Indeed, such changes were observed since Darwin's time and led to the inception of the theory of evolution. The recent rise in global CO_2 concentration, through its greenhouse effect, leads to increases in the global temperature and rising sea levels [1]. This phenomenon will impose variable selection pressure on different species, leading to the extinction of certain species [1]. According to the Intergovernmental Panel on Climate Change (IPCC), the anthropogenic climate change is expected to increase the global temperature by 1.5 °C above the pre-industrial era by the middle of the twenty-first century [1]. As predicted, global warming and climate change will affect the biodiversity and life on earth and will also have a direct effect

on human health, particularly impacting the spread of infectious diseases. This rise in global temperature and change in seasonal variation may lead to widespread endemics of vector-borne diseases including parasitic, viral, fungal, and bacterial infections [2].

Infections caused by respiratory viruses are known for their seasonal variation and their association with climate change. To give an example, a study of H7N9 and H5N1 viruses in China showed that temperature variation played a role in the distribution of both strains; however, interestingly humidity played a factor in H7N9, while atmospheric pressure was more associated with H5N1 infections [38]. Surgical site infections (SSIs) are among other infections found to be affected by seasonal variation. Incident of SSIs is found to be at the highest rates in August, although this may have been related to the "July effect" where new staffing turnaround occurs. However, the study concluded that the seasonal effect persisted after adjusting for hospital settings (academic vs. private) [39].

The predicted spread of infectious diseases with climate change will carry devastating consequences to human health and the immunocompromised population in particular. This is expected to carry significant health risks to the SOT/HSCT population in particular as it can lead to higher rates of organ rejection, morbidity, and mortality. As the prevalence of immunosuppressed population is expected to rise in the following years, studying this aspect of infectious diseases will help design plans to tackle this emerging problem in this vulnerable population.

Climate Change and Parasitic Infections

Climate change is expected to alter the current epidemiological trend of parasitic infections, by affecting the host and vector interplay secondary to population shift of vectors, hosts, and reservoirs. It is believed that the current epidemiology of *Schistosoma* spp. may suffer changes in its geography. Such trends can be unpredictable and pose a risk for the emergence of donor-derived infections as current donor travel history screening methods lack the understanding and ability to predict future changes in the environment [40]. Similar to the epidemiological change of *Schistosoma* spp., the geographic distribution of other parasitic infections will be affected. A study from Hawaii suggests that there will be a shift in the *Angiostrongylus cantonensis* epidemiology, the agent of eosinophilic meningitis, as it is expected to expand to higher altitudes within the Hawaiian Islands [41]. Global warming is thought to cause an increase in the incidence of helminthic infections in specific geographical regions. At the same time, other regions will have a possible reduction in the rates of such infections, as there will be a shift favoring certain environments from one area to another [42]. The human data needed to predict the future trends of other parasitic infections known to affect SOT recipients such as *Strongyloides stercoralis* are currently lacking [4]. However, a veterinary study from Ireland suggests that warmer and more humid weather driven by climate change may increase the rates of gastrointestinal sheep nematode infections [43].

Climate Change and Vector-Borne Infections

It is estimated that 17% of all infectious diseases are due to vector-borne diseases including dengue, chikungunya, Zika virus, malaria, leishmaniasis, and lymphatic filariasis in tropical and subtropical regions [7]. Solid organ transplant patients are at risk of acquiring infections through donors who are infected with vector-borne pathogens, such as chikungunya, *Eastern equine encephalitis virus*, WNV, and *Leishmania* [42, 44–47]. Vectors such as *Aedes aegypti* and *Aedes albopictus* are observed to follow humans' movement; however, the long-term prediction models suggest global warming will primarily drive future spread. It is expected that global warming will provide a suitable medium for both *Ae. aegypti* and *Ae*. *albopictus* to expand into new territories in Europe and North America. This will facilitate the spread of chikungunya, dengue, yellow fever, and ZKV infections [48]. WNV has established its presence in the United States with reported cases of transmission to organ recipients [47]. It is expected that with the increase of global temperatures and changes in the weather driven by climate change, dengue, chikungunya, and ZKV will consolidate their current foothold in the globe's tropical and subtropical regions around many seasons and will likely spread to more temperate areas within the continent of North America [49]. These viruses are reported to infect SOT and HSCT recipients; however, the extent of their impact on such populations requires more study.

Experimental mosquito models revealed that increases in temperature toward the optimum of 29 °C would lead to higher rates of infected mosquitos with ZKV, which in turn will lead to the higher transmission of this virus. This suggests the spread of ZKV from current areas to high-latitude temperate regions [50]. Atypical clinical presentations of ZKV infections have been observed in solid organ transplantation recipients during the posttransplantation period; however, donor-derived infection rates and outcomes are yet to be studied. Following new trends in the spread of such viruses will help healthcare providers and organ procurement organizations to screen donors and educate recipients properly [45].

Multiple mathematical models have been utilized to assess the effect of climate change and the spread of tick-borne illnesses. Such models predicted the spread of tick-borne illness through the dissemination of associated vectors driven by the changes in climate in different parts of the world. One model predicted the rise in temperatures might lead to the spread of *Amblyomma americanum* (lone star tick) to more northern and eastern parts of the continental United States. Such expected expansion will lead to the spread of *Rickettsia* spp. (e.g., *Rickettsia rickettsii*, *Rickettsia parkeri*), *Ehrlichia* spp. (e.g., *Ehrlichia chaffeensis*, *Ehrlichia ewingii*), *Francisella tularensis*, and Heartland virus [51]. Surveillance data from Canada showed expansion of the *Ixodes scapularis* and non-scapularis ticks in the Ontario and Quebec regions of Canada which can be related directly or indirectly to climate change and its effect on host animals [52, 53]. Such vectors carry infectious agents including Lyme disease and *Powassan virus*. Additionally, an experimental model *Rhodnius prolixus* at different temperatures showed that an increase in temperature from 26 °C to 30 °C led to decreases in the development time of *Rhodnius prolixus*

accompanied by the increase of infective forms of *Trypanosoma cruzi* associated with this vector [54]. Tick-borne and insect vector-borne illnesses can be transmitted through blood transfusion, tissue, cell, and organ donation.

Similar approaches are being taken to better understand future changes in parasitic infections. Use of the Maxent machine learning to study lymphatic filariasis in Africa has helped predict a possible spread of lymphatic filariasis to higher altitudes in the continent of Africa affected by global warming [55]. In another study, human population growth and population shift are both predicted to play a significant role in the expected increase of the spread of these infections. However, it is also believed that climate change will favor the development of *Simulium* species (black fly), which is responsible for the spread of *Onchocerca volvulus* [43].

More than 200 million people around the globe are at risk of contracting malaria including SOT and HSCT recipients [56–58]. Malaria is one of the parasitic infections affected by climate change with a shift of geographical distributions of its vector (*Aedes* species) toward higher altitudes. In a study exploring the epidemiology of malaria in Ethiopia and Colombia, researchers observed the expansion of malaria infection to higher elevations with rising temperatures [59]. Such trends impact the incidence of donor-derived parasitic infections in organ transplantation. This will require monitoring of such patterns and vigilance as unconventional manifestations may occur in the immunocompromised patient and are associated with high morbidity and mortality.

Climate Change and Fungal Infections

SOT and HSCT recipients are at increased risk of developing invasive mycoses, and among fungal infections, endemic mycoses pose a special risk to this vulnerable population [60]. Interseasonal variability is observed in endemic mycoses, and as climate change is expected to result in increases in seasonal temperatures around the globe, the spread of certain fungal infections into areas not previously affected is possible. Indeed, the current pattern of climate change is expected to shift the geographical distribution of endemic fungal infections [61]. A study of coccidioidomycosis in Arizona throughout 1998–2001 showed evident seasonal variability with an increase in incidence of infections during the months of November through February. Additionally, it was also revealed that there was an increase in the annual incidence of this endemic mycosis over the studied period [62].

The relationship between environment and fungal organisms is complex as it is driven by various factors among which climate and available nutrients play an important role. Fungal pathogens from both *Ascomycetes* and *Basidiomycetes* pose a risk to humans and other mammals. Pathogens within *Ascomycetes* like *Coccidioides* spp., *Histoplasma* spp., and *Candida* spp. are found to be more thermotolerant and therefore more likely to cause infections, in contrast to *Basidiomycetes* which are less thermotolerant. However, selected *Basidiomycetes* such as *Cryptococcus* spp. are known thermotolerant pathogens. Thermotolerant *Basidiomycetes* such as *Cryptococcus laurentii* have caused infections in immunocompromised individuals

[63]. Therefore, the rise in global temperatures may select for certain fungi, which are thermotolerant and pathogenic in mammals. The rise in temperatures worldwide could facilitate new fungal pathogens likely to present initially in the immunocompromised patient population.

Climate Change and Bacterial Infections

Climate change and global warming are expected to cause changes in the spread and emergence of bacterial infections [2]. In a recent study of antimicrobial resistance, geographical patterns of temperature increase within the United States led to a rise in the rates of antibiotic resistance among different bacterial species, and the trend persisted despite adjusting for variables including human population growth [64]. In another study using an experimental model of *Vibrio coralliilyticus* that infects coral reefs, an increase of temperature to 27 °C increased the organism's virulence and caused an upregulation in efflux mechanisms. This was associated with antimicrobial resistance; such findings may be extrapolated to other microorganisms that could infect humans. However more studies are required to confirm these findings [65]. Although climate change is thought to cause the spread of certain bacterial infections, the effect on the expansion of *Vibrio* species is uncertain [66]. In a study of El Niño/Southern Oscillation (ENSO) relationship to *Vibrio cholera* spread in Bangladesh, ENSO prolonged the duration of warmer seasons which created a favorable environment for the bacterium to thrive. A similar trend is expected in non-cholera *Vibrio* spp. with the predicted warming of waters worldwide [67, 68]. This was observed in an outbreak of *V. parahaemolyticus* in northwestern Spain, where it was suggested that the outbreak resulted from regional seawater warming following the introduction of the organism to the area [69].

Conclusion

Geographic shifts in population and global demographic changes have resulted in significant changes in the epidemiology of common and emerging infectious diseases. The incidence and prevalence of infectious diseases is directly linked to human movement, placing communities at risk of exposure in new geographic locations, during travel, and upon return to their original communities [16]. Climate change has resulted in the displacement of large populations and is linked to the increase in infectious diseases. Addressing these challenges requires a multidisciplinary, humane, and nondiscriminatory approach that includes public health, economic, policy-making, environmental, and medical expertise [16]. These changes also directly impact the risk of infection in organ, cell, and tissue donors and recipients. It is imperative that transplant centers provide appropriate screening and testing and maintain surveillance and transmissibility data that can be shared. In addition, centers should provide risk mitigation and reporting strategies, conduct

research and quality improvement projects, and insure that transplant providers are familiar with the changing epidemiology of infectious diseases [4].

Finally, anthropogenic climate change will significantly alter many features of life on earth. The emergence of infectious diseases through changes in the geographical distribution of pathogens and their vectors will likely have major impact on human health. Knowledge of this phenomenon and its negative consequences on public health is crucial for proper preparation and initiation of targeted plans to combat new emerging and re-emerging infectious diseases impacting immunocompromised populations most significantly.

Key Points

- Solid organ and hematopoietic stem cell transplantation recipients are vulnerable populations at risk for the infectious complications relating to climate change.
- It is expected that population growth, migration, and shift will introduce new challenges within the field of infectious diseases.
- Anthropogenic climate change and global warming will affect many aspects of human life and alter the epidemiology and emergence of infectious diseases.
- Knowledge of the epidemiological changes in infectious diseases is imperative in the management of transplant recipients.

Introduction

Despite significant advancements in immunosuppression, prophylactic strategies, and pre- and posttransplant management, candidates and recipients of both solid organ and hematopoietic stem cell transplants continue to be at higher risk for healthcare-associated infections when compared to other patients. Prolonged wait times and new allocation systems leave some patients reliant on indwelling devices like central venous catheters, ventilators, and urinary catheters both before and after transplantation, and the hospital environment itself serves as a potential source for infections with opportunistic pathogens. Improved access to molecular diagnostics and molecular typing has improved the ability to identify outbreaks and address source control. In addition, application of process improvement techniques and partnering between institutional and transplant leadership and infection prevention and control have led to a remarkable improvement in outcomes that were once considered inherent to transplant including healthcare-associated infections.

Here we review select infection prevention strategies that are applicable to transplant patients and review specific pathogens that pose risk to both candidates and recipients. General infection prevention practices are applicable to these vulnerable patient populations and include hand hygiene, respiratory hygiene, vaccination promotion, adherence to care bundles, and antimicrobial stewardship. In addition, patient placement and targeted surveillance for specific pathogens and syndromes may have a pivotal role in the prevention of infection with certain infections.

Hand Hygiene

Hand hygiene is one of the most basic yet important aspects of infection prevention and control. Viruses, bacteria, and fungi can all be spread to and from the environment, staff, and patients via the hands of healthcare personnel (HCP). Hand hygiene prevents horizontal transmission of multidrug-resistant organisms (MDROs), including *Clostridioides difficile*, and reduces the risk of healthcare-associated infections (HAI). Despite this knowledge, HCP hand hygiene is poor even when working with vulnerable transplant recipients [1], highlighting the need for targeted interventions. Clinical staff and patients should have easy access to sinks and alcohol-based hand rub (ABHR) as part of a comprehensive strategy to improve compliance [2]. Prospective monitoring through direct observation or electronically assisted monitoring with real-time feedback can increase hand hygiene compliance [3, 4].

Patient hand hygiene is also important for infection prevention. Patient hand contamination with MDROs is common, and this can be transmitted to and from their environment [5]. An observational study of transplant recipients confirmed that hand hygiene compliance among patients is low, possibly contributing to pathogen transmission [6]. Visitor hand hygiene is important because visitors frequently touch surfaces in the healthcare environment that are also touched by both patients and

HCP, thereby increasing the risk of transmission of nosocomial pathogens [7]. Thus, patient and visitor education encouraging hand hygiene and instructing the proper way to perform hand hygiene should be incorporated into a multimodal program addressing infection prevention.

Central Line-Associated Bloodstream Infections

Central venous catheters (CVCs) are used frequently in the pre- and posttransplant period for hemodynamic monitoring, blood sampling, and administration of medications and blood products. In addition to the convenience of direct venous access, they confer a risk of infection due to bypassing of the protective barrier of the skin. Central line-associated bloodstream infections (CLABSI) are a dangerous complication of CVCs, conferring increased length of stay, increased healthcare costs, and increased mortality risk [8, 9].

Transplant recipients and those awaiting transplant are at high risk for CLABSI, due to high prevalence of CVCs, prolonged hospital lengths of stay, prolonged duration of CVCs, and compromised immunity. Patients awaiting heart transplant frequently have pulmonary artery catheters, which allow for continuous monitoring of left ventricular filling pressures and confer a high urgency status for transplantation. At one institution, the CLABSI rate for patients with pulmonary artery catheters was five times higher than the CLABSI rate for intensive care unit (ICU) patients [10].

Patients who are pre- or immediately post-hematopoietic stem cell transplantation (HSCT) are at additional risk for bloodstream infections secondary to mucosal barrier injuries due to prolonged neutropenia. Single-center studies focusing on HSCT patients report a 20–60% incidence of bloodstream infections in the immediate posttransplant period and higher incidence in patients with acute graft-versus-host disease (GVHD) compared with rates prior to development of GVHD [11, 12]. HSCT candidates undergoing conditioning and HSCT recipients should perform oral hygiene throughout the day to reduce the risk of oral mucositis and secondary bacteremia [13].

A care bundle is a group of evidence-based practices which when performed together are associated with improved outcomes. Each included intervention is considered good practice. Compliance with care bundles should be audited, and feedback should be given to improve compliance and address barriers to compliance. Bundled interventions have proved to decrease CLABSI in ICUs and prompted a paradigm shift. CLABSI now were considered avoidable, and in many centers transplant populations are highlighted for increased incidence of CLABSI [14].

Indeed the majority of CLABSI are likely preventable. In a pivotal statewide trial, the implementation of a CVC insertion bundle including hand hygiene, full barrier precautions, cleaning the insertion site with chlorhexidine gluconate (CHG), avoiding the femoral site, and removing unnecessary CVCs resulted in a 66% sustained decrease in CLABSI in the ICU setting [15]. Additional strategies

to prevent CLABSI focus on maintenance of the necessary CVC. These include daily CHG bathing to reduce the bacterial load on the skin and daily patient hygiene [12, 16]; disinfection of catheter hubs prior to access, needleless connectors, and injection ports; dressing changes with CHG-impregnated dressings every 5–7 days or sooner if visibly soiled, wet, or loose; use of antibiotic-impregnated catheters; and use of ethanol-impregnated disinfection caps [17–22].

Compliance with central line insertion and maintenance bundles is associated with lower CLABSI rates [23–25]. In order to ensure CVC bundled care, compliance is sustained on a patient, unit, and health system level; audit and reminders of bundle elements may increase consistency and subsequently reduce the risk of bloodstream infection [26].

Bundled CVC care has been shown to reduce CLABSI rates in transplant recipients as well. Implementation of process improvement strategies including standardization, monitoring with feedback, and plan-do-study-act cycles contributed to a 61% decrease (4.2–1.8 per 1000 CVC days) in a liver transplant ICU [14]. Implementation of a CVC maintenance bundle resulted in a significant CLABSI reduction in pediatric HSCT patients [27]. Identification of drivers for a rising CLABSI rate in a pediatric hematology-oncology unit and rapid development of interventions, such as identification of patients at high risk for CLABSI and involvement of senior nurses to assist less experienced nurses in dressing changes, resulted in a CLABSI rate reduction from 2.03 to 0.39 per 1000 CVC days [12].

Catheter-Associated Urinary Tract Infections

Catheter-associated urinary tract infection (CAUTI) is a common HAI, resulting in increased cost [8] and increased length of stay [28]. Like CLABSI, CAUTI are largely preventable. The greatest risk factor for CAUTI is prolonged duration of indwelling urinary catheterization. Urinary catheters are often placed unnecessarily and remain in place longer than needed. Prevention measures include limiting insertion of indwelling urinary catheters, use of aseptic technique for insertion by a trained provider, regular perineal care, maintaining unobstructed flow of urine, and removal of the catheter as soon as it is no longer necessary.

CAUTI disproportionately affect solid organ transplant (SOT) recipients, with the most data available for kidney transplant recipients. In an analysis of kidney transplant recipients in the United States from 2002 to 2012, 7.5% of kidney transplant recipients developed CAUTI [29]. Patient-specific risk factors for CAUTI in kidney transplant include age, female sex, and pre-transplant loss of function. Several studies confirm that prolonged duration of indwelling urinary catheter in kidney transplant recipients is a risk factor for both CAUTI and bacteremia [30–32].

Hospitals can reduce urinary catheter utilization by developing and implementing criteria for acceptable indications for indwelling urinary catheter use, such as when there is acute urinary obstruction, to assist in healing of pressure ulcers, or for select surgical procedures like kidney transplantation [33]. There are several

approaches to facilitate compliance with facility-specific utilization guidelines. A nurse-led approach incorporating multidisciplinary rounds on inpatient units that focused on appropriate indications for insertion and timely removal of urinary catheters was effective in reducing the number of catheter days on several units [34]. Reminders for indwelling urinary catheter removal and stop orders embedded within the electronic health record have been effective in decreasing catheter use and significantly reducing CAUTI rates in multiple studies [35]. Since limiting duration of urinary catheters is recommended, the risk of early catheter removal in kidney transplant must be balanced with the potential risk of perioperative urologic complications. The optimal duration of catheterization in this population remains controversial; however early removal should be considered in the appropriate patient [36, 37]. A multidisciplinary team focused on CAUTI-prevention education of nurses and other clinical staff led to a reduction in the CAUTI rate in the transplant care unit where rates had been higher than in the general hospital population [38].

There are no specific differences in the recommendations for maintenance of indwelling urinary catheters in transplant recipients compared with other patient populations. The Centers for Disease Control and Prevention (CDC) recommends use of aseptic technique with sterile equipment for urinary catheter insertion [39]. In a recent randomized controlled trial in Australia, use of chlorhexidine solution for meatal cleaning at the time of catheter insertion resulted in a decreased incidence of CAUTI compared with use of sterile saline [40]. For maintenance after insertion, however, meatal care with antiseptic solutions has shown no demonstrable benefit over routine perineal hygiene [41].

In addition to routine hygiene, maintenance efforts to reduce CAUTI focus on ensuring unobstructed flow of urine. Preventing kinking in catheter tubing allows for free flow of urine from the urethra to the collection bag. Lastly, keeping the collection bag below the level of the bladder and regular emptying of the collection bag prevent reflux of urine from the unsterile bag to the urethra [39]. Involving ancillary HCP (e.g., transporters and physical therapists) in an interdisciplinary promotion of urinary catheter maintenance is important as all members of the healthcare team may be involved in the maintenance of necessary urinary catheters [42].

Clostridioides difficile

Clostridioides difficile infection (CDI) causes a spectrum of disease ranging from asymptomatic colonization or diarrhea due to mild infection to ileus, megacolon, bowel perforation, and septic shock. It is the most common HAI and poses unique infection control risks due to the environmental persistence of infectious spores.

Risk factors for CDI include frequent contact with healthcare settings, receipt of antimicrobials, hospitalization on inpatient units with high rates of overall antimicrobial use [43], immune compromise, poor hand hygiene compliance, and lapses in environmental disinfection. Thus it is not surprising that SOT and HSCT

recipients have significantly higher rates of CDI than do general medical or surgical inpatients [44, 45].

Up to 29% of hospitalized patients are colonized with *C. difficile* [46]. This colonization rate may be higher in HSCT patients and is not well described in SOT recipients [47]. Patients who are colonized are more likely to subsequently develop symptomatic CDI [48]. Antimicrobial stewardship, hand hygiene, and environmental disinfection are important strategies to reduce rates of both symptomatic infection and transmission.

Recommended commercial testing modalities for *C. difficile* include a stool toxin test as part of a multistep algorithm or nucleic acid amplification test (NAAT) alone. There are drawbacks to each type of test; two- or three-step algorithms that include a stool toxin test have relatively low sensitivity, while NAAT without patient-specific symptoms to guide testing does not differentiate between colonization and symptomatic disease. Diagnostic testing should be considered in patients with three or more unformed stools in 24 h or less, who have not had prior testing within the preceding 7 days and who do not have alternative causes of diarrhea, such as laxative use. Testing of asymptomatic patients is not recommended [49], and there are no recommendations to use contact precautions for patients who are asymptomatically colonized. Test of cure should not be performed to guide either treatment duration or cessation of transmission-based precautions.

For patients with diarrhea, contact precautions including gowns and gloves should be initiated preemptively pending *C. difficile* test results and continued if positive until 48 h after diarrhea resolution to prevent transmission to other patients from HCP hands, clothing, and mobile medical equipment. It is preferable to have patients with CDI in single-patient rooms with separate toileting facilities. In the setting of space limitations, incontinent patients should be prioritized for single-patient rooms. If cohorting is required, patients with the same strain of CDI (e.g., two patients with the *C. difficile* B1/NAP1/027 strain) rather than different strains can be cohorted [49]. This information, however, may not be readily available. Shedding of *C. difficile* spores in the stool may be prolonged even after symptom resolution. In centers where there are high rates of CDI, maintaining contact precautions until discharge may be warranted.

Use of ABHR or handwashing with soap and water is recommended when caring for patients with CDI. Compliance with ABHR is higher than with traditional handwashing; however ABHR is not sporicidal and thus may pose a higher risk of transmission of *C. difficile* spores despite good compliance. In settings where there are outbreaks or sustained high rates of CDI, hand hygiene with soap and water is preferred.

Bleach or other sporicidal surface disinfectants are needed to eliminate environmental persistence of spores. Daily and terminal room cleaning with a sporicidal agent may help reduce the risk of transmission of *C. difficile* to patients, especially when there are high baseline rates of CDI [49]. The addition of ultraviolet light terminal disinfection may reduce the risk of *C. difficile* transmission, although studies have shown mixed results [50, 51]. Despite environmental disinfection interventions that result in objective measures of improved environmental cleaning,

a multicenter randomized study found no effect of this on the incidence of healthcare-associated CDI [52]. This highlights that there are many other important factors that affect the incidence of CDI, including pre-existing *C. difficile* asymptomatic colonization, antimicrobial use and overuse, testing stewardship, hand hygiene, disinfection of shared mobile medical devices, and compliance with contact precautions.

Surgical Site Infections

Despite improvements in perioperative management, surgical site infections (SSIs) continue to threaten SOT recipients early after transplantation. Healthcare and antimicrobial exposures are ubiquitous in SOT, and with increased wait times, there is a parallel increased risk for MDROs. The highest rates of SSI are reported in intestinal and multivisceral abdominal organ transplants [53].

Evidence-based strategies aimed toward SSI reduction in the general surgical population can be applied to SOT [54]. These include close attention to maintenance of sterility, surgical technique, minimizing operative time, and minimizing transfusion requirements. The role of the anesthesiologist has been defined and includes reducing environmental contamination, catheter and airway management, as well as perioperative temperature, oxygenation, and glycemic management [54, 55]. Organ-specific risk factors for SSI have been recently reviewed [53].

In centers with increased incidence of *S. aureus* infections, there may be a role for active surveillance and decolonization with mupirocin and/or CHG. Decrease in *S. aureus* SSIs has been demonstrated in cardiac and lower joint surgeries when decolonization is included as part of a care bundle [56]. Although not specific to SSI prevention, predictive models suggest utility in thoracic transplantation with the goal of decreasing posttransplant *S. aureus* infections [57]. Decolonization of SOT candidates can be problematic as durability is incomplete [58], and unless a live donor is available, the timing of transplant remains unpredictable.

Perioperative antimicrobial selection should be determined by the transplanted organ. Preferred antimicrobial regimens tend to be heterogeneous and transplant center-specific [59]. Organ-specific risk factors may require modification or augmentation of regimens (i.e., addition of antifungal prophylaxis) [53]. Although not systematically studied, alteration in prophylaxis based on donor and recipient microbiology as well as institutional antibiograms is likely warranted. Societal recommendations for dosage, including weight-based dosing, and timing including re-dosing are applicable [60]. Extended durations are rarely warranted and should be discouraged.

Recently, the need for patient engagement in HAI prevention has been highlighted [61]. The role of the patient and caregiver may be paramount in SSI prevention [62]. Smoking cessation, diabetes management, and hygiene including compliance with hand hygiene and bathing can influence infection risk. Both patients and their caregivers should be encouraged to promote HCP hand hygiene and appropriate wound care. In addition, educating patients about signs and

symptoms of infection can prompt early identification of potential SSIs that may prevent morbidity.

Preventing Infections Associated with the Healthcare Environment

Transplant recipients are not only at risk for the same wide variety of infections that affect patients with intact immune systems; they are also at a unique risk for infections related to bacteria, mycobacteria, and molds found in the healthcare environment. While HSCT guidelines outline specific infection prevention and control practices [13], there are no standard infection prevention and control strategies among SOT programs [63]. Limiting exposure to environmental molds, such as *Aspergillus*, and water-related opportunistic pathogens, such as *Legionella* species and nontuberculous mycobacteria (NTM), should be a focus of infection prevention and control efforts in the healthcare settings. In addition, access to molecular typing may aid in the identification of potential sources and inform mitigation strategies.

Environmental Mold

Nosocomial mold infections among transplant recipients result from respiratory exposure to fungal spores. Air and water can be sources of pathogenic fungi. Opportunistic molds such as *Aspergillus* and *Fusarium* can be present in a hospital's water supply and may be ingested or inhaled when in water droplets formed from hospital showers or sinks. Water damage to sheetrock from leaks can lead to mold growth and subsequent aerosolization of mold spores within the hospital. Plants, unwashed fruits and vegetables, and fresh or dried flowers can harbor *Aspergillus*. Elevator shafts may pose an additional risk, as shaft surfaces are hard to clean, air moving within the shaft can harbor mold spores, and patients may be exposed during transit within the hospital.

There have been several published reports of environmental mold infections in immune-compromised patients, including transplant recipients, related to hospital linens. Outbreaks of *Rhizopus* have been linked to hospital linens that have been washed in low temperatures, stored in humid and/or dusty conditions, or stored in bins exposed to dust [64, 65]. Facilities supplying linens to the healthcare setting should wash, store, and transport linens in a clean environment, use high wash temperatures, and ensure linens are completely dry prior to packaging. Hospitals should prevent dust contamination of linens during transport, keep linen storage bins clean, and not top off linens prior to patient use (first in, first out premise) [66].

Hospitalized HSCT recipients should be placed in protective environment (PE) rooms [13, 67]. Use of PE rooms for SOT recipients, including lung transplant recipients, is variable among transplant centers [63]. PE rooms are designed to protect severely immune-compromised patients from human and environmental

airborne pathogens. These rooms have positive air pressure in relation to the hallway, with high-efficiency particulate air (HEPA) filtration to remove particles $\geq$0.3 μm in diameter that can pose an infectious risk and $\geq$12 air exchanges per hour to bring in fresh air and remove stale air. In a tertiary care hospital setting, patients with HSCT or hematologic malignancy who had significant exposure outside of the PE room during their hospitalization had higher risk for invasive mold infections [68].

The differential in air pressure should be monitored continuously, ideally by automated systems that alert appropriate staff when the pressure difference is lost. In order to prevent air containing spores from outside the room getting in, and to maintain positive pressure, PE rooms should be sealed, with filling in of gaps between walls, floors, ceilings, windows, and doors [13].

Use of HEPA filtration is especially important when construction is conducted within or near the hospital. A heightened risk to immune-compromised patients comes from the aerosolization of mold spores during construction within or in proximity to a hospital, and outbreaks of healthcare-associated environmental mold infections have occurred in relation to adjacent construction in hospitalized immune-compromised patients [69].

Construction plans should include measures to control mold and should be made in conjunction with the hospital's infection prevention and control department, who can develop an infection control risk assessment (ICRA). ICRAs in this scenario focus on measures to control and minimize airborne dissemination of fungal spores, such as resealing of hospital windows, use of portable HEPA filters in rooms of susceptible patients, use of N95 particulate respirators for patients during travel within and outside of the hospital, and planning for staff caring for susceptible patients to enter and exit the hospital away from the site of construction [66, 70].

Due to multiple potential environmental sources, hospitals should perform surveillance for healthcare-associated mold infections particularly during and after construction events and in highly susceptible patients. This can include utilization of the electronic health record or surveillance software to identify patients with radiographic changes consistent with invasive mold infections; regular review of microbiology laboratory reports for growth of *Aspergillus* and other opportunistic molds; monitoring of therapeutic antifungal use; and location tracing of infected patients to identify high-risk environmental exposures [71]. Additionally, scheduled environmental assessments for water damage and dust, and environmental sampling for identification of mold, can be used to target mitigation efforts [66].

Waterborne Pathogens

In addition to invasive mold infections, transplant recipients and other immune-compromised patients are at higher risk for infections due to waterborne pathogens. The hospital water supply is increasingly identified as a source of nosocomial acquisition [72], likely related to the size and complexity of healthcare facility water systems and the vulnerability of patients treated in these facilities. Outbreaks

of infections related to water exposure within a hospital have included *Legionella* species, nontuberculous mycobacteria, *Pseudomonas aeruginosa*, and other Gram-negative bacteria. These organisms are often referred to as opportunistic premise plumbing pathogens (OPPP). Sources identified in outbreak investigations include potable water, sinks, aerators, showers, immersion tubs, ice and ice machines, and decorative fountains. Transmission of pathogens occurs through both direct and indirect contacts, ingestion, aspiration, and/or aerosolization.

Legionella, atypical mycobacteria, as well as *Pseudomonas aeruginosa* and other Gram-negative bacteria are normal inhabitants of drinking water. These bacteria may be chlorine- and heat-resistant and can form biofilms on plumbing surfaces, making them difficult to eradicate from a hospital's water supply once detected [73]. Older water systems can promote stagnation, corrosion, and the biofilm formation, thus propagating the growth of OPPP.

Water management programs targeting conditions conducive to growth of *Legionella* and other OPPP can reduce their growth in water and prevent transmission to susceptible patients. Mitigation strategies (Table 1) for potential sources have been previously published [72]. Copper-silver ionization of water is one disinfection method used by healthcare facilities to control growth of *Legionella* spp.; it reduces the risk of *Legionella* positivity in environmental samples, and it may have effects on *Pseudomonas* and other Gram-negative bacteria by binding to bacterial cell walls and destroying biofilms that can harbor bacteria [74, 75]. Monochloramine, a combination of chlorine and ammonia, is also used to limit growth of *Legionella* and other opportunistic pathogens in hospital water supplies [76]. However, neither disinfection system is perfect. *Legionella* may still be detected in hospital water systems despite use of copper-silver ionization [77], and there is the potential for an increase in detection of mycobacteria in water systems with use of monochloramine disinfection [78].

Plumbing design to limit dead-end pipes and subsequent water stagnation can help limit OPPP overgrowth [66]. Other interventions include use of reverse osmosis filters on faucets and shower heads, maintaining circulating water at high temperatures with addition of cold water at the point of use (sinks, showers), or periodic superheating of the water system to limit bacterial growth in circulation [79, 80].

Legionella pneumophila and other *Legionella* species are opportunistic pathogens that can cause a life-threatening pneumonia in susceptible patients. Transmission occurs via inhalation of aerosols and can come from showers, faucets, or cooling towers in the community or healthcare setting. An outbreak of *L. pneumophila* serotype 3 among HSCT patients in a new bone marrow transplant unit in an Israeli hospital was linked to heavy contamination of potable water with the same serotype [81]. Interventions implemented included restrictions on drinking tap water and showers for HSCT patients, in addition to superheating and hyperchlorination of the water system. An outbreak of *Legionella micdadei* pneumonia among kidney and heart transplant recipients at a US hospital was linked molecularly to *L. micdadei* isolated from hot water sources, including showers and sinks in patient rooms and the hospital-wide hot water recirculation loop [82]. Mitigation strategies included superheating and subsequent chlorination of the

Table 1 Healthcare-associated reservoirs for opportunistic premise plumbing pathogens and potential risk mitigation strategies in the setting of healthcare-associated cases or isolation of potential pathogens during routine sampling

Reservoir	Potential pathogens	Mitigation strategies for high-risk units
Potable (tap) water	*Legionella* species *Pseudomonas aeruginosa* Gram-negative bacteria Nontuberculous mycobacteria	Ensure that semicritical devices including respiratory devices are not rinsed in tap water (use sterile water) During water disruptions refrain from using or drinking tap water (e.g., showering, rinsing, or ingesting) Periodic sampling of water for *Legionella* spp. especially in high-risk units including organ transplant units and hematopoietic stem cell transplant units Remove aerators or develop an appropriate maintenance and disinfection plan for high-risk units especially in the setting of detected *Legionella* spp. in water samples or evidence of hospital-onset disease Discourage automated faucets due to the inability to achieve high outlet temperatures and inability to flush Discourage decorative water features (e.g., fountains) Discourage showers or develop an appropriate maintenance and disinfection plan of shower heads If basins are used for bathing, a plan should be in place for disinfection of basins or the basins should not be reused Potential disinfection methods include copper ionization, hyperchlorination, superheating, and filtration – a water management plan should be in place and reviewed periodically with infection prevention and control and facilities experts Heighten awareness and surveillance for legionellosis, unusual nontuberculous mycobacterial infections, and increased incidence of hospital-onset respiratory infections with Gram-negative bacteria
Sinks	Gram-negative bacteria including carbapenem-resistant *Enterobacteriaceae*	Ensure separation of handwashing sinks from sinks where contaminated waste may be disposed (e.g., hopper or utility sink) Ensure a maintenance and disinfection plans for sinks (including drains) located in patient rooms where aerosolization or splashing may occur
Heater-cooler devices	*Legionella* species *Pseudomonas aeruginosa* Gram-negative bacteria Nontuberculous mycobacteria	Ensure that maintenance and disinfection are occurring as per manufacturer's instructions Heighten awareness and surveillance for nontuberculous mycobacteria after cardiac surgery including transplant Position the device to allow vent to exhaust away from the surgical field

water system. *Legionella* outbreaks have also been linked to decorative water fountains in the healthcare setting [77, 83]. Mortality from Legionnaire's disease is 25% based on national surveillance data; however rates specific to transplant recipients are not known [84].

Nontuberculous mycobacteria can be found in soil, water, and dust, and these environmental sources can lead to community-acquired or nosocomial infection. NTM have been linked to multiple outbreaks in healthcare settings, often related to the hospital or municipal water supply. One such outbreak occurred among pediatric HSCT patients after the opening of a new hospital building. An increase in isolation of the rapidly growing mycobacteria *M. chelonae* from clinical cultures was traced to the new building's water supply. Water samples collected from hospital faucets, showers, and ice grew *M. chelonae* and other NTM. Infection prevention and control efforts included use of only bottled water for consumption in HSCT patients and reinforcement of a policy to run showers for 2 minutes prior to patients entering to reduce the mycobacteria density in water [85]. This policy had been put in place several years earlier in response to an outbreak of *M. mucogenicum* bacteremia linked to exposure of patients with central venous catheters to *M. mucogenicum*-contaminated shower water [86].

Another US hospital noted an increase in the incidence of *M. abscessus* isolated from respiratory sample cultures after opening a new hospital building, disproportionately affecting lung transplant recipients [87]. Environmental cultures from biofilms of water sources in the hospital addition grew *M. abscessus*, and it was hypothesized that micro aspirations from tap water led to lung colonization and subsequent infection. Interventions to prevent and control further exposure to *M. abscessus* included use of sterile water instead of tap water for oral care, respiratory therapy, consumption, and enteral tube flushes for all lung and heart transplant recipients, ICU patients, and patients with disrupted GI tracts [87]. The authors noted that low flow rates in the hospital addition's water distribution system, put in place to conserve water, may have facilitated higher water concentrations of *M. abscessus*.

Disseminated NTM infections, specifically *M. chimaera*, have been associated with the use of extracorporeal circulation in cardiac surgeries [88]. These heater-cooler devices (HCDs) are used ubiquitously in heart transplantation. Identification of the potential for these devices to aerosolize NTM as well as other waterborne pathogens led to several control efforts. These included revisions and a request for adherence to the manufacturers' instructions for maintenance and disinfection of these devices; use of sterile or filtered water; and positioning the device in order to vent to exhaust away from the operative field. Although not previously routine practice, NTM should be considered in the differential diagnoses of otherwise unexplained infections in patients after cardiac surgery including SSI. Legionellosis and infections with Gram-negative bacteria have also been linked to HCDs.

An outbreak of *Pseudomonas fluorescens*-related febrile neutropenia in HSCT recipients was linked by molecular typing to a contaminated drinking water dispenser in a hospital in the United Kingdom. This hospital performed routine

weekly pharyngeal screening for *Pseudomonas* carriage at baseline in hematology patients, allowing for identification of pharyngeal colonization in the absence of other positive clinical cultures [89]. A hospital in Finland used pulsed-field gel electrophoresis to link 11 cases of *Pseudomonas aeruginosa* bacteremia in HSCT recipients to isolates from showers and sinks with the same PFGE pattern in their bone marrow transplant unit [90]. No further cases of *Pseudomonas aeruginosa* infection with the same PFGE pattern occurred after implementation of infection control measures, which included hand disinfection, disinfection of shower pipes and shower heads, and use of hot water when cleaning. Similarly, other outbreaks due to other multidrug-resistant Gram-negative bacteria including carbapenem-resistant *Enterobacteriaceae* (CRE) have been linked to contaminated sinks using molecular typing including whole genome sequencing [91–93]. Separating handwashing sinks from areas used for disposal of contaminated waste and disinfection and/or reconfiguration of existing pipes or water systems are important strategies to address identified risks.

Similar to surveillance for other HAI such as CLABSI or CAUTI, use of the electronic health record to identify patients with nosocomial pneumonia can guide targeted interventions, such as testing for *Legionella* infection and other waterborne opportunistic pathogens in susceptible patients. Additionally, targeted environmental surveillance that includes culture of the hospital water supply in areas housing high-risk patients can identify the affected areas and guide eradication efforts [77]. Special attention should be given to the performance of institutional hazard analyses and revisions of water management plans to ensure ongoing attention to the potential environmental risk to transplant populations and other susceptible hosts.

Colonization with Multidrug-Resistant Organisms

Multidrug-resistant organisms (MDROs) include methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and Gram-negative organisms including extended-spectrum β-lactamase (ESBL) or CRE. *Candida auris*, an emerging healthcare-associated yeast, is also considered a MDRO because of its antifungal resistance profiles, its unique ability to colonize the skin, and its persistence in the healthcare environment [94].

Enterococci are gastrointestinal common commensals. Gastrointestinal VRE carriage is the major reservoir of the organism in the healthcare setting. VRE can survive on surfaces, and transmission can occur via healthcare workers, mobile medical equipment, or shared toileting facilities [95]. Similar to VRE, ESBL-producing and carbapenem-resistant Gram-negative bacteria can persist through gastrointestinal carriage.

Like VRE and multidrug-resistant Gram-negative organisms, patients tend to be the reservoir for transmission of *S. aureus*. *S. aureus* colonizes the nares and skin in up to 30% of healthy people. Patients with MRSA colonization are more likely to develop MRSA bacteremia than patients who are not colonized [96, 97]. Nosocomial MRSA infections are often associated with breaks in skin and mucosal barriers

including intravascular catheters, endotracheal tubes, or recent surgery and confer significant morbidity and mortality risk [98, 99]. The epidemiology of MRSA in organ transplantation has recently been reviewed [100].

The prevalence of MDRO in the healthcare setting has increased globally over the last several decades [101–103]. In data reported to the CDC's National Healthcare Safety Network, MRSA and VRE are the most commonly identified MDRO associated with device-related infections or SSI [104, 105]. SOT recipients in particular have a high prevalence of CRE [106–109], and VRE colonization is common in HSCT recipients [110] and organ transplant candidates and recipients [95]. In terms of CRE risk, international travel and healthcare exposures including SOT and HSCT in other countries may potentially introduce novel mechanisms of resistance to transplant units [109].

Risk factors for MDRO acquisition are ubiquitous in transplantation. These include high rates of antimicrobial use for both prophylaxis and treatment, frequent and/or prolonged hospitalizations, invasive procedures, high device utilization rates, and medical comorbidities such as kidney failure [100].

As with MRSA, MDRO colonization often precedes invasive disease. In the setting of active surveillance, liver transplant candidates and recipients with asymptomatic MRSA or VRE colonization were at increased risk for invasive MRSA or VRE infection, respectively, when compared with patients who were not colonized, and VRE colonization was associated with an increased risk of mortality [111]. A meta-analysis of 23 studies looking at the effect of MRSA and VRE colonization in liver and other SOT recipients found a similarly increased risk of infection with colonization in the pre- and posttransplant periods [112]. Additionally, a prospective study of liver transplant recipients with active surveillance for rectal MDRO colonization found that even intermittent colonization was significantly associated with subsequent MDRO infection [113]. In a retrospective study of liver recipients, carbapenem-resistant *Klebsiella pneumoniae* colonization was a significant risk factor for invasive carbapenem-resistant *K. pneumonia*e [114].

Interventions such as antimicrobial stewardship; monitoring of environmental disinfection – including disinfection of mobile medical equipment – monitoring of hand hygiene compliance; active surveillance; antiseptics applied to the skin, nares, and oral mucous membranes; and standard and contact precautions can help reduce MDRO colonization and prevent transmission to other patients [115]. Measures to lower the risk of invasive infection include the instating and monitoring compliance with the aforementioned evidence-based bundles to insert and maintain vascular and urinary catheters and oral care and ventilator management to prevent lower respiratory tract infections in ventilated patients.

The CDC and European guidelines recommend the use of standard and contact precaution for patients with MDRO colonization or infection [115–117]. In select settings the role of contact precautions and the duration of contact precautions may require reexamination especially for ESBL producers [109, 118], MRSA and VRE. Two large trials found these precautions were no more effective than standard precautions in reducing MRSA or VRE transmission [119, 120]. A systematic review and meta-analysis of 14 studies found that discontinuing contact precautions

for MRSA and VRE did not lead to increased infection rates [121]. An additional meta-analysis of nine studies looking at infection prevention and control measures to reduce transmission of VRE found that improved hand hygiene compliance, but not contact precautions, decreased the VRE transmission rate [122]. Additionally, contact precautions are associated with fewer bedside visits from healthcare personnel and more preventable adverse events [123]. In the setting of outbreaks, the use of contact precautions may be warranted [124].

Active surveillance for MDROs in asymptomatic patients can identify patients at higher risk for invasive infection and facilitate targeted interventions, such as skin and mucous membrane antisepsis to reduce MDRO colonization or broader empiric antimicrobial management for sepsis. Recent publications have shown that active surveillance with implementation of standard plus contact precautions for carbapenem-resistant *Enterobacteriaceae* (CRE) reduces CRE colonization and infection [125, 126]. However, there is a lack of strong evidence that universal screening for CRE in asymptomatic pre- and posttransplant recipients is of benefit [127].

In a multicenter cluster randomized trial, daily chlorhexidine bathing of patients in ICUs and HSCT units reduced the risk of MDRO acquisition and subsequent bloodstream infection [16]. A large cluster randomized trial of ICU patients in multiple hospitals found that universal decolonization with nasal mupirocin and CHG bathing and, to a lesser degree, targeted MRSA screening and decolonization were more effective than active MRSA surveillance with standard and contact precautions in reducing rates of MRSA colonization and bloodstream infection [128]. In a single center, active surveillance for MRSA colonization in liver transplant recipients with targeted infection control interventions (i.e., contact precautions, cohorting, intranasal mupirocin for decolonization) reduced MRSA colonization and invasive infection [129].

Respiratory Viruses

Respiratory viral infections can contribute to significant morbidity in the immune-compromised host [130]. During periods of intense immunosuppression, early after transplantation or in the setting of GVHD, both SOT and HSCT recipients are at increased risk of viral infection-related complications. These potential complications include progression from upper respiratory tract infections to lower tract infections and pneumonia, bacterial and fungal superinfections, and respiratory failure [131]. In addition, respiratory viral infections have been associated with bronchiolitis obliterans in lung transplant recipients and long-term airflow decline in HSCT recipients.

Molecular diagnostic platforms provide both rapid and accurate results and should be utilized early. Staff should be encouraged to adhere to standard precautions including hand hygiene, disinfection of shared equipment, and respiratory hygiene and cough etiquette. Due to the high rates of morbidity observed in HSCT recipients, some centers recommend universal masking either year-round or during periods of increased community activity of respiratory syncytial virus (RSV) or

influenza [132]. Systematic evaluations have not been performed supporting universal masking, and controversy exists regarding the preferred mask [133, 134]. Moreover, contact precautions (use of gowns and gloves) are recommended for some respiratory viruses in addition to standard precautions [115].

Persistent and asymptomatic viral shedding is common in immunosuppressed populations [131]. Thus, defining the optimal duration of transmission-based precautions in the inpatient setting is difficult, and variability exists between centers.

Influenza

Although traditionally influenza season commences in the Fall and can persist well into Spring, novel influenza viruses with pandemic potential may emerge at any time. Indeed, many lessons were learned in 2009 with the emergence of H1N1 in both the community and healthcare settings [135, 136].

Nosocomial acquisition and healthcare-associated outbreaks among transplant recipients (both SOT and HSCT) have been reported. In general, an outbreak investigation is initiated in the setting of a single hospital-onset case. Updated guidance regarding outbreak control is available and is applicable to both the SOT and HSCT patients [137]. In order to avoid nosocomial and/or sustained transmission, institutions are recommended to encourage vaccination, screen for symptoms, emphasize appropriate patient placement and early diagnostics, initiate early treatment, and establish a procedure for addressing ill healthcare personnel.

Annual vaccination with inactivated influenza vaccine for patients and household contacts is strongly encouraged. It is important to note that both antibody- and cell-mediated immune responses are likely suboptimal early posttransplantation [138]. However, vaccination of SOT and HSCT patients has been associated with improved outcomes [139]. Potential strategies to improve immune response in the SOT population include offering booster doses or high-dose vaccine [140, 141]. Current recommendations include initiating annual influenza vaccine 6 months after HSCT. In the setting of increased community activity, vaccination can be offered as early as 3–4 months after HSCT [138].

During influenza season aggressive symptom screening of HCP, patients, and visitors is recommended. Many institutions limit nonessential visitors and enforce visitor age restrictions on high-risk units (i.e., HSCT units). Patients and visitors should be educated regarding symptoms, respiratory hygiene, and cough etiquette, and ill visitors should be excluded.

Influenza is transmitted through large droplets generated through talking, coughing, and sneezing. Transmission can occur through indirect contact with a contaminated environment and inoculation of mucosal surfaces. Airborne transmission can also occur especially in the setting of aerosolizing procedures, but the superiority of using respirators over surgical masks has not been established [142]. Currently, in addition to standard precautions, droplet precautions are recommended to reduce the risk of transmission. Patients should be prioritized to a single room when influenza is suspected or confirmed. Cohorting of

symptomatic cases based on strain type may be prudent; however cohorting strategies should be discussed with infection preventionists or public health authorities.

In the setting of sustained transmission, nonessential admissions should be delayed, and consideration should be given to redirecting new admissions. Patient transport and movement should be minimized. Symptom screening of staff should be performed daily, and ill staff should immediately mask and be removed from direct patient care. Current recommendations are to exclude these individuals from working with patients until afebrile for 24 h without antipyretics and no earlier than 5 days after illness onset. In the setting of HSCT, the CDC recommends work exclusion or temporary reassignment for as long as 7 days from symptom onset.

Chemoprophylaxis with a neuraminidase inhibitor (i.e., oseltamivir) should be offered to roommates and ward mates of patients with influenza, irrespective of vaccination status [137]. Monitoring and audit of both hand hygiene and environmental disinfection should be prioritized. Patients should be empirically treated when influenza is suspected pending diagnostic results [139]. HCP who are not vaccinated should be vaccinated and offered chemoprophylaxis for 2 weeks after vaccination. In the setting of antigenic drift of circulating virus from vaccine strains, chemoprophylaxis should be considered for all influenza-exposed HCP irrespective of vaccination status.

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) has been associated with morbidity in both SOT and HSCT [143]. The incidence of nosocomial RSV infections often mirrors that of increased community activity. Frequently increased activity is seen during the Fall and early Winter. Transmission is due to direct inoculation of mucous membranes and inhalation of droplets or by indirect inoculation by fomites from a contaminated environment. Outbreaks have occurred in both inpatient and ambulatory settings [144].

Despite evidence of droplet transmission, the routine use of masks is controversial. There has not been conclusive evidence suggesting masks decrease transmission even in the setting of an outbreak. The conjunctiva and nasal mucosa are major portals of entry, and the addition of masks and eye protection should be considered as part of standard precautions if exposure to respiratory secretions is anticipated [115]. A recent systematic review suggested that eye protection was more effective at reducing transmission than the addition of a mask as part of a multiple component outbreak response [145]. Patients with known or suspected RSV should be prioritized for single-patient rooms and placed in contact precautions. Cohorting, if necessary, should be coordinated with an institution's infection prevention and control department.

In the absence of an effective vaccine or chemoprophylaxis, primary prevention of nosocomial transmission is paramount. Prophylaxis with palivizumab, a RSV-specific monoclonal antibody, is variable among surveyed SOT centers [146, 147]. The American Academy of Pediatrics offers guidance regarding the use of

palivizumab in pediatric populations during RSV season [148–150]. Off-label use in adults in an outbreak setting has been described [151].

Like influenza, in the setting of an outbreak of RSV, aggressive screening of visitors, HCP, and patients should occur. Visitor limitations and age restrictions may be required. Cohorting of both patients and staff and restricting patient movement as well as augmented monitoring of hand hygiene and environmental disinfection are recommended. In addition, HCP and visitors are encouraged to practice respiratory and cough etiquette. Ill HCP should be immediately removed from patient care; however, the optimal duration of exclusion or reassignment remains unclear. It should be noted that often individuals can be asymptomatic and can serve as a source for ongoing transmission [144]. Active laboratory surveillance in the absence of symptoms cannot be categorically recommended but can be considered in settings of sustained transmission [144].

Adenovirus

Contrary to both RSV and influenza, adenovirus infections do not demonstrate seasonality [152]. In immunocompetent hosts adenovirus causes a variety of infections depending on serotype. Infections can range from the asymptomatic or mild upper respiratory tract infection to epidemic keratoconjunctivitis and gastroenteritis. More serious infections that more often plague the immune-compromised host include pneumonia, hepatitis, hemorrhagic cystitis, encephalitis, and disseminated disease [153, 154].

Adenovirus is transmitted through direct contact with a patient's environment or via fomites and respiratory secretions. Serotypes associated with gastroenteritis can be transmitted through the fecal-oral route. Adenovirus requires both contact and droplet precautions in addition to standard precautions. Due to prolonged shedding, it is recommended that patients remain in precautions for the duration of the hospitalization [115].

Like RSV, there are no proven prophylactic strategies to prevent adenovirus transmission in the setting of an outbreak. The strategies outlined for both influenza and RSV including symptom screening, visitor restriction, increased audit of hand hygiene, PPE compliance, and disinfection are recommended. Adenovirus can be quite tenacious, and evaluating the role of the environment and potentially contaminated shared equipment is vital in stemming a potential outbreak [155]. The live vaccine currently available only to US military recruits is contraindicated in SOT and HSCT.

Other Respiratory Viruses

Other respiratory viruses (Table 2) can cause morbidity in both SOT and HSCT recipients. Partnering with infectious diseases and infection prevention and control is vital to controlling and preventing outbreaks. Like RSV and adenovirus,

Table 2 Respiratory viruses frequently encountered in the healthcare setting and recommended transmission-based precautions and prophylaxis strategies

Respiratory virus	Seasonality	Transmission-based precautions in addition to standard precautions	Recommended duration of precautions	Primary prophylaxis	Postexposure prophylaxis
Adenovirus	None	Contact and droplet precautions	Duration of hospitalization	None	None
Coronavirus[b]	None	Standard	N/A	None	None
Seasonal influenza[c]	Fall to Winter	Droplet precautions	24 h after resolution of fever and respiratory symptoms or 7 days after symptom onset whichever is longer – viral shedding can be prolonged	Vaccination of HCP, patients, and household contacts with inactivated influenza vaccine Neuraminidase inhibitor (e.g., oseltamivir) prophylaxis in the setting of increased incidence or contraindication to vaccination	Vaccination Neuraminidase inhibitor (e.g., oseltamivir) prophylaxis in the setting of exposure irrespective of vaccination status
Human metapneumovirus	None	Contact precautions[a]	Duration of illness	None	None
Parainfluenza	Depends on subtype, PIV3 more common in Spring and Summer but can be year-round	Contact precautions[a]	Duration of illness – viral shedding can be prolonged	None	None
Respiratory syncytial virus	Fall to early Winter	Contact precautions[a]	Duration of illness – viral shedding can be prolonged	Palivizumab recommended for high-risk patients as per AAP guidelines	None

[a]Masks can be added as part of standard precautions
[b]Excludes severe acute respiratory syndrome coronavirus (SARS-CoV), Middle East respiratory syndrome coronavirus (MERS-CoV), and 2019 novel coronavirus (2019-nCoV)
[c]Excludes pandemic or novel influenza viruses

there are no proven prophylactic measures available; thus adherence to standard and recommended transmission-based precautions is crucial. In the setting of nosocomial acquisition, a multicomponent approach to outbreak control is recommended.

Varicella-Zoster Virus

Varicella may be transmitted through direct contact with the rash or through airborne transmission during primary or disseminated infection. Additional transmission-based precautions may be recommended for patients on minimal immunosuppression with uncomplicated dermatomal zoster that be covered; however standard precautions can be used once disseminated disease has been excluded. Patients with primary VZV or herpes zoster involving more than two adjacent dermatomes should be placed in airborne and contact precautions. Patients should remain in airborne and contact precautions until lesions are dry and crusted, which can take longer in the profoundly immune compromised.

The advent of the varicella zoster vaccine has been pivotal in the prevention of primary varicella infections (chickenpox), and the timing of vaccination in transplant candidates has been reviewed [140, 156, 157]. In HSCT, patients can be vaccinated if no longer on immunosuppression and if over 2 years from HSCT without evidence of GVHD [157, 158]. Household contacts should receive age-appropriate VZV vaccinations. Transplant recipients should be isolated from contacts recently vaccinated with live-attenuated vaccines who develop a varicella-like rash. HCP are considered immune to VZV with laboratory confirmed immunity or written documentation of receipt of two doses of varicella vaccine [159].

In the setting of an exposure to varicella, nonimmune household contacts are encouraged to seek immunization. In terms of herpes zoster vaccination, household contacts should preferentially be offered the inactivated subunit vaccine rather than the live-attenuated vaccine. A categorical recommendation regarding subunit herpes zoster vaccine in SOT cannot be given at this time; however safety and efficacy data are emerging and trials are ongoing [140].

In the setting of nonimmunity, administration of Varicella zoster immune globulin (VZIG) within 10 days of an exposure is recommended [160]. Immunosuppressed patients with significant exposure may be required to furlough or be placed into airborne and contact precautions for 8–21 days postexposure. This period can extend to up to 28 days in the setting of receipt of VZIG. This recommendation is based on the average incubation of VZV being 2 weeks and transmission occurring 5–6 days prior to onset of the rash.

Use of antivirals for postexposure prophylaxis has not been systematically evaluated. It can be considered in the setting of patients unable to receive passive prophylaxis prior to 10 days postexposure. Current recommendations include a 7-day course of acyclovir or valacyclovir beginning 7–10 days after exposure. Many recommend longer durations.

Measles

In 2018–2019, the resurgence of measles worldwide after eradication in many countries has led to a refocus on the prevention of measles in the healthcare setting [161, 162]. Use of the live vaccine is contraindicated in SOT. In the setting of HSCT, vaccination is recommended in the absence of ongoing immunosuppression and GVHD. Current recommendations are to consider vaccination over 2 years from transplant. Irrespective of timing of SOT or HSCT, however, vaccination of household contacts is encouraged [140, 163].

Measles is highly contagious and requires immediate recognition and placement in airborne precautions. Patients are infectious 4 days prior to and 4 days after onset of the rash. The classic prodrome of cough, coryza, and conjunctivitis can be subtle and may be missed. In the setting of potential exposure and ongoing transmission, HCP should remain vigilant and err on the side of caution.

In the setting of an exposure where patients do not have documented immunity (defined as receipt of two doses of MMR vaccine or laboratory confirmation of immunity), transplant patients should receive immunoglobulin within 6 days of exposure [164]. In most cases patients with exposure who do not have evidence of immunity will be asked to quarantine with monitoring for symptoms for 21 days after exposure if no receipt of postexposure prophylaxis and 28 days after exposure with receipt of immunoglobulin.

Outbreaks of measles have occurred within healthcare institutions involving both HCP and patients [163, 165, 166]. Currently HCP vaccination and assessment for immunity are recommended [159].

Healthcare Personnel Vaccination

HCP, like household contacts, are encouraged to receive all age-appropriate vaccinations including those where inactivated vaccines are not available. Currently, vaccination against influenza, varicella, measles, mumps, rubella, pertussis, and hepatitis B is recommended [159]. In the setting of inadvertent exposures to communicable diseases, healthcare providers should contact their institutional infection prevention and control department and occupation health providers in order to determine the role of prophylaxis, reassignment, or furlough in the case of documented nonimmunity and significant exposure.

Conclusion

Recommendations for infection prevention and control practices in the general inpatient and ambulatory population are applicable to both SOT and HSCT populations. It should be noted, however, that these populations do pose additional infection prevention challenges due to endogenous and exogenous

immunosuppression, frequent exposure to healthcare, and antimicrobial exposures. Promotion of vaccination of patients, families, and HCP affords some protections from viruses and bacteria; however, vaccine hesitancy continues to exist in some communities. It is important for institutional leadership, transplant leadership, and infection prevention and control experts to partner and ensure that these unique populations are included in process improvement initiatives including those directed toward HAI prevention.

Key Points

- Hand hygiene compliance plays a pivotal role in preventing healthcare-associated infections.
- Care bundles and interdisciplinary teamwork have been associated with reduction in device-associated infections like central line-associated bloodstream infections and catheter-associated urinary tract infections in transplant patients.
- Transplant candidates and recipients are at increased risk for infections with environmental and waterborne pathogens, and mitigation strategies are available including patient placement, infection control risk assessments at the time of construction, and comprehensive water management plans.
- The use of molecular typing can aid in identifying the potential sources of outbreaks and inform mitigation strategies.
- Vaccination of healthcare personnel, household contacts, and patients can prevent severe illness from communicable diseases like influenza and reemerging infections like measles.

Introduction

Antimicrobial stewardship has been recognized as a key strategy to combat the growing threat of antibiotic resistance. Antimicrobial stewardship is defined as coordinated interventions designed to improve and measure the appropriate use of antimicrobial agents by promoting the optimal antimicrobial drug regimen including dosing, duration of therapy, and route of administration [1]. The primary goal of antimicrobial stewardship is to optimize patient outcomes while minimizing the development of resistance, toxicity, and other untoward consequences such as *Clostridioides difficile* [2]. It has emerged as a national priority in the USA with regulatory mandates requiring all acute care hospitals and ambulatory care centers to establish antimicrobial stewardship programs (ASP). The Centers for Disease Control and Prevention has developed core elements of a successful antibiotic stewardship program (Table 1) which complement guidance published by the Infectious Diseases Society of America and Society for Healthcare Epidemiology of America on implementation of an antimicrobial stewardship program [3].

Antimicrobial stewardship is highly relevant for transplant recipients where infectious complications remain a leading cause of morbidity and mortality following solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT). Transplant candidates and recipients represent a population at high risk for antimicrobial resistance due to frequent and prolonged exposure to antibiotics for prevention and treatment of infections. They are at increased risk for drug toxicity due to polypharmacy and complex drug interactions often in the setting of underlying hepatic or renal dysfunction. Additionally, they require use of high-cost antimicrobials and contribute substantially to the overall antimicrobial budget [4]. Transplant recipients have a higher incidence of *C. difficile* infection when compared to the general population; *C. difficile* infection is associated with significant morbidity including increased risk of graft rejection in certain populations (e.g., kidney

Table 1 Summary of CDC core elements of hospital antibiotic stewardship program

Leadership Commitment: Dedicating necessary human, financial, and information technology resources
Accountability: Appointing a single leader responsible for program outcomes. Experience with successful programs show that a physician leader is effective
Drug Expertise: Appointing a single pharmacist leader responsible for working to improve antibiotic use
Action: Implementing at least one recommended action, such as systemic evaluation of ongoing treatment need after a set period of initial treatment (i.e., "antibiotic time out" after 48 h)
Tracking: Monitoring antibiotic prescribing and resistance patterns
Reporting: Regular reporting of information on antibiotic use and resistance to doctors, nurses, and relevant staff
Education: Educating clinicians about resistance and optimal prescribing

transplant recipients) [5]. Furthermore, emerging data regarding the impact of antibiotic use on the microbiome, graft versus host disease (GVHD) [6], and relapse risk [7] suggest that antimicrobial stewardship efforts may have broader impact on important clinical outcomes.

It is important to consider antimicrobial stewardship among both transplant candidates and recipients as antimicrobial use prior to transplant may have a significant impact on selection of resistance and thus capacity for downstream use of certain antibiotics. Furthermore, antibiotic use prior to HSCT may impact intestinal microbiota composition at the time of transplant. Weber and colleagues found that compared to posttransplant, early exposure to antibiotics (day −7 to 0) was associated with greater disruption of commensal microbiota and was an independent risk factor for transplant related mortality (TRM) including GVHD-related TRM [8]. Additionally, decreases in gut microbiota diversity prior to HSCT has been associated with increased risk of bloodstream infection posttransplant [9].

Diagnostic and therapeutic uncertainties were identified as the major challenges to antimicrobial stewardship in transplant patients in a survey of adult and pediatric infectious disease physicians and pharmacists at US SOT and HSCT centers [10]. Timely accurate diagnosis and management of infections in transplant patients can be difficult due to delayed test turnaround time as well as underlying comorbidities which may limit ability to perform invasive diagnostic procedures such as biopsy or other surgical interventions required to achieve source control. Difficulty establishing a diagnosis coupled with lack of outcomes data to guide duration of therapy among transplant patients often leads to prolonged antibiotic use in this immunocompromised population. Additionally, concern over the potential for antibiotic-resistant organisms may lead to escalation of therapy thereby contributing further to the cycle of antibiotic resistance. Finally, prescriber opposition and differences in risk perception or motivation between the ASP team and primary team have been identified as important barriers to stewardship in transplant populations [10].

This chapter reviews practical considerations when implementing antimicrobial stewardship programs targeting transplant recipients and candidates and describes opportunities for optimizing antimicrobial use.

Implementing Antimicrobial Stewardship in Transplant Patients

A multidisciplinary approach is important for successful implementation of an ASP among transplant patients. These patients are often managed by a team approach including physicians, mid-level providers, nurses, and pharmacists; hence, it is critical to engage all of these individuals as key stakeholders when developing stewardship interventions. See Fig. 1.

An infectious disease physician and infectious disease-trained pharmacist generally serve as the backbone of the ASP team. The number of ASP team members needed varies based on hospital size. For example, a staffing calculator by the Veterans Health Administration determined that 1.0 full-time equivalent clinical

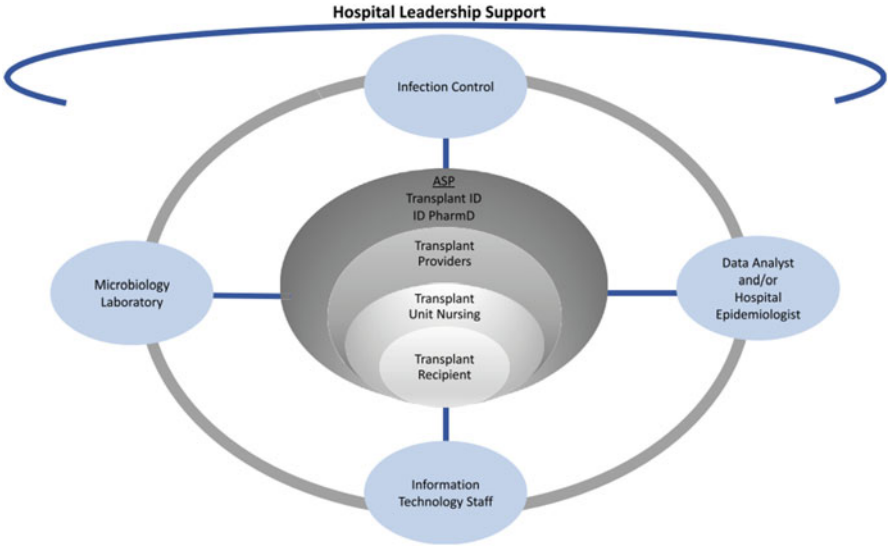

Fig. 1 Multidisciplinary approach to antimicrobial stewardship in transplantation [35]. (Permission for use of this table granted from Elsevier Inc.)

pharmacist per 100 occupied beds was needed to perform antimicrobial stewardship in a general hospital population [11]. Familiarity with the complexities of infections and novel therapeutics in immunocompromised patient population is key as these patients utilize a significant proportion of antimicrobials. Involving transplant and oncology infectious disease colleagues in ASP decisions encourages adherence to guidelines and recommendations [12]. Understanding providers' perceptions and behaviors regarding antimicrobial prescribing patterns particularly in the face of diagnostic uncertainty and complex clinical situations provides insight into ASP approaches to this population. Additionally, close partnership with the infection prevention team is important to develop strategies to prevent transmission of multidrug-resistant organisms.

Microbiology laboratory representatives are also instrumental for ASPs when integrating diagnostic modalities with appropriate antimicrobials and clinical management decisions. For instance, increasingly available rapid molecular diagnostic techniques for positive blood cultures and respiratory and gastrointestinal pathogens have had implications for the care of transplant patients but often require ASP guidance in conjunction with microbiology to optimize their benefit. Likewise, assistance from information technology personnel can be key to interface with providers via order sets, electronic decision support tools, and guidance documents.

Nursing staff may provide valuable contributions to ASP activities. A 2017 White Paper by Centers for Disease Control and Prevention and American Nursing Association outlined opportunities and emphasized the value of including and educating registered nurses in antimicrobial stewardship, particularly because they serve on the frontline of patient care [13]. Additionally, nurses are often already

engaged in infection prevention efforts which complement antimicrobial stewardship activities (e.g., *C. difficile*).

Administrative support is instrumental to maintaining a successful ASP. As accreditation standards for antimicrobial stewardship evolve, hospital administrators have a vested interest in establishing and maintaining antimicrobial stewardship efforts. ASP policies, reporting parameters, and funding require regular engagement and information exchange with members of hospital administration and various medical center committees.

There are a broad range of activities that ASP programs can initiate or expand when implementing antimicrobial strategies in SOT and HSCT recipients (Table 2).

Formulary Management

The ASP team plays a key role in making formulary decisions about antimicrobial agents through the hospital's pharmacy and therapeutics committee. Formulary choices should take into consideration not only therapeutic efficacy, adverse effects, and cost but also local infectious disease epidemiology and resistance patterns in

Table 2 Antimicrobial stewardship strategies and interventions in SOT and HSCT recipients

Antimicrobial stewardship intervention	Examples
Formulary management	Participation in Pharmacy &Therapeutics Committee Formulary review Management of drug shortages
Pre-prescription authorization	High-cost drugs used by transplant recipients New antimicrobial agents
Post-prescriptive review (prospective audit and feedback)	Targeted antibiotics (e.g., carbapenems, antipseudomonal agents, double-anaerobic coverage) Handshake stewardship
Antimicrobial agent selection	Transplant-specific antibiogram Individualized antibiotic plan (e.g., based on history of or colonization with MDRO) Precision medicine using advanced molecular diagnostics to characterize resistance genes
Antibiotic allergy assessment	Beta-lactam allergy testing Pre-transplant antibiotic allergy evaluation
Dose optimization	PK/PD-based dosing and monitoring (e.g., vancomycin, aminoglycosides, extended infusion β-lactams, voriconazole, posaconazole)
Intravenous-to-oral conversion	Antibiotics, antivirals (e.g., IV ganciclovir to oral valganciclovir) and antifungals (e.g., echinocandin to oral triazole)
Clinical pathways and guideline development	Febrile neutropenia, antifungal prophylaxis and treatment, CMV prophylaxis and treatment, posttransplant vaccination
Diagnostic test stewardship	*C. difficile* testing, surveillance blood and urine cultures

the context of the different populations served [12]. For transplant patients, it is important to review formularies with particular attention to new antibiotics targeting multidrug-resistant organisms (MDROs), as well as antifungals and antivirals that may be used for prophylaxis and treatment in the peri-transplant period. As part of the formulary review process, ASPs should consider what additional processes are needed to ensure the safe prescribing, distribution, and use of the drug. This may include pre-authorization or restriction, guideline development, medication use evaluation (MUE) plans, and educational efforts [14]. Additionally, it will be important for ASPs to coordinate with the microbiology laboratory regarding availability of antimicrobial drug susceptibility tests for new agents.

Recent challenges faced by ASPs that have direct impact on the management of infections among transplant patients include antimicrobial drug shortages [15] and the dramatic rise in costs of certain medications (e.g., aerosolized ribavirin and pyrimethamine) [16, 17]. The ASP can play a key role in managing these scenarios through development of drug use guidelines during drug shortages and whenever a prescriber orders selected high-cost drugs. Such guidelines may incorporate consideration of therapeutic alternatives and often require direct ASP communication with providers.

Pre-prescription Authorization and Post-prescriptive Review

One core strategy to reduce use and cost of certain antimicrobials is pre-prescription authorization, known simply as pre-authorization [2]. Typically an ASP pharmacist or infectious disease physician must provide approval for use of an antimicrobial prior to release [18]. Pre-prescription authorization may include high-cost drugs used in transplant patients, such as intravenous posaconazole, inhaled ribavirin, and newer antimicrobial agents targeting resistant pathogens. This strategy has been shown to reduce costs in transplant units [19]. A carbapenem restriction policy in one center resulted in a significant decrease in meropenem use for hematology-oncology and bone marrow transplant units [20]. Efforts to promote appropriate use of carbapenems may prevent emergence of carbapenem resistance.

Post-prescriptive review, also known as prospective audit and feedback (PAF), is another foundational antimicrobial stewardship intervention that engages the provider after an antibiotic is prescribed [3]. PAF involves review of clinical and laboratory results to guide further therapy and allows opportunities to address de-escalation and duration. One study investigating post-prescriptive reviews in hematopoietic cell transplant patients reported trends in reduced third- and fourth-generation cephalosporin prescribing and increased compliance with ASP recommendations [21].

In a survey of US adult and pediatric HSCT and SOT centers, pre-authorization and post-prescriptive review were among the six most common antimicrobial stewardship interventions [10]. Both strategies have been evaluated in centers that include oncology and/or transplant patients with a resultant decrease in antimicrobial utilization and costs without resulting in harm [18, 22].

Handshake stewardship is an emerging ASP strategy that builds upon PAF and refers to active engagement with frontline providers including review of all

antimicrobials and a rounding-based, in-person approach to feedback by a pharmacist-physician team [23]. This approach may be particularly useful for ASPs when establishing credibility and rapport with transplant teams. Participation in in-person rounds increases visibility and familiarity with the transplant services and provides a unique opportunity for bidirectional exchange of information and education [24]. However, this approach is labor- and time-intensive, and not all hospitals may have the resources to support this. Establishing regular meetings to increase face time with providers may be more feasible if resources are limited; in one study of pediatric hematology-oncology and HSCT patients, this strategy in combination with others was found to be effective in reducing antimicrobial use and cost without adverse outcomes [22].

Antimicrobial Agent Selection

Transplant patients present unique considerations when it comes to empiric antimicrobial selection, including previous antibiotic exposure, history of resistant organisms, organ dysfunction, and medication interactions [18]. A transplant-specific antibiogram can be useful in guiding empiric antimicrobial selection. One study observed significant differences in susceptibilities in blood and urine isolates of *E. coli*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa* from SOT recipients as compared to the hospital-wide antibiogram [25]. In another study, a disease-specific antibiogram for urinary tract infections in kidney transplant recipients found that *E. coli* urinary isolates were significantly more resistant to multiple antibiotic drug classes compared to the institutional antibiogram [26]. One strategy proposed by some HSCT centers is the development of individualized antibiotic plans for future inevitable episodes of febrile neutropenia, based on results of screening cultures to identify colonization with MDROs [18]. Pre-lung transplant patients represent another group in which an individualized antibiotic plan at the time of transplant may be developed based on prior bronchoalveolar lavage cultures and past history of *Aspergillus* or mycobacterial colonization, with additional modifications based on available donor cultures at time of transplant. A "precision medicine" approach to antibiotic selection using advanced molecular diagnostic techniques has also been increasingly recognized as an important strategy for the management of transplant patients with MDROs. This approach may be helpful in guiding use of novel antibiotic combinations [27].

A conceptual framework developed by the Agency for Healthcare Research and Quality (AHRQ) Safety Program for Improving Antibiotic Use that is readily adaptable to the transplant patients is the 4 moments of antibiotic decision-making [28] (Table 3).

Antibiotic Allergy Assessment

Antibiotic allergy assessment has been increasingly recognized as an important stewardship intervention that may help to guide antibiotic selection and use of preferred agents. Penicillin allergies are most commonly reported in up to 10–15% of the general

Table 3 Incorporating the 4 moments of antibiotic decision-making into daily practice [28]

Question[a]	Patient scenario	ASP strategy
1. Does this patient have an infection that requires antibiotics?	Renal transplant patient with asymptomatic bacteriuria	Clinical pathways and guideline development Post-prescriptive review
2. Have I ordered appropriate cultures before starting antibiotics? What empiric antibiotic should I initiate?	HSCT patient with febrile neutropenia	Clinical pathways and guideline development Dose optimization Transplant-specific antibiogram
3. Cultures have returned. Can I change from IV to oral therapy?	Liver transplant patient with fluconazole-sensitive candidemia	IV-to-PO conversion
4. What duration of antibiotic therapy is needed for this patient's diagnosis?	HSCT patient with surveillance blood culture demonstrating growth of coagulase negative *Staphylococcus*	Diagnostic test stewardship Post-prescriptive review

ASP antimicrobial stewardship program, *HSCT* hematopoietic stem cell transplant, *IV* intravenous, *PO* oral

[a]Questions posed by Tamma and colleagues [28]; patient scenarios and ASP strategies are original

population [3, 29]. When compared to nonallergic patients, those with a penicillin allergy label have increased exposure to alternative and less optimal antibiotic therapy, increased risk for antibiotic resistance, and higher healthcare costs [29].

There are limited data on the prevalence of antibiotic allergies among transplant patients. In a study of 4671 patients with hematologic malignancies of which approximately 20% underwent HSCT, 35% reported antibiotic allergy with 14% having a beta-lactam allergy [30]. In an Australian liver transplant cohort of 313 patients, 16% reported at least one antibiotic allergy [31]. Similar to the general population, antibiotic allergy labels in immunocompromised populations largely consisted of beta-lactams, particularly penicillin [30–32]. In patients with hematologic malignancies, antibiotic allergy labels have been associated with use of more antibiotic classes [30], increased antibiotic duration [30, 32], longer lengths of stay [30], higher readmission rates [30, 32], higher rates of *C. difficile* [30], and reduced concordance with prescribing guidelines [32]. Integrating an antibiotic allergy testing program at one large center successfully led to the prescription of narrower-spectrum beta-lactams, more guideline appropriate antibiotic use, and use of fewer restricted antibiotics. Forty-eight percent of these patients were immunocompromised with up to 8% developing febrile neutropenia during their clinical course [33].

Some centers may consider incorporating antibiotic allergy assessment as part of the routine pre-transplant evaluation to optimize posttransplant antibiotic use, though further data are needed to assess the impact of such programs.

Dose Optimization and Drug Interactions

Dose optimization using pharmacokinetic (PK) and pharmacodynamic (PD) principles is a key function of an antimicrobial stewardship program managing transplant patients [18]. Critical illness, impaired renal function, differences in PK/PD among selected patient populations (e.g., cystic fibrosis), and frequent drug-drug interactions underscore the importance of a stewardship team with experience in the management of complex transplant scenarios. PK monitoring and adjustment programs for aminoglycosides and vancomycin are encouraged and can decrease adverse effects and costs [3]. Extended infusion compared to standard dosing for broad-spectrum β-lactams has been associated with decreased costs though there are limited data in general and transplant populations to assess the impact on clinical outcomes [3]. In one single-center, nonblinded, randomized clinical trial of febrile neutropenia, extended infusion β-lactams was found to be associated with improved treatment outcomes when compared to bolus infusion with the greatest benefit observed among those patients with clinically documented infections and, in particular, pneumonia [34]. The importance of antiviral PK and PD principles has been recognized in the management of CMV infections with the goal of reducing toxicities, decreasing the emergence of resistance and improving treatment response [35]. Therapeutic drug monitoring of antifungal agents including voriconazole and posaconazole has been associated with a reduced risk of adverse drug events and improved outcomes [36].

Use of older antimicrobial agents, such as polymyxins, in the face of MDROs often requires expert infectious disease pharmacy consultation to optimize dosing. Additionally, ASP pharmacists play a critical role in reviewing complex medication lists for drug-drug interactions and assessing the need for dose modification or use of an alternative agent. One of the most common examples is the use of calcineurin inhibitors and triazoles. As additional therapies emerge for the management of transplant patients, it is important that the ASP team recognizes the potential for new drug-drug interactions and monitor accordingly.

Intravenous-to-Oral Conversion

Timely intravenous-to-oral (IV-to-PO) agent conversion is recommended as an ASP intervention to reduce costs, hospital length of stay, outpatient parenteral antimicrobials, and need for intravenous catheters [3]. Approximately half of surveyed transplant center ASPs reported IV-to-PO conversion as a stewardship strategy [10]. Although the presence of mucositis among HSCT recipients may

preclude oral therapy, IV-to-PO conversion may be considered among transplant recipients for whom oral absorption is not a concern. A recent study found no difference in 30-day mortality among patients (approximately 10% SOT and 6% HSCT) who received early oral step-down versus continued parenteral therapy for the treatment of *Enterobacteriaceae bacteremia* with adequate source control [37]; larger studies in transplant recipients are needed to validate the safety of this approach. Antifungals are an important target in transplant patients as echinocandins can be transitioned to oral fluconazole for susceptible *Candida* blood isolates and IV-to-PO triazoles utilized in management of invasive fungal infections [18, 35]. Oral valganciclovir has been shown to be noninferior to IV ganciclovir for treatment of CMV disease among SOT patients who are able to absorb oral medication and do not have severe gastrointestinal CMV disease [38].

Clinical Pathways and Guideline Development

Development of clinical pathways and guidelines is another important ASP strategy and was described as an intervention performed by over 70% of HSCT and SOT centers surveyed [10]. There are many opportunities for guideline development including antifungal prophylaxis and treatment of invasive fungal infections, management of CMV infections including antiviral prophylaxis, as well as posttransplant vaccination. Implementation of guidelines for management of febrile neutropenia has been associated with reduction in empiric vancomycin [39, 40] and carbapenem use [41] (see section on "Febrile Neutropenia"). A clinical pathway for febrile neutropenia among pediatric oncology patients presenting to the emergency room was shown to improve time to antibiotics and reduce septic shock, ICU admissions, and mortality [42].

Engagement of appropriate stakeholders including both the transplant (e.g., HSCT or SOT) and transplant infectious disease (ID) consult teams with opportunities for feedback and education is key prior to implementation of clinical pathways. Guidelines can be disseminated in a variety of ways including presentations, standardized order sets, pocket cards, ASP website, and computerized decision support. In addition to guideline implementation and dissemination, it is important to assess adherence to treatment guidelines and to monitor intended outcomes [3].

Diagnostic Test Stewardship

Diagnostic test stewardship aims to optimize and reduce inappropriate use of diagnostic tests and thus unnecessary antibiotic use. It involves efforts to modify the process of ordering, performing, and reporting of diagnostic tests [43]. As part of the American Board of Internal Medicine (ABIM) Choosing Wisely initiative, the Society for Healthcare Epidemiology of America (SHEA) identified orders for urine cultures, blood cultures, and stool tests for *C. difficile* in the absence of signs and symptoms of infection as high-priority targets for provider education to reduce

overdiagnosis and overtreatment [44]. This is highly relevant to transplant patients where diagnostic tests are frequently performed due to concern for possible infectious complications among a vulnerable population.

While several studies have demonstrated the effectiveness of computerized clinical decision support (CCDS) and other tools in reducing *C. difficile* tests and rates in general hospitalized patient populations [45, 46], there are limited published data in transplant populations. A bundled intervention including CCDS-based interventions and educational efforts led to a significant reduction in *C. difficile* tests with a trend toward fewer *C. difficile* infection (CDI) events among SOT recipients [45]. Implementation of *C. difficile* diagnostic stewardship strategies among HSCT candidates and recipients poses some unique challenges. HSCT patients represent a high-risk population for CDI due to frequent healthcare and antibiotic exposure along with impaired host immunity [47], but high prevalence of diarrhea due to chemotherapy and transplant-related complications such as graft versus host disease (GVHD) may lead to high rates of testing and thus overdiagnosis of CDI in a population with a high baseline prevalence of colonization [48]. Further research is needed to refine criteria for *C. difficile* testing among HSCT patients.

Surveillance blood cultures are performed at some transplant centers for early detection of bloodstream infections among allogeneic HSCT recipients receiving high-dose glucocorticoids, with neutropenia, or central venous catheters [49]. Among centers that perform surveillance blood cultures, there is variability in the frequency (e.g., daily, weekly) and conditions in which surveillance cultures are performed; however, in general, studies have suggested that surveillance blood cultures have limited value and infrequently detect clinically significant pathogens while leading to excess antibiotic use [49].

Another area of opportunity for improved diagnostic stewardship is limiting screening for and treatment of asymptomatic bacteriuria and is discussed in detail in Section Vb.

While overuse of diagnostic tests when not indicated may lead to unnecessary antibiotic use, appropriate use of diagnostic studies may be helpful in limiting antibiotic use. For example, respiratory viral PCR testing was associated with decreased antibiotic use for upper respiratory infections at an ambulatory cancer center [50].

Syndrome- and Drug-Specific Targets

ASP programs can also consider a variety of infectious disease syndrome and/or drug targets when implementing stewardship interventions.

Antibiotic Stewardship

Febrile Neutropenia

The 2016 Infectious Diseases Society of America (IDSA) Guidelines on Implementing an Antibiotic Stewardship Program recommend development of

institution-specific guidelines for fever and neutropenia (F&N) in hematology-oncology patients which can reduce unnecessary antibiotic use without adverse outcomes [3]. Several studies suggest that implementation of pathways for F&N management is associated with improved clinical outcomes [42, 51].

There are several aspects to the management of F&N that represent potential targets for antimicrobial stewardship: (1) addition of vancomycin to initial antibiotic therapy or for persistent febrile neutropenia and (2) duration of empiric antibiotic therapy and de-escalation. Routine addition of gram-positive coverage to an anti-pseudomonal beta-lactam for initial empiric therapy of F&N has not been associated with improved outcomes [52, 53]. Guidelines from IDSA, NCCN, and ECIL indicate that vancomycin should only be used in selected scenarios when managing a patient with F&N (Table 4). Despite these recommendations, vancomycin is often given along with an antipseudomonal beta-lactam as part of empiric therapy for febrile neutropenia. In a retrospective study of 128 patients with F&N most of whom had an underlying hematologic malignancy, 62% had an inappropriate indication for vancomycin use [54]. Another scenario in which vancomycin is commonly used is as an add-on to empiric antipseudomonal beta-lactam monotherapy following several days of persistent fever. In a randomized clinical trial, the addition of vancomycin did not have any impact on time to defervescence among neutropenic patients with persistent fever 48–60 h after the initiation of empiric piperacillin-tazobactam monotherapy [55]. Implementation of a clinical pathway including specific guidance on vancomycin use was associated with a significant reduction in inappropriate use from 35.9% to 11.4% pre- and post-pathway implementation, respectively ($p = 0.001$) [39].

Table 4 Indications for empiric vancomycin use among patients with febrile neutropenia

Indications	2011 IDSA Guidelines	2011 ECIL	2019 NCCN Guidelines
Clinically apparent, serious IV catheter-related infection (e.g., chills or rigors with infusion through catheter and cellulitis around the catheter entry/exit site)	X	X	X
Blood cultures positive for gram-positive bacteria before final identification and susceptibility testing	X		X
Known colonization with MRSA or penicillin-/cephalosporin-resistant pneumococci	X	X	X
Clinical instability (e.g., hypotension, shock) pending culture results	X	X	X
Soft tissue infection	X	X	X
Pneumonia documented radiographically	X	X	
Severe mucositis, if fluoroquinolone prophylaxis and *ceftazidime* used as empiric therapy	X		

IDSA Infectious Diseases Society of America, *ECIL* European Conference on Infections in Leukaemia, *NCCN* National Comprehensive Cancer Network, *IV* intravenous, *MRSA* methicillin-resistant *Staphylococcus aureus*

There is some variation among national and international guidelines regarding the duration of empiric antibiotic therapy in F&N. Clinical practice guidelines by the IDSA [56] and National Comprehensive Cancer Network (NCCN) [57] recommend continuing empiric broad-spectrum antibiotic therapy until absolute neutrophil count (ANC) recovery (ANC $\geq$500 cells/ mcL). An alternative approach is suggested in patients in whom an appropriate treatment course has been completed with resolution of all signs and symptoms of infection; in these cases, oral fluoroquinolone prophylaxis may be considered until ANC recovery. The ECIL guidelines indicate that empiric antibiotics may be discontinued after $\geq$72 h of intravenous antibiotics in patients who have been hemodynamically stable since presentation and afebrile for $\geq$48 h or more, regardless of ANC or expected duration of neutropenia [58]. Recent studies have suggested that earlier discontinuation or de-escalation of antibiotic therapy may be a reasonable approach [59]. A randomized clinical trial of high-risk patients with hematologic malignancies and febrile neutropenia found that discontinuation of empiric antibiotic therapy after 72 h of apyrexia and clinical recovery resulted in less antibiotic exposure compared to an ANC recovery directed approach and was safe [60].

Asymptomatic Bacteriuria in Organ Transplant Recipients

The 2019 IDSA Clinical Practice Guidelines for Asymptomatic Bacteriuria and 2019 American Society of Transplantation Infectious Disease Community of Practice Guidelines for Urinary Tract Infections in Solid Organ Transplant Recipients recommend against treatment of asymptomatic bacteriuria (ASB) after 1 or 2 months post-kidney transplant, respectively [61, 62]. This includes ASB with multidrug-resistant organisms.

Two prospective randomized comparative trials suggest no benefit of treatment versus no treatment of ASB in renal transplant recipients. Origüen et al. analyzed 112 patients with bacteriuria identified $\geq$ 2 months posttransplant who were randomized to treatment versus no treatment of ASB episodes identified by screening urine cultures performed at clinic visits over a 2-year follow-up period [63]. The primary outcome, acute pyelonephritis, occurred with the same frequency in each group. Secondary outcomes, long-term graft function, all-cause mortality, cumulative incidence of UTI, acute graft rejection, *C. diff* infection, and colonization or infection with MDROs were also the same. Among patients who received treatment of ASB, microbiologic cure was achieved in only 51%, while 33% of those untreated cleared bacteriuria spontaneously [63]. Another prospective quasi-randomized trial assigned 88 recipients of kidney transplants with ASB identified by monthly screening urine cultures over a 1-year period to antibiotic treatment versus observation alone. There were no difference in outcomes: bacteriuric episodes, symptomatic UTIs, and graft function [64].

The threat of inducing drug-resistant organisms by treating ASB outweighs the theoretical benefit of treatment [61, 62]. American Society of Transplantation Guidelines for UTI in Solid Organ Transplant highlight retrospective studies suggesting increased development of drug resistance as a consequence of treating ASB or UTI. Studies of trimethoprim-sulfamethoxazole used for both *Pneumocystis*

carinii and UTI suppression in renal transplant are also linked to the emergence of UTIs from ESBL and/or carbapenemase-producing *Enterobacteriaceae* [62]. In one study, treatment of asymptomatic *E. coli* or *E. faecalis* bacteriuria led to selection of resistant organisms in 78% of treated cases with no difference in progression to UTI between treated and untreated groups [65].

There is insufficient evidence to inform recommendations for ASB screening and treatment within 1–2 months following transplant [61, 62]. Some have justified ASB screening and treatment during the early posttransplant period due to concerns about progression to pyelonephritis, sepsis, and early graft dysfunction and rejection [61, 62]. Balancing these potential outcomes with the risk of inducing drug-resistant organisms requires careful consideration.

Distinguishing asymptomatic bacteriuria (ASB) from urinary tract infection (UTI) is a recognized challenge in renal transplant patients. Indwelling ureteral stents, surgical manipulation of the urinary tract, and induction immunosuppression are UTI risk factors unique to renal transplant recipients [61, 62]. See Table 5 for definitions of ASB, simple cystitis, complicated UTI, and pyelonephritis in renal transplant recipients.

In recipients of nonrenal organ transplants, there is no evidence to support screening for or treating ASB [61, 62]. Much of the data comes from the Spanish Network for the Study of Infections in Transplantation (RESITRA) registry of 2,405 organ transplant recipients citing low incidence of cystitis and UTI-derived bacteremia in nonrenal organ transplant recipients. In the registry, incidence of cystitis per 100 recipient years was 3.09 for liver, 2.41 for heart, and 1.36 for lung transplant recipients compared with 13.84 for renal transplant; UTI was the source of bacteremia in 3% of liver, 3% of heart, and 0% of lung transplant recipients compared with 39% of renal transplant patients [66].

Antiviral Stewardship

Aerosolized Ribavirin for Management of RSV

Aerosolized ribavirin has long been considered the standard of care for management of RSV upper respiratory tract infection (URTI) and lower respiratory tract infection (LRTI) [67]. However, aerosolized ribavirin is expensive, cumbersome to administer, and associated with adverse effects such as bronchospasm and teratogenicity. In recent years, the cost of aerosolized ribavirin has increased to nearly $30,000 per day [16]. For all of these reasons, aerosolized ribavirin represents an important opportunity for antiviral stewardship and development of institutional guidelines regarding use. Recent studies suggest that oral ribavirin may be a safe and effective alternative to aerosolized ribavirin for treatment of RSV infection. In a retrospective study of 124 HSCT recipients with RSV infection, there was no difference in rates of progression to LRTI and mortality among patients receiving oral compared to aerosolized ribavirin [68]. In one study that evaluated 21 lung transplant patients who received either aerosolized or oral ribavirin for RSV infection, no significant differences in 6-month outcomes were noted between the two groups [69].

Table 5 Classification of asymptomatic bacteriuria in urinary tract infection (UTI) in renal transplant recipients

Classification	Description	Laboratory definitions
Asymptomatic bacteriuria	No urinary of systemic symptoms of infection	$>10^5$ CFU/mL uropathogen[a,b]
Acute simple cystitis	Dysuria, urinary urgency/frequency, or suprapubic pain but no systemic symptoms and no ureteral stent/nephrostomy tube/chronic urinary catheter	>10 WBC/mm^3 [c] $>10^3$ CFU/mL uropathogen[b]
Acute pyelonephritis/complicated UTI	Fever, chills, malaise, hemodynamic instability, or leukocytosis (without other apparent etiology); flank/allograft pain; or bacteremia with same organisms as in urine Dysuria, urgency, frequency, suprapubic pain may or may not be present	>10 WBC/mm^3 [c] $>10^4$ CFU/mL uropathogen[b]
Recurrent UTI	>/= 3 UTIs in prior 12-month period	As above

Adapted from Table 1 from AST ID COP UTI Guidelines [62]. Permission for use of this table granted from John Wiley & Sons, Inc.

CFU colony forming units, *mL* milliliter, *WBC* white blood cell, *mm* millimeter

[a]While routine treatment of asymptomatic bacteriuria is not recommended, if considering treatment (e.g., in the immediate posttransplant period), a repeat urine culture is recommended to assess persistence of the same uropathogen. Spontaneous resolution is common

[b]*Staphylococcus epidermidis* (except if ureteral stent present), lactobacillus, and *Gardnerella* sp. are unlikely to be uropathogens. Regarding CFU/mL, while most patients will UTI will have $>10^5$ CFU/mL of a uropathogen in a midstream urine sample, some patients with pyelonephritis may have only 10^4–10^5 CFU/mL of a uropathogen, and some patients with cystitis may have even fewer CFU/mL (most data on cystitis with low CFU/mL is only for *E. coli*). Not all labs report $<10^4$ CFU/mL

[c]While not an absolute criteria (depending on the performance characteristics of the urinalysis or presence of neutropenia), <10 WBC/mm^3 should prompt consideration of a diagnosis other than UTI

Cytomegalovirus (CMV)

With the threat of CMV resistance and the introduction of new antivirals, CMV management is a target of antimicrobial stewardship interventions. Locally developed guidelines for CMV prophylaxis and treatment, respectively, are utilized by 82% and 70% of 71 US transplant centers surveyed regarding stewardship strategies [10]. Data on the effectiveness of such strategies are limited, but multidisciplinary collaboration is encouraged to optimize management [70].

A pharmacist-driven antimicrobial stewardship intervention in the outpatient setting was reported at one transplant center performing SOT [70]. In this quasi-experiment, CMV DNA surveillance results were conducted by a pharmacist and recommendations for drug therapy provided at the time of result notification based on institution, organ-specific protocols and compared to the previous standard of care. Time-to-CMV eradication was decreased (25.5 vs. 29 days; $p = 0.003$); there were also non-statistically significant decreases in CMV-related admissions, CMV disease, and episodes of CMV resistance at 1 year [70].

ASP programs may also consider evaluating the impact of new antivirals (e.g., letermovir use for CMV prophylaxis) on subsequent use of existing agents such as ganciclovir and foscarnet.

Antifungal Stewardship

Antifungal stewardship is important among SOT and HSCT recipients, who disproportionately experience a large burden of fungal infections and excess use of antifungal drugs compared to other hospitalized patients [4, 71, 72]. Invasive *Candida* and *Aspergillus* infections represent the most common invasive fungal diseases (IFD) in SOT and HSCT recipients [73]. Given their morbidity and mortality in these populations, antifungal prophylaxis is routine in high-risk HSCT [72] and SOT recipients, particularly in the first 100 days posttransplant [74]. The high cost of IFD prevention [4], management [75], and emerging antifungal resistance [72, 75] are rationales for establishing antifungal stewardship strategies using national antimicrobial stewardship guidelines [3]. Antifungal overuse, potential toxicity with prolonged use, attention to drug-drug interactions, and need for drug level monitoring are additional reasons to establish antifungal stewardship programs focused on transplant patients.

Opportunities exist to optimize antifungal use. Prolonged antifungal therapy and prophylaxis account for 42–66% of antifungal overuse [75]. Delays in IFD recognition and poor sensitivity of fungal diagnostics contribute to this [72, 75]. Given the poor outcomes associated with delays in appropriate therapy for IFD, many clinicians choose to start empiric antifungal treatment [71, 72]. Empiric antifungal therapy accounts for up to two thirds of inpatient antifungal prescribing; de-escalation of empiric therapy remains one of the most challenging aspects of antifungal stewardship [71].

Post-prescriptive review and feedback is a recommended antifungal stewardship intervention [71] which has been reported to reduce antifungal consumption and cost [75]. Intravenous-to-oral conversion for azole-sensitive candidemia is recommended by national antimicrobial stewardship guidelines [3]. Often, post-prescriptive review and feedback is combined with other interventions, such as guideline implementation, prescriber education, therapeutic drug monitoring, and incorporation of fungal diagnostics to optimize antifungal use [75]. High-risk hematologic malignancy, HSCT, and SOT (particularly lung transplant) patients are recommended target populations [71].

National ASP guidelines suggest that non-culture-based fungal markers may help to optimize antifungal use [3]. Incorporating fungal markers such as galactomannan, (1,3)-β-D-glucan, or fungal PCR (single or multi-pathogen) into IFD diagnostic and therapeutic algorithms for high-risk patients may assist in decreasing duration of empiric antifungal therapy in high-risk hematologic malignancy and allogeneic HSCT patients [3, 71, 72]. In SOT recipients, there is limited utility for serum fungal biomarkers due to reduced sensitivity; bronchoalveolar aspergillus galactomannan is

the preferred biomarker for diagnosis of invasive pulmonary aspergillosis in SOT patients [76].

Transplant recipients can benefit from attention to therapeutic drug monitoring and drug-drug interactions (DDIs) to avoid toxicities. Patient comorbidities and the complex pharmacokinetics of concurrent immunosuppressive drug regimens put transplant recipients at increased risk. DDIs with antifungal therapy are common, especially in SOT and HSCT patients treated with triazoles, with the potential for associated adverse drug events [75]. Therapeutic drug monitoring of voriconazole can improve efficacy, safety, and compliance in patients with IFD [71, 75]. IDSA Guidelines for management of aspergillosis recommend therapeutic drug monitoring of voriconazole, itraconazole, and posaconazole; currently there is insufficient data to support isavuconazole level monitoring [77]. Cost, accessibility, and turnaround time of fungal diagnostics and antifungal therapeutic drug monitoring are implementation factors to consider at each institution [75].

Antimicrobial Stewardship Program Metrics

Previously described antimicrobial use, process, and outcomes measures [3] should be applied to assess the impact of an antimicrobial stewardship program on transplant populations (Table 6). Ideally, metrics should be captured in a way that enables tracking and feedback by a service line and/or unit. Additionally, the impact of interventions to improve antibiotic use should be assessed. Limitations may include identifying appropriate benchmarks for transplant programs for metrics such as days of therapy (DOT). Assessment of process measures such as guideline adherence and intervention acceptance rates requires robust data capture and analytic tools but may be possible with enhanced electronic medical record (EMR) programs. It is important to partner with transplant services to identify clinically meaningful quality and outcome metrics although feasibility of data capture and presence of confounders when interpreting outcomes such as readmissions and mortality may pose challenges [76].

Conclusion

Transplant candidates and recipients benefit greatly from antimicrobial stewardship because they are at high risk for complications from antimicrobial-resistant organisms and drug toxicities. Implementation of antimicrobial stewardship strategies requires a multidisciplinary approach and should target infectious syndromes and specific antimicrobials. Metrics need to be carefully chosen based on a stewardship intervention goal, such as antimicrobial use, guideline, or order utilization, or a selected patient outcome.

Table 6 Antimicrobial stewardship metrics for transplant programs [3]

Antimicrobial metrics	Considerations
Process metrics	
Antibiotic utilization	
Days of therapy (DOT)	Preferred method for measuring antibiotic utilization, used by the CDC National Healthcare Safety Network (NHSN) for antimicrobial use reporting
Defined daily dose	Alternative method for sites that cannot obtain patient-level antibiotic use data
Adherence to facility-specific antibiotic treatment guidelines	Requires robust system for data capture
ASP intervention acceptance rate	Requires robust system for data capture
Outcome metrics	
Clostridioides difficile infection (CDI)	Required reporting of hospital-onset CDI (HO-CDI) to NHSN; partner with infection prevention team to track transplant unit HO-CDI rates. Limitations: HO-CDI rates influenced by multiple factors including infection control and diagnostic testing practices
Antibiotic resistance	Resistance trends can be tracked through transplant-specific antibiograms
Antimicrobial costs	Use prescription and administration rather than purchasing data and report as cost per patient day
Adverse drug events/toxicities	Limited by feasibility of event capture
Readmission related to infections	Limited by feasibility of event capture

Key Points

- Antimicrobial stewardship is an essential component of transplant programs to improve patient outcomes and reduce the threat of antimicrobial resistance and the risks of drug toxicity.
- A multidisciplinary approach including physicians, mid-level providers, nurses, and pharmacists that leverages the existing team-based structure of transplant programs is important for successful implementation of antimicrobial stewardship strategies.
- Antimicrobial stewardship strategies and interventions applicable to SOT and HSCT recipients include formulary management, pre-prescription authorization, post-prescriptive review, antimicrobial agent selection, antibiotic allergy assessment, dose optimization, IV-to-oral conversion, clinical pathways and guideline development, and diagnostic test stewardship.
- A variety of opportunities exist in antibiotic, antiviral, and antifungal stewardship targeting specific drugs commonly used among transplant patients and infectious disease syndromes frequently encountered by transplant patients.
- Antimicrobial stewardship programs should partner with key stakeholders in transplant services to capture and report relevant process and outcome metrics and to identify opportunities for improvement.

Introduction

Emerging multidrug-resistant bacterial, viral, and fungal infections are a common cause of morbidity and mortality after solid organ transplantation (SOT) and hematopoietic cell transplantation (HCT) worldwide. With limited antimicrobial options to combat these pathogens, prevention of infection is critical for optimal patient and graft outcomes. Antimicrobial prophylaxis (AP) is routinely used to prevent infections in SOT and HCT recipients. In the current era of emerging resistant infections the efficacy of prophylactic regimens may be diminished in these patients and thoughtful, personalized approaches are warranted. Conceptually, AP used to prevent infection should aim to be efficacious while minimizing toxicities, cost, and

Table 1 Risk factors for early posttransplant infections

Intraoperative infection risk factors	Donor and recipient pretransplant risk factors	Early posttransplant infection risk factors
Prolonged surgery or substantial transfusion requirement Choice of surgical technique (roux-en-Y biliary anastomosis for liver transplantation) Technical problems affecting the transplant's functional integrity and vascular supply (lung: Bronchial anastomotic leaks; liver: Hepatic artery thrombosis; pancreas: Duodenal leaks; kidney: Vesicoureteral reflux etc.)	Chronic malnutrition Colonization: MDR-bacteria or yeasts (ESBL, CRAB, MRSA, CRE, drug-resistant *Candida*) Filamentous fungi (*Aspergillus*, Mucor) Endemic fungi (*Histoplasma, Coccidioides*) Latent infections: *Mycobacterium tuberculosis, M. avium or M. abcessus* Viruses (CMV, VZV, HSV, EBV, HIV, HHV8) *Toxoplasma gondii, Strongyloides stercoralis, Trypanosoma cruzii*	Prolonged mechanical ventilation Protracted use of indwelling devices (central line catheters, abdominal or chest drains, ureteral catheters) Persistent hematomas or leaks (biliary, urinary, bronchial) Prolonged renal replacement therapies (hemodialysis) Repeated open surgery Prolonged exposure to broad-spectrum antibiotics Nosocomial exposure (respiratory viruses, filamentous fungi, drug resistance bacteria)

antimicrobial resistance using the lowest effective dose for the shortest acceptable duration. In the following sections, antimicrobial prophylactic strategies will be reviewed in the context of emerging antimicrobial resistance.

There are many factors that impact a patient's individual risk of infection, and thereby alter the indications of a prophylactic strategy. Some of these reasons are summarized in Table 1.

Perioperative Antibacterial Prophylaxis in Solid Organ Transplantation

Incidence of surgical site infections (SSI) range widely in SOT recipients, from 3 to 53%, and vary by the organ transplanted. By nature of organ-specific surgical differences, causative pathogens also vary, although reporting bias often leads to more frequent descriptions of infections with multidrug-resistant organisms (MDROs) [1]. Greater antimicrobial use prior to SOT has been associated with MDRO infection post-transplant [2]. Surgical antibacterial prophylaxis (SAP), used to prevent SSI, is standard of care for solid organ transplant operations. During the operative procedure, antibacterials minimize the burden of bacteria in the surgical site environment to decrease infections and promote healing [1]. World Health Organization guidelines suggest SAP should be administered within 120 min before the incision and re-dosed throughout based on the agent's half-life and procedure duration [3]. There is limited and low quality evidence to inform the

Table 2 Suggested peri-transplant antibacterial prophylaxis for prevention of early posttransplant infections

Transplant	Antibiotics for 24–72 h posttransplant[a] (duration as short as possible)
Kidney	Cefuroxime or cefazolin
Liver	Cefuroxime, ampicillin-sulbactam or piperacillin-tazobactam
Pancreas	Piperacillin-tazobactam, or ampicillin-sulbactam for 5–7 days
Heart	Cefuroxime or cefazolin
Lung	Cefuroxime or cefepime Tailor to recipient/donor bronchial cultures after transplant
Intestinal	Piperacillin-tazobactam or cefepime + metronidazole, variable duration

[a]Should be tailored to reflect local epidemiology and antibiogram, as well as culture results from recipient before and after transplant

recommendation for optimal pre-incision SAP timing. Historical studies and guidance have, somewhat arbitrarily, recommended dosing 30–60 min prior to incision. However, a recent systemic review and meta-analysis found no significant difference between the 120–60 min dosing when compared to the 60–0 dosing [4]. The shortest effective duration should be used to minimize toxicities of antibacterials. For an example of a solid-organ transplant SAP regimen, refer to Table 2. Though national and international guidelines recommend stopping SAP at closure of surgical incision, transplant-specific evidence and guidance is limited leading to significant variation in duration across centers. A recent single-center, randomized controlled pilot study found no significant differences in liver transplant SSI rates when SAP limited to intra-operative dosing was compared to SAP extended to 72 h [5]. SAP agent choice also varies between institutions and should be based on local epidemiology while considering patient-specific microbiological factors such as recipient and donor colonization. As MDROs are more frequently implicated in SSIs, antibacterial agents targeting these pathogens may be more frequently used. MDRO colonization has been associated with post-transplant infection though differences in site of colonization and organ transplanted are important [1]. For example, lung transplants are more significantly impacted by changes in respiratory flora, renal transplant by urogenital organisms, and liver transplant by biliary pathogens. Evidence to assess the impact of altering SAP to account for MDROs with which recipients are colonized is lacking. However, attempts to target colonizing MDROs with SAP are common practice in many centers. Adjunctive strategies to eradicate MDRO colonization and restore gut microbial diversity through gut decontamination and fecal microbiota transplantation are being explored in certain centers through research protocols, but at this time they are of uncertain benefit and their utility in routine, transplant care has not yet been established [6]. Transmission of MDROs from donors to recipients has been described and antimicrobials targeted to these organisms have prevented recipient infection [7]. In these situations, communication between organ procurement organizations and accepting transplant centers is critical to establish the optimal perioperative treatment regimen. Transplanting organs from donors with MDR Gram-negative organisms in special circumstances may become more feasible as new agents targeting MDR Gram-negative

organisms are developed. Current guidelines recommend 7–14 days of antimicrobial therapy for recipients of organs from infected donor [7].

Antibiotic Prophylaxis After Transplantation

In the post-transplant setting, trimethoprim-sulfamethoxazole (TMP-SMX) is the most commonly used prophylactic antibacterial agent. It is the first-line option for *Pneumocystis jiroveci* prevention and may also help to prevent other opportunistic infections with *Listeria, Toxoplasma gondii, Legionella, Nocardia,* and certain gastrointestinal pathogens. After SOT and allogeneic (allo-) HCT TMP-SMX is continued for at least 6 months and may be extended in patients requiring longer or intensified immunosuppression (e.g., treatment for graft vs. host disease (GVHD)) or immunomodulatory co-infections such as CMV and EBV. Given the importance of TMP-SMX prophylaxis, patients with reported sulfa allergies and other intolerances should be evaluated for a rechallenge after transplant, or pretransplant, if time permits, through an infectious disease, or allergy consultation. In a recent single-center, retrospective study a rechallenge protocol was safe and successful [8]. Resistance mutations in *P. jiroveci* dihydropteroate synthase (DHPS), an enzyme involved in folate metabolism, have been described and result from long-term TMP-SMX exposure in HIV settings. However, these mutations seem to have limited clinical importance in relation to treatment failure and transplant-specific data are inadequate [9]. TMP-SMX resistant *Nocardia* isolates have been described in both SOT and HCT though reported rates vary widely by geography and species [10]. Though *Nocardia* infections may occur while patients are receiving TMP-SMX prophylaxis, other clinical factors contributing to net-state of immunosuppression likely play a role. In kidney transplant (KT) recipients TMP-SMX also reduces the occurrence of urinary tract infections (UTI) though emerging resistance in certain institutions and regions may limit its efficacy [11]. Additional antibacterials added during ureteral stent removal after KT have not been found to be efficacious and should be avoided [12]. Other antibacterials such as fluoroquinolones have been used as UTI primary prophylaxis in KT recipients though with rising rates of fluoroquinolone resistance and a growing list of associated toxicities this drug class is not recommended for prevention [11].

After HCT, antibacterial regimes depend on agent toxicities, and begin around the time of administration of the conditioning regimen, after stem cell infusion, or at the time of engraftment. Antibacterial prophylaxis is not typically given to autologous HCT recipients as these patients engraft more quickly and have less-severe mucositis. Fluoroquinolones are most commonly used to prevent neutropenic fever in high-risk patients given their activity against Gram-negative bacilli such as *Pseudomonas aeruginosa* and Enterobacteriaceae as well as viridans group streptococcus. In randomized trials, antibacterial prophylaxis has been associated with less Gram-negative infections with no significant reduction in mortality. Meta-analyses have reported mixed effects on all-cause mortality [13]. The increasingly worrisome side effect profile of the fluoroquinolones and associated consequences of their use

including emerging MDR infectious complications, *Clostridioides difficile* infection, and gastrointestinal dysbiosis demand a close evaluation of these drugs for routine prophylaxis. Additionally, worldwide rates of fluoroquinolone resistance continue to rise and may limit efficacy of prophylaxis particularly when local *Escherichia coli* resistance rates are greater than 20% [14–16]. Antibacterial prophylaxis is typically continued until engraftment. Patients with chronic graft-versus-host disease actively receiving immunosuppression remain at risk for encapsulated bacteria. Antibacterial prophylaxis against *Streptococcus pneumoniae* is recommended and may extend into the post-engraftment period [16]. In regions with growing rates of penicillin and fluoroquinolone resistant *S. pneumoniae*, alternative drug choices must be considered. Further studies are needed to better define personalized risk and evaluate other antibacterial classes to employ as prophylactic agents in required settings. Recently, cefpodoxime was evaluated as an alternative to fluoroquinolone prophylaxis and was associated with similar rates of neutropenic fever and AP failure [17].

Antifungal Prophylaxis After Transplantation

In non-lung SOT, *Candida* is the most common fungal organism responsible for invasive infection [18]. Infections with azole-resistant, non-*albicans Candida* species, particularly *C. glabrata,* are an emerging threat. Many countries have also witnessed a concerning rise in drug-resistant *C. auris* infections transmitted in hospital settings. Though universal prophylaxis for *Candida* is common after small-bowel transplantation, a targeted strategy is recommended for other abdominal and thoracic organ recipients [19]. For a suggested antifungal prophylaxis pathway, refer to Table 3. Echinocandins, azoles, and formulations of amphotericin B have been studied and have demonstrated successful reductions in invasive *Candida* infections. Though fluconazole is commonly recommended as a first-line prophylactic agent, hospital epidemiology, patient risk factors, and colonization should be used to create a personalized strategy, employing alternative broad-spectrum agents as needed to prevent post-operative infections with resistant species. Isavuconazole, a newer, broad-spectrum, triazole approved for the treatment of invasive aspergillosis (IA) and mucormycosis, is a promising prophylactic agent for emerging fungal infections. However, limited data exists for prophylactic use and its role for *Candida* prophylaxis after SOT is unclear. Though isavuconazole was inferior to caspofungin when used as treatment for invasive candidiasis [20], a recent single-center, retrospective study found no increase in *Candida* or other yeast infections using isavuconazole prophylaxis in lung transplant recipients [21].

Similarly, *Candida* prophylaxis during the pre-engraftment period after myeloablative, allogeneic HCT reduces *Candida* infections, and universal prophylaxis is recommended [22]. Though fluconazole is the currently recommended prophylactic agent of choice, other broader spectrum tri-azoles, echinocandins, and polyenes have been studied [23]. Breakthrough infections with azole-resistant *Candida* species have been described, and in combination with the risk of invasive molds

Table 3 Fungal infection prevention peri-transplant

Transplant	Fungus	Risk factors	Prophylaxis	Suggested duration[a]
Kidney	*Pneumocystis* *Candida*	All patients Candiduria	TMP-SMX[a] Fluconazole	6 months 7–14 days
Pancreas/ intestine	*Pneumocystis* *Candida*	All patients All patients	TMP-SMX Fluconazole, echinocandin	6 months 2–4 weeks
Liver	*Pneumocystis* *Candida*	High meld score (>30), ATG, CMV disease, second transplant Based on combinations of risk factors: Protracted antibiotics >5 days, yeast colonization >3 body sites, ICU >5 days, posttransplant hemodialysis, retransplantation or need for second surgery, choledocojejunostomy, high transfusion requirement, and pancreatitis	TMP-SMX Echinocandin or fluconazole	6 months 2 weeks
Lung	*Pneumocystis* *Candida* *Aspergillus*	All patients None All patients or according to risk factors: Proven colonization, high-doses steroids, retransplantation, acute rejection, CMV infection	TMP-SMX Aerosolized amphotericin B, voriconazole	Lifelong 4–6 weeks, lifelong
Heart	*Pneumocystis* *Candida*	All patients None	TMP-SMX	12 months versus lifelong (depending on toxoplasma status)

[a]TMP-SMX is preferred agent. Atovaquone is preferred alternative for patients who are also at risk of toxoplasmosis. Dapsone and Pentamidine are alternative options

may necessitate echinocandin or extended spectrum azole prophylactic strategies in many centers.

Aspergillus fumigatus is the most commonly identified etiology of IA after SOT. Though uncommonly reported in the United States, other countries are observing increasing rates of azole-resistant *A. fumigatus* which have been associated with high mortality [24]. While risk of IA after SOT varies by transplanted organ, prophylactic strategies after liver and lung transplantation have been most studied. Universal prophylaxis with a mold-active agent is not recommended after liver transplantation

and an approach targeted to risk factors for IA is favored [25]. In certain studies, triazoles and echinocandins have successfully prevented IA but breakthrough *Aspergillus* infections have been occasionally reported [25]. Though many centers employ universal prophylactic strategies after lung transplantation, preemptive therapy has also been shown to be successful and is an acceptable approach [25]. Triazoles such as itraconazole and voriconazole are common prophylactic agents used after lung transplantation and have demonstrated reductions in IA. A recent single-center evaluation of experience with aerosolized amphotericin B lipid complex with and without micafungin during transplant hospitalization found the prevalence rate of invasive candidiasis and non-*Candida* invasive fungal infections was 11.4% and 8.8%, respectively [26]. Although isavuconazole primary prophylaxis has not been well studied nor should be considered standard of care, a recent single center report found it safe and effective for the prevention of mold infections in lung transplant recipients and found no increase in candida or other yeast infections [21].

Aspergillus accounts for a majority of invasive mold infections after HCT. While fluconazole is recommended as first-line prophylaxis, its lack of *Aspergillus* activity has led some centers to employ mold-active azoles for primary prophylaxis, particularly for patients transplanted for acute myelogenous leukemia or patients who received haploidentical, or umbilical cord blood grafts. Voriconazole and posaconazole are most commonly used and micafungin and itraconazole may be considered as alternatives. Isavuconazole has been studied as treatment for invasive molds in HCT recipients. Though it is a promising agent to prevent emerging fungal infections after HCT, studies for this use are limited. A recent single-center, retrospective study evaluating isavuconazole primary prophylaxis for HCT recipients and patients with hematologic malignancies observed an increased rate of breakthrough invasive mold infections [27]. Conversely, in a similar, single-center, open-label trial of isavuconazole primary prophylaxis after HCT, 3.1% of patients experienced breakthrough candidemia and no patients developed mold infections [28]. Finally for patients with GVHD, posaconazole has been shown to prevent IA and reduce fungal related deaths when used as prophylaxis [16]. In patients with prior invasive fungal infections, secondary prophylaxis should be strongly considered particularly during periods of prolonged neutropenia or intensified immunosuppression. Uncommon fungal infections may also emerge while on triazole prophylaxis after HCT, leaving limited options for treatment or secondary prophylaxis [29].

Coccidiomycoses after SOT and HCT can cause significant morbidity and mortality. SOT recipients transplanted in *Coccidioides*-endemic regions should receive primary azole prophylaxis post-transplant. SOT deceased donors, especially pulmonary, who spent significant time living in the southeast of the United States, should also trigger posttransplant prophylaxis in their recipients. Living donors, where transplant timing is more flexible, should be clinically and serologically screened for *Coccidioides* risk, and prophylaxis strategy determined accordingly. Similarly, transplant candidates should be assessed for prior travel to or residence in endemic regions and screened with chest imaging and serologic testing to help guide posttransplant prophylaxis strategies. Additionally, given the significant risk of coccidiomycoses relapse following primary infection in SOT, lifelong azole secondary prophylaxis

should be considered [30]. Though fluconazole is most commonly used, other triazoles are active against *Coccidiodes* and have been used successfully for treatment [31]. However, limited prophylaxis data has been reported for alternative azoles.

Primary prophylaxis for histoplasmosis and blastomycosis is not recommended. In patients who have recently recovered from histoplasmosis or blastomycosis, secondary prophylaxis with antigen monitoring may be considered during periods of intense immunosuppression [30]. For example, even lung recipients can be managed by following serial urinary histoplasma antigens rather than embarking on protracted antifungal prophylaxis. Recommendations for prophylaxis of endemic mycoses after HCT are lacking. Similar nuanced strategies using epidemiologic risk and serologic screening should be considered. Further, while azole prophylaxis is more common after HCT, personalized, secondary prophylaxis should be considered during periods of prolonged neutropenia and during GVHD therapy.

Mycobacterial Prophylaxis After Transplantation

Drug-resistant *Mycobacterium tuberculosis* (TB) has been increasingly described throughout the world and has been reported in transplant recipients [32]. Transplant recipients who have been in contact with persons known to be infected with drug-resistant TB should receive prophylaxis. Though fluoroquinolones are not recommended as first line agents for latent tuberculosis infection (LTBI) due to limited efficacy data and their many toxicities, they have been used for prevention of MDR TB and may be considered if concern for resistance exists [33]. Optimally, LTBI therapy should be initiated and completed before SOT or HCT. If prophylaxis is used in the posttransplant setting, careful attention is needed to avoid drug-drug interactions of rifamycins with HCT conditioning regimens and GVHD prophylaxis as well as SOT maintenance immunosuppression. Other emerging, difficult-to-treat, non-tuberculous mycobacterial (NTM) infections often complicate pre- and post-lung transplant care. Specifically, pretransplant identification of *Mycobacterium abscessus* presents a significant challenge to lung transplant candidacy. Decisions to move forward with lung transplantation in such patients infected or colonized with this organism, though not absolutely contraindicated, should be diligently individualized. A recent single center experience reported optimal outcomes when nuanced, tolerable, and effective antimicrobials were used to treat and clear AFB smears and cultures pretransplant and extended into the posttransplant setting [34, 35].

Influenza Prophylaxis After Transplantation

Data does support post-exposure prophylaxis against influenza in high-risk patients [36]. Historically, neuraminidase inhibitor resistance rates for influenza have varied seasonally but have been relatively low in pandemic and post-pandemic virus. Antiviral resistance is more common in HCT and SOT recipients and is associated with prolonged viral shedding in the setting of immunosuppression and oseltamivir exposure [37]. Nosocomial clusters of resistant influenza A and B have been

described. Transplant recipients who are exposed to close household contacts or involved in a nosocomial outbreak should receive post-exposure antiviral prophylaxis. If concern for antiviral resistance exists in seasonal virus or in a healthcare setting, post-exposure prophylaxis with an oseltamivir alternative should be considered. The H275Y mutation, most frequently responsible for oseltamivir resistance, does not reduce zanamivir activity. Inhaled zanamivir should be used as first-line post-exposure prophylaxis if exposure to oseltamivir-resistant virus is suspected. Baloxavir marboxil, a novel inhibitor of cap-dependent endonuclease, may also have a role in post-exposure prophylaxis though no data for this indication exists and studies of this agent in SOT and HCT are lacking. Pre-exposure prophylaxis in high-risk patients, for example, lung transplant recipients in the winter, has not been studied in formal settings, and is generally not recommended.

Herpes Simplex Virus and Varicella Zoster Virus Prophylaxis After Transplantation

Since the advent of HCT and SOT herpesvirus infections have been a common cause of post-transplant infectious complications. For suggested prophylactic details of antiviral prophylaxis, in SOT, refer to Table 4. However, significant advances in antiviral therapy and testing have drastically decreased their associated morbidity and mortality. Acyclovir (ACV) and valacyclovir (vACV) are active against herpes simplex virus (HSV) type-1 and 2 and may be used for HSV prophylaxis. These agents also have minor activity against cytomegalovirus (CMV) though are not recommended first line for prophylaxis and should not be used for treatment. Historically acyclovir and valacyclovir resistant HSV has been reported in 2.5% of SOT recipients [38]. Rates are higher in HCT recipients ranging from 4% to over 30% [39]. ACV and vACV prophylaxis are recommended and routinely used in the first 30 days following allo-HCT and may be extended if reactivations are recurrent or during periods of intensified immunosuppression. Additionally, given the activity against VZV, antiviral prophylaxis can be given routinely for 1 year to VZV seropositive recipients. HSV resistance to ACV is most frequently mediated by mutations in the *viral thymidine kinase* gene conferring cross-resistance to other oral herpes-active agents. Treatment of drug-resistant HSV typically includes alternative agents such as intravenous foscarnet or topical cidofovir for cutaneous recurrences. Given these agents have substantial toxicities they are not recommended for prophylactic use [16]. Brincidofovir has in vitro activity against HSV though there is no data to support its use for posttransplant prophylaxis. Maribavir and Letermovir, CMV-active agents, do not have activity against other herpesviruses such as HSV and VZV.

Cytomegalovirus Prophylaxis After Transplantation

Cytomegalovirus (CMV) remains a common infectious complication after SOT and allo-HCT. Risk is largely dictated by donor and recipient serostatus and remains an independent risk factor for negative outcomes. The highest risk serostatus pairing in

Table 4 Human herpesvirus prophylaxis after kidney, pancreas, liver, or heart transplant

Induction agent	Donor CMV	Recipient CMV	Prophylaxis
Basiliximab or steroids	**Positive**	**Negative**	**Valganciclovir 3-6 m**
	Positive	**Positive**	
	Negative	**Positive**	
	Negative	**Negative**	Acyclovir, famciclovir, or valacyclovir 3–6 m
Anti-thymocyte globulin or alemtuzumab induction	**Positive**	**Negative**	**Valganciclovir 6 m**
	Positive	**Positive**	
	Negative	**Positive**	
	Negative	**Negative**	Acyclovir, famciclovir, or valacyclovir 6 m

Comments on viral prophylaxis:

•Dosages of all antiviral agents need to be adjusted for renal function. The eGFR or creatinine clearance should be used (not simply the serum creatinine).

•For prophylaxis, the first doses may be intravenous ganciclovir or oral valganciclovir, converting intravenous to oral once patient tolerating oral medications. Data supports the safety and efficacy of either administration for treatment (not prophylaxis, although should be similar) [48, 49].

•"Mini-dosing" not recommended as it increases the risk of resistant/refractory CMV infections.

•Lung transplant prophylaxis would often be similar, with longer courses of prophylaxis more common.

•For centers wishing to take a mixed approach, preemptive monitoring can be done more readily with R+ recipients using Basiliximab or steroid induction.

•Monitoring while on prophylaxis only done if clinically indicated by symptoms; consider weekly monitoring after prophylaxis completed for 8–12 weeks in higher risk patients, those with deep lymphopenia, and those on more potent immunosuppression [50].

SOT and HCT are different: seropositive solid organ donor grafts transplanted into CMV seronegative recipients pose the greatest risk; conversely seronegative HCT donor grafts given to CMV seropositive recipients are more concerning in stem cell transplantation. The incidence of ganciclovir (GCV)-resistant CMV after SOT and HCT is 0%–3% and 0%–4%, respectively, and has been reported up to 14.5% in haploidentical-HCT recipients [40, 41]. Risk factors for resistant CMV infection include prolonged anti-CMV drug exposure with inadequate dosing, high-degree immunosuppression, and donor/recipient serostatus mismatch. Though preemptive therapy and antiviral prophylaxis prevention strategies have been studied, prophylaxis with valganciclovir (vGCV) is most commonly employed after SOT while preemptive therapy is favored after HCT given concerns for vGCV/GCV-induced marrow toxicity (Table 4). Recently, other antiviral agents have been studied for CMV prevention. Letermovir, a novel inhibitor of the viral terminase complex (encoded by *UL56*) has recently been approved by the United States Food and Drug Administration for CMV prophylaxis in the first 100 days after allo-HCT for seropositive recipients. In a multicenter phase III trial, patients who received letermovir prophylaxis through week 14 after HCT developed less CMV infection and had lower all-cause mortality at week 24 [42]. Though letermovir appears to have less myelosuppressive effects, it has a low barrier to resistance which may limit

its use to prophylaxis. A phase III trial evaluating letermovir prophylaxis for CMV prevention after kidney transplantation is ongoing. Letermovir has a distinctly different viral target than DNA polymerase inhibitors GCV and vGCV making it an attractive option for CMV secondary prophylaxis in patients with GCV/vGCV resistant virus. Published experience with letermovir secondary prophylaxis in SOT and HCT is limited to case reports at this time, and cannot be routinely recommended. Investigational agents, brincidofovir, a lipid conjugate of cidofovir, and maribavir, a DNA synthesis inhibitor, may also retain activity against resistant CMV. Maribavir has not demonstrated benefit when used for primary CMV prophylaxis after liver transplantation and after engraftment in HCT [43]. Neither drug is currently available outside trials or compassionate access pathways. Similarly, a recent placebo-controlled phase III trial of brincidofovir primary prophylaxis found similar rates of CMV when compared to placebo with more serious adverse events noted in the patients given brincidfovir [43]. No data exists for secondary prophylaxis using these agents. Though antiviral prophylaxis is favored at many solid organ transplant centers a recent randomized controlled trial found incidence of CMV disease was significantly lower at 1 year in patients undergoing preemptive therapy when compared to antiviral prophylaxis. Patients who received antiviral prophylaxis were also found to have less CMV-specific neutralizing antibody and T-cell responses compared to those patients who received preemptive therapy [44]. The exact role of CMV-specific immune monitoring strategies used to dictate preemptive therapy or prophylaxis has not yet been established and more studies are needed.

BK Polyomavirus Prophylaxis After Transplantation

BK polyomavirus reactivation leading to viruria and DNAemia is common after transplant. Though patients may be asymptomatic, BK polyomavirus may cause polyomavirus-associated nephropathy after kidney transplantation and hemorrhagic cystitis after allo-HCT. Other organ recipients are rarely clinically impacted. The key element of treatment and prevention for BK is reduction of immunosuppression. Fluoroquinolones can inhibit BK polyomavirus replication in vitro and have been studied to prevent BK replication and subsequent disease. Randomized trials have found no benefit of fluoroquinolones used for prophylaxis or treatment of BK. The most recently published trial found ciprofloxacin was not only ineffective at preventing BK DNAemia but also associated with an increased risk of fluoroquinolone-resistant infections [45]. Brincidofovir has also been evaluated in complex BK, but generally not accepted as a viable option at this time.

Parasitic Prophylaxis in Transplantation

Globally, changing environmental and patient demographic variables will likely impact the epidemiology of infections seen in the posttransplant setting. *Strongyloides stercoralils,* a parasite endemic to the tropics and subtropics, has

Table 5 Suggested duration of toxoplasmosis prophylaxis after heart transplant (based on Serologic Combinations)

Serologic combination	Risk group	Treatment and Dosing	Duration of therapy
Donor seropositive/ recipient seronegative	Highest risk	TMP-SMX DS[a] (some centers use SS) every day (if DS dose reduce to Bactrim SS q day if GFR < 30) $\times$ 12 months then TMP-SMX SS every day (no need for dose reduction with renal insufficiency even ESRD/dialysis).[b]	Lifetime, if possible
Recipient seropositive (donor either serostatus)	Moderate risk	TMP-SMX SS[a] every day (no need for dose reduction with renal insufficiency even ESRD/dialysis)	Can stop at 1 year after transplant, or when on low-dose immunosuppression whichever is *later/longer* Restart if intensification of immunosuppression for same period as after transplant.
Donor seronegative/ recipient seronegative	Lowest risk	Same as for recipient seropositive for Pneumocystis and other prevention, although not needed for toxoplasmosis	

[a]Trimethoprim-sulfamethoxazole (TMP-SMX) SS (single strength) is sulfamethoxazole 400 mg and trimethoprim 80 mg, while TMP-SMX DS (double strength) is 200% that dose
[b]If true TMP-SMX allergy documented, second-line prophylaxis would be dapsone 100 mg a day or atovaquone 1500 mg a day. With dapsone, methemoglobinemia or breakthrough toxoplasmosis infection could occur, and G6PD should be checked prior to starting treatment (to avoid hemolysis if G6PD deficient)

also been described in the southeastern United States. De novo infection, reactivation of chronic, latent infection, and donor-derived infection have all been described in SOT and HCT recipients and can be associated with significant morbidity and mortality [46]. Though transplant center and organ procurement organization practice is variable, screening deceased and living donors as well as transplant candidates with epidemiological risk factors is recommended [46]. Because cases have been seen with recipients of all organs, prophylaxis is recommended for recipients of all organs coming from seropositive donors (refer to Table 5).

Oral ivermectin is the treatment of choice for seropositive candidates, ideally before transplant. Additionally, treating recipients of donors who have tested positive for *Strongyloides* with oral ivermectin can minimize the risk of donor-derived infection [46].

Infections caused by *Trypanosoma cruzi*, the protozoan parasite causing Chagas disease, most commonly occurs in Latin America and has been reported in the United States in areas with large Latin American communities [47]. *T. cruzi* is primarily transmitted by the reduviid bug resulting in de novo infection though may be transmitted through transplantation or present as reactivation in transplant recipients in the setting of immunosuppression. Prevention relies on screening transplant donors and candidates. In the posttransplant setting, preemptive parasitological and PCR testing are recommended to allow for treatment in patients who develop evidence of *T. cruzi* reactivation or transmission [47]. Though benznidazole

and nifurtimox, antitrypanosomal agents used to treat T. *cruzi,* have been used for prophylaxis, their associated toxicities make preemptive therapy the strategy of choice. In the United States, posttransplant prospective monitoring strategies should be coordinated with the Centers for Disease Control and Prevention, and when early preclinical parasitemia is detected, therapy can be started, rather than using any drug prophylactically.

The parasite *Toxoplasma gondii* can also be a significant clinical issue post-transplant; it most commonly presents in mismatched heart transplants, where transfer within the donor cardiac muscle is possible. Approximately 10% of the North American population is seropositive to *T. gondii*, leaving a substantial portion of the community at risk. Other solid organ transplants and HCT recipients appear to be at lower, but not zero risk. Trimethoprim-sulfamethoxazole (TMP-SMX) is the preferred agent for high-risk prophylaxis in heart transplants. For patients who are sulfa intolerant atovaquone 1500 mg daily can be used. Both these agents are effective for joint prophylaxis against *Pneumocystis jiroveci*, unlike dapsone or pentamidine which have no meaningful protection against toxoplasmosis (Table 5).

Conclusion

Infections complicate the care of patients after transplant, and antimicrobial prophylaxis has long been a cornerstone of infection prevention in this setting. However, as emerging, multidrug-resistant infections become more common, routine prophylactic regimens may have less efficacy. Thoughtful antimicrobial prophylaxis strategies are needed to protect patients from these pathogens as well as antimicrobial toxicities. Future research should focus on personalized approaches to prophylaxis to optimize targeted antimicrobials and durations, while evaluating the role of newer antimicrobials for prophylaxis.

Key Points

- Antimicrobial agents commonly used post-transplant may have limited efficacy in the era of emerging, multidrug-resistant infections.
- Antimicrobial prophylaxis should aim to be efficacious while minimizing toxicities, cost, and antimicrobial resistance using the lowest effective dose for the shortest acceptable duration.
- Intraoperative, donor/recipient, and early post-transplant factors should be used to guide personalized prophylaxis strategies.
- Surgical antimicrobial prophylaxis to prevent surgical site infection should consider prior recipient MDRO colonization and may need to be extended post-transplant if targeting donor organisms.
- Trimethoprim-sulfamethoxazole remains the linchpin of prophylaxis after SOT and HCT preventing a broad range of opportunistic infections.

- With rising rates of fluoroquinolone resistance and the worrisome side effect profile of this drug class, their use should be minimized when possible.
- Studies evaluating alternative approaches to prevent infection after cancer chemotherapy-related neutropenia are needed.
- More data are needed to understand the prophylactic role of newer antiviral and antifungal agents in the setting of emerging resistance.

Introduction

Hematopoietic stem cell and solid organ transplantation is increasing throughout the world. With this increasing incidence of transplantation, the age and medical complexity of transplant candidates continue to increase. With this increased medical complexity comes increased social complexity, with immigration and global travel potentially increasing risk of acquiring infectious diseases. Transplant candidates or recipients may reside in or have migrated between geographic regions where different organisms are endemic. Further, the geographic distribution of pathogens can change over time. Pretransplant screening can identify infections that may disqualify the recipient as well as treat active or latent infections prior to undergoing transplantation (Tables 1 and 2). Also, recognizing potential risk factors can guide use of prophylactic treatment in the recipient, decreasing the risk of infection.

Approaches to pretransplant screening of infectious diseases as well as management of positive screening studies vary across transplant centers. A thorough medical history, including place of residence, travel history, occupation, exposure to animals and pets, hobbies, sexual practices, recreational drug use, and prior infections should be obtained from the transplant candidates [1]. The pretransplant period is an optimal time for providers to counsel candidates on vaccines and exposure risks associated with travel, outdoor hobbies, pets, and consumption of unpasteurized and raw foods. Moreover, it is best to initiate or complete treatment for latent infections prior to undergoing transplantation and starting immunosuppression.

Bacterial Infections

Pretransplant infection can influence the risk for post-transplant bacterial infection, especially for patients admitted to the hospital or with history of frequent hospitalizations while awaiting transplantation. It is therefore crucial to review this history including review of positive culture results to estimate post-transplant infection risk and target perioperative prophylaxis and empiric postoperative therapy. Each transplant type demonstrates a specific class of infectious syndromes that are common. For kidney transplant candidates with end-stage renal disease, history of urinary tract infection, or peritonitis associated with peritoneal dialysis, especially with resistant organisms, may be associated with post-transplant infection, including bacteremia [2]. Patients with anatomical issues including need for self-catheterization, bladder augmentation, or urostomy are also at increased risk for urinary tract infection after

Table 1 Pathogens that may infect transplant candidates and recipients with associated risk factors and management approaches

Pathogen	Risk factor	Approach
Bacterial infections		
Gram-positive and gram-negative infections	Indwelling devices, alterations in anatomy	Tailoring of antibiotic prophylaxis
Tuberculosis	Geographic exposure, incarceration	Prophylaxis with INH or rifampin
Nontuberculous mycobacterium	Cystic fibrosis, bronchiectasis	Pretransplant treatment if evidence of active infection, post-transplant treatment
Fungal infections		
Histoplasmosis	Geographic exposure: Mississippi and Ohio River valleys, Asia, and South America	Pretransplant treatment if evidence of active infection
Blastomycosis	Geographic exposure: Canada, US states bordering the Mississippi and Ohio Rivers	Pretransplant treatment if evidence of active infection
Coccidioidomycosis	Geographic exposure: Southwestern US, Mexico	Pretransplant treatment if evidence of active infection, post-transplant prophylaxis
Paracoccidioidomycosis	Geographic exposure: Latin America	Pretransplant treatment if evidence of active infection
Cryptococcosis	Bird exposure, immunosuppression, cirrhosis	Pretransplant treatment, consideration of post-transplant prophylaxis
Aspergillus and other molds	Hematologic malignancy, cystic fibrosis, immunosuppression, environmental exposure	Pretransplant treatment if evidence of active infection, post-transplant prophylaxis
Viral infections		
HIV	Sex, IVDU	Antiviral treatment
Hepatitis B	Sex, IVDU, geographic exposure	Antiviral treatment
Hepatitis C	Sex, IVDU, hemodialysis	Antiviral treatment
HHV-8	Geographic exposure (Africa, Brazil, Mediterranean, Caribbean), MSM	Post-transplant monitoring
West Nile virus	Mosquito exposure	Delay of transplantation until clinical syndrome resolved
Flavivirus (DENV, CHIKV, and ZIKV)	Geographic exposure, mosquito exposure	Delay of transplantation until clinical syndrome resolved
Parasites		
Chagas disease	Geographic exposure (Latin America)	Pretransplant treatment if evidence of active infection, post-transplant monitoring
Schistosomiasis	Geographic exposure (South America, Africa, and Asia)	Pretransplant treatment if evidence of active infection
Strongyloides	Geographic exposure (worldwide)	Pretransplant treatment

(continued)

Table 1 (continued)

Pathogen	Risk factor	Approach
Malaria	Geographic exposure (sub-Saharan Africa, Asia, and Latin America)	Pretransplant treatment if evidence of active infection, post-transplant monitoring
Leishmaniasis	Geographic exposure (Latin America, the Mediterranean, the Middle East, India)	Pretransplant treatment if evidence of active infection, post-transplant monitoring
Toxoplasmosis	Geographic exposure (worldwide)	Post-transplant monitoring

transplantation [3–5]. Liver and multivisceral transplant candidates may have peritonitis and other abdominal infection before transplant as well as associated bacteremias in the setting of prolonged need for intravascular catheterization which may potentially complicate the post-transplant course, especially when surgical complications occur [6–8]. For lung transplant candidates, a common issue is the presence of chronic colonization and recurrent infection with bacteria, especially for patients with cystic fibrosis. These may include *Staphylococcus aureus*, multi-drug resistant (MDR) *Pseudomonas*, *Acinetobacter*, or *Alcaligenes*, as well as mycobacterial infections (see below). These pathogens are frequently carried in the sinus cavities as well, and may subsequently infect the newly transplanted lung or lungs [9]. *Stenotrophomonas* infection was not associated with increased post-transplant mortality in a time-varying analysis in a cohort of patients with cystic fibrosis some of whom underwent lung transplantation; it is possible that negative relationships reported with *Stenotrophomonas* infection are due to association with severity of disease and history of extensive antibiotic use rather than direct pathogenic effect [10]. Other studies have also demonstrated no association with adverse outcomes in patients infected with *Stenotrophomonas* or *Achromobacter* [11].

For heart transplant candidates, a common pretransplant infection complicating transplantation is bacteremia after ventricular assist device (VAD) implantation, which can negatively impact patient survival [12]. However, there are data that VAD explantation can be curative of infection without significant impact on post-transplant course [13, 14], and this approach is suggested in both AST and ISHLT guidelines, albeit with expert infectious diseases input to guide management [15, 16]. Debridement before or during transplantation is useful to prevent infection recurrence and to obtain material for cultures that may guide treatment [15]. Bone involvement at the sternum, however, may not be cured by simple explantation and should prompt a strategy for debridement to ensure control of infection after immunosuppression starts. Review of history of previous infections including urinary tract infection, pneumonia, or blood stream infection is especially important for patients undergoing repeat transplantation or with prolonged hospitalization while awaiting transplantation. Dental evaluation with intervention for potentially problematic areas is ideal if it is medically safe to pursue in transplant candidates. Dental evaluation is

Table 2 Risk factors for post-transplant infection

Risk type	Risk details	Potential pathogens	Approach
Pretransplant immunosuppression	Receipt of prednisone, MMF	Bacteria, fungi	Review of infection history, treatment if active infection
Cystic fibrosis	Bronchiectatic lung leading to pulmonary colonization	MDR organisms, MRSA, NTM, aspergillus	Design of perioperative prophylaxis, treatment if active infection
Sexual history	Multiple sexual partners	STDs including syphilis, HIV, hepatitis	Vaccination, repeat screening while awaiting transplantation
Recreational drug use	IVDU, cannabis smoking or vaping	Intravascular infection, aspergillus and other molds	Review of infection history, treatment if active infection
Pets	Birds (parrots or pigeons), cats, reptiles	Cryptococcus, bartonella, Q fever, salmonella, campylobacter, toxoplasma	Review of infection history, treatment if active infection
Hobbies	Camping, spelunking, motorbiking, fresh water exposure	Cryptococcus, cocccidioides, Histoplasma, mold infection	Screening and prophylaxis if indicated
Food exposure	Unpasteurized dairy products or juices, raw foods	Mycobacterial infection, toxoplasma, norovirus	Review of infection history, treatment if active infection
Occupations			
Construction, landscaping, farming	Exposure to dust and soil	Coccidioides, aspergillus	Screening by serology or antigen testing
Work with animals	Potential for animal-borne infections	Cryptococcus, bartonella, Q fever, salmonella, campylobacter, toxoplasma	Screening if evidence of active infection
Health care worker	Risk for exposure to patients	TB	Screening and prophylaxis if indicated
Geographic exposures			
Mediterranean		HHV-8, HTLV	Screening
Caribbean		HHV-8, HTLV, strongyloides, TB	Screening
Asia		HTLV, TB, strongyloides, schistosoma, malaria	Screening

(continued)

Table 2 (continued)

Risk type	Risk details	Potential pathogens	Approach
Middle East		TB, strongyloides, schistosoma	Screening
Africa		TB, strongyloides, malaria	Screening
Latin America		TB, strongyloides, schistosoma, malaria	Screening
Southwest US/Mexico		Coccidioides	Screening

also important for hematopoietic stem cell transplant (HSCT) candidates where a common source of bacterial infection after immunosuppression is the mouth [17].

For HSCT candidates, history of previous myelosuppressive chemotherapy and accompanying hospitalization can lead to bacterial colonization with resistant organisms, which may cause recurrent infection [18].

MDR organisms are of special importance as the standard perioperative and post-transplant antibiotic regimens may not be sufficient. This is true for extended-spectrum beta-lactamase (ESBL) producing gram-negative infections, but is a particular problem with carbapenem-resistant *Enterobacteriaceae* (CRE). Epidemiologic risk factors for ESBL infection include previous exposure to broad-spectrum antibiotics, stay at a long-term care facility, or ICU stay [19, 20]. Risk factors for CRE are more geographic, with increased rates of colonization and infection in endemic areas, with studies performed in high prevalence areas such as New York City and Pittsburgh in the USA [21, 22]. History or positive testing demonstrating colonization with CRE increases risk for post-transplant infection up to fivefold [23, 24]. Studies of patients colonized with CRE have demonstrated that post-transplant infections are more common, with potential adverse impact on clinical outcomes [25]. However, interventions such as routine screening or attempts at decolonization have not proven to be effective in improving clinical outcomes and are not recommended at this time [26, 27].

Bacterial Pathogens of Special Interest

Burkholderiacepacia complex colonization and infection may be seen in patients with cystic fibrosis, and is associated with death or need for transplantation [28]. Although sometimes viewed as a contraindication to transplantation, ISHLT guidelines state that if sufficiently treated before transplant and if there is reasonable expectation for post-transplant control of infection, patients would be acceptable if transplanted at an experienced center [29]. However, within the species and subspecies of *Burkholderia*, there is data demonstrating that *B. cenocepacia*, genomovar III, is associated with a high risk of poor outcomes including possible mediastinitis and chest wall infections after transplantation, with higher rates of post-transplant infection and death compared with *B. cepacia, multivorans, stabilis,* and other

non-*cenocepacia Burkholderia* species [30–33]. In a meta-analysis, pretransplant colonization with *B. cenocepacia* complex was one of the few variables associated with poor outcomes after transplantation, while *Pseudomonas aeruginosa* colonization was not [34]. In contrast to the non-*cenocepacia* strains described above, *B. gladioli* is a *Burkholderia* species that is rare, but also associated with poor outcomes after transplantation [32]. However, several single-center reports of lung transplant recipients with non-*cenocepacia Burkholderia* demonstrate excellent clinical outcomes [31, 35, 36]. This demonstrates that the speciation and complete identification of *Burkholderia* subspecies is crucial for transplant evaluation, with *B. cenocepacia* (genomovar III) as a relative contraindication though other subspecies of *Burkholderia* are less concerning. However, if new antimicrobial approaches for resistant species emerge, this approach may need to be reevaluated.

Another important bacterial infection with potential negative impact post-transplant is syphilis. For this reason, it is recommended by the AST and UNOS/OPTN that all transplant candidates undergo screening with RPR testing, with treponemal-specific testing for confirmation when positive [1]. Transplant candidates with evidence of positive testing for syphilis should undergo further evaluation for neurologic involvement if indicated. For those with late latent disease without evidence of neurosyphilis, three once weekly treatments of 2.4 million units of benzathine penicillin should be administered prior to transplantation to prevent disease progression when immunosuppression is introduced.

Mycobacterial Infections

Tuberculosis

All transplant candidates should be screened for active and latent tuberculosis (TB). A careful history of prior exposure to tuberculosis should include details about prior tuberculin skin test (TST) and interferon gamma release assay (IGRA) testing results, exposure to individuals with active TB in the household or workplace including healthcare workers, prior residence or travel to areas highly endemic for TB, and history of homelessness or incarceration [37]. Any history of active or latent TB and details regarding length and type of treatment should be obtained and documented.

A TST can be used for screening with a test considered positive if there is $\geq$5 mm of induration at 48–72 h [38]. Experts recommend a second skin test 2 weeks later in patients with negative reactions if feasible, as the TST can convert from being falsely negative to positive due to a "boosting effect" in some with remote *Mycobacterium tuberculosis* (MTB) exposure [37, 39]. A history of Bacillus Calmette–Guerin (BCG) vaccination should not influence the screening for latent TB in transplant candidates. However, interferon gamma release assay (IGRA) testing is preferred to TST in this case as IGRA results will not be impacted by prior receipt of BCG. Furthermore, IGRA testing is reported to be more sensitive than TST in detecting LTBI in transplant candidates with advanced liver disease or end-stage renal disease

[39, 40]. A current negative screening test in patients awaiting organ transplantation does not refute a prior positive test. If TST and IGRA testing is negative or indeterminate, it is recommended that all transplant candidates also undergo screening with a chest X-ray. A chest computed tomography (CT) scan may be warranted in those with epidemiologic risk for latent or asymptomatic active TB to evaluate for granulomatous disease prior to immunosuppression start [41]. This recommendation applies to both solid organ transplant (SOT) and HSCT candidates.

Nontuberculous Mycobacteria

Evidence of colonization or infection with nontuberculous mycobacteria (NTM) can pose a special challenge prior to transplantation, especially for lung transplant candidates. These organisms are found in a wide range of environmental sources including soil, water, and plants, and may cause both colonization and invasive disease, complicating evaluation of positive respiratory cultures in transplant candidates [42–44]. Positive cultures pretransplant are associated with post-transplant positive cultures or clinical disease, even after bilateral lung transplant, suggesting that intraoperative contamination or the presence of lymphatic reservoirs are sources of reinfection [45, 46].

M. abscessus

Although a range of NTM have been associated with pre- and post-transplant infection, it is *M. abscessus* that is associated with the greatest incidence of invasive disease after transplantation including wound infection and pulmonary disease, and therefore isolation of resistant isolates has been considered to be a relative contraindication to transplantation, especially in lung transplant candidates with cystic fibrosis [29, 46, 47]. In a survey of practices in lung transplant centers worldwide, 76% considered *M. abscessus* infection to be a relative contraindication and 19% reported considering it to be in itself a contraindication to transplantation [48]. Reviews from experienced transplant centers demonstrate rates of patient and graft survival post-transplant that are comparable to patients without *M. abscessus* infection, albeit in carefully selected transplant candidates [49–52]. Diagnostic testing is important, including extensive antibiotic susceptibility testing, determination of inducible macrolide resistance, and identification to the subspecies level [46]. Experts generally recommend that patients be treated until asymptomatic and until smear negative and ideally culture negative pretransplant, and for a minimum of 6 weeks after transplantation [46].

Non-*M. abscessus* Non-*M. tuberculosis* Mycobacterial Infections

M. avium complex, *M. kansaii*, and *M. fortuitum*, and other NTM can also cause pretransplant infection that may cause post-transplant disease, especially in lung transplant candidates with cystic fibrosis or bronchiectasis. In a multicenter study of patients with cystic fibrosis, the prevalence of NTM infection was 13%, with

M. avium complex as the most prevalent species (72%) [53]. Many authors suggest that the prevalence of NTM infections are increasing over time [45, 54], which has been suggested as possibly due to global warming, although increased reporting and improved recovery methods are other possible explanations [43]. Leukopenia, immunosuppression, cystic fibrosis, and bronchiectasis are risk factors for development of infection [45, 47], so positive cultures from transplant candidates with these characteristics should be evaluated carefully for possible evidence of invasive disease, especially when accompanied by clinical symptoms of radiographic changes consistent with invasive disease. Geographic patterns of disease have also been identified, with *M. simiae* and *M. abscessus* more common than *M. avium* complex in Israel and presumably elsewhere in the Middle East [55], while in the UK, *M. abscessus* was the most common followed by *M. avium* complex [56], while inTaiwan, Korea, and Japan, *M. avium* complex is the most common isolate [57–60]. In terms of individual behavior, one case-control multicenter study in the USA identified residing in a single family house, the rusty or unclear appearance of tap water, and swimming in indoor pools to be associated with risk for NTM in patients with cystic fibrosis [61, 62]. In addition, prevalence of NTM infection has been shown to vary geographically within the USA, with increased rate of isolation in the southeastern USA and Hawaii, with a significant association with increased vapor pressure, a measure of moisture content of the air [61]. Some experts have recommended increasing the temperature of hot water heaters in homes and avoiding indoor swimming pools to decrease NTM risk.

Fungi

Endemic Fungal Infections

In North America, endemic fungal infections include coccidioidomycosis, blastomycosis, and histoplasmosis, while paracoccidioidomycosis is seen in South America. Endemic mycosis can present atypically and cause disseminated and severe disease in transplant recipients as compared to immunocompetent individuals, which stresses the importance of pretransplant screening [63]. Undergoing transplantation without adequate control of fungal infections increases morbidity and mortality post-transplant. The latest American Society of Transplantation (AST) guidelines recommend that a pretransplant candidate with evidence of invasive fungal infection should be treated until there is clinical, radiographic, and microbiologic resolution [1]. Endemic mycoses maybe difficult to diagnose as infection may be dormant. Therefore, obtaining a thorough history about travel, occupational exposures, pets, and outdoor hobbies/activities is important during the pretransplant screening process.

Histoplasmosis

The incidence of histoplasmosis post-SOT and HSCT is uncommon ($\leq$1%) but infection can cause severe, often disseminated, life-threatening disease [64]. In

transplant recipients, histoplasmosis may result from reactivation of latent infection. There are two subspecies that cause illness in humans – *Histoplasma capsulatum,* which has a global distribution, and *H. capsulatum duboisii*, which is found in Africa [65]. In the USA, histoplasmosis is highly endemic in the Mississippi and Ohio River valleys, namely the "Histo Belt." More than half of the population residing in the Histo Belt are exposed to *H. capsulatum*. *Histoplasma* infection in North America can also be found in patients originally from Asia and South America [66]. Routine pretransplant screening of transplant candidates is currently not recommended even in endemic areas, because of the low incidence of post-transplant histoplasmosis [63]. Incidental findings of calcified pulmonary, hilar, and splenic granuloma in radiographs can be consistent with prior *H. capsulatum* infection but do not warrant post-transplant prophylaxis in patients who are otherwise asymptomatic.

Blastomycosis

The incidence of blastomycosis in transplant recipients is rare in comparison to histoplasmosis and coccidioidomycosis [64, 67]. In North America, blastomycosis is endemic in the states bordering the Mississippi and Ohio Rivers, the Midwestern states, and extending into Kentucky, Arkansas, Tennessee, Louisiana, and the Canadian provinces that border the Great Lakes. It has also been reported in New York and Canada along the St. Lawrence River [68]. The distribution of *Blastomyces* may extend beyond the previously described geographic areas, as reporting of cases is voluntary in most states and is only required in six states. Most patients diagnosed with blastomycosis have a history of exposure to soil, wooded areas, lakes, or rivers, however, the exact natural habitat of *Blastomyces* has been difficult to identify. Routine pretransplant screening for blastomycosis is currently not recommended but should be considered in transplant candidates from endemic areas with lung and skin lesions of unknown etiology [69].

Paracoccidioidomycosis

Paracoccidioidomycosis is endemic to Latin America and typically affects men who work in agriculture [70]. Approximately 80% of cases of paracoccidioidomycosis have been identified in Brazil, particularly in the states of Sao Paulo, Parana, Rio Grande do Sul, Goias, Rio De Janeiro, and Rondonia [71]. Cases have also been identified in Venezuela, Ecuador, Columbia, and Argentina. Routine pretransplant screening is not recommended except in those from endemic areas with pulmonary findings and skin lesions of unclear etiology.

Coccidioidomycosis

Coccidioides spp. exhibit specific areas of geographic endemicity, with *Coccidioides immitis* found in California, especially the California Central Valley or San Joaquin Valley extending to southern California and Mexico, while *Coccidioides posadasii* is present in Arizona, New Mexico, Texas, Mexico, and South America, although the

clinical disease caused by these two organisms is similar [72, 73]. Recent reports of *C. immitis* in Northern California, Washington, and Utah suggest the possibility of spread of the current endemic region [74, 75], possibly related to global warming. Spores are stable in the environment for long periods of time, and when inhaled transform into spherules which replicate and then can disseminate throughout the body [76]. Risk factors for coccidioidomycosis infection include Filipino or African American ancestry, exposure in endemic areas via occupations such as landscaping, fieldwork, or construction, and history of immunocompromise including pregnancy and diabetes mellitus, and there are multiple reports suggesting that this incidence is increasing in both California and Arizona [76–78]. An important aspect of pretransplant evaluation is that infection may be completely asymptomatic, and that although pulmonary manifestations are the most common, the disease can also cause extrapulmonary manifestations including meningitis, osteomyelitis or joint infection, and cutaneous disease [79].

Patients with history of symptomatic infection will often recall subacute presentation with fatigue and cough followed by fever and shortness of breath, leading to hospitalization and improvement in symptoms with initiation of antifungal therapy. Although eosinophilia may be seen during acute presentations of infection, it is generally not seen after treatment of disease and is not useful for patient screening. Pretransplant screening for patients from endemic areas or with history of travel to or through endemic areas should include *Coccidioides* IgM and IgG antibody testing, typically using EIA testing [63]. Positive EIA test results should be investigated further with immunodiffusion (ID) and complement fixation (CF) testing which have higher specificity to confirm the diagnosis [80]. CF is also useful as a surrogate for disease activity, with higher titers associated with increased risk for disseminated disease. The role of *Coccidioides* antigen testing in screening of asymptomatic patients is unknown, although this test has demonstrated excellent sensitivity and specificity in evaluation of patients with CNS disease [81].

Pretransplant evaluation of candidates generally falls into one of three groups: Patients with personal history of coccidioidomycosis, patients with no symptoms or known history who present with positive screening tests, and patients living in an endemic area. For patients with a history of infection, outside records should be obtained as possible to determine the anatomic sites involved as well as the severity of the disease. Length and type of treatment should be documented as possible. Based on the site of disease involvement, radiographic testing should be performed to confirm resolution of disease and establish a baseline prior to transplantation [77]. For example, a patient with a history of pulmonary disease should have repeat noncontrast chest CT performed to evaluate for evidence of active infection. The presence of thick- or thin-walled cavitary lesions are concerning for active infection, or possibly progression with start of immunosuppression [82]. Calcified nodules, in contrast, especially if demonstrated to be stable over time, are less likely to progress. For patients with large lung lesions or other indicators of active disease, it may be reasonable to await transplantation after the start of azole therapy and demonstrated radiographic response.

Patients with positive laboratory testing in the absence of symptoms are often difficult to interpret. Positive EIA testing even in the absence of confirmatory testing by ID or CF should be evaluated carefully, especially if the patient is from an endemic area or has history of possible occupational exposure. Rates of IgM or IgG EIA positivity in asymptomatic patients from endemic areas can range from 1% to 4% [83]. Additional radiographic testing should be performed, starting with noncontrast chest CT to evaluate for presence of large nodules or cavitary lesions with potential for progression, as described above. PET scan should be considered for infection localization in patients with high pretest probability by laboratory testing but negative chest CT given the possibility of bone or joint disease [79]. As above, the decision should then be made as to whether to begin antifungal therapy and possibly delay transplantation if feasible, or to start antifungal prophylaxis at the time of transplantation.

The third group of potential transplant candidates needing evaluation are patients with no history of coccidioidomycosis, and negative serology testing, but with plans for ongoing residence in an endemic area. Blair et al. have recommended 12 months of therapy in this setting for kidney or liver transplant recipients in Arizona, while others have recommended longer courses, especially for lung transplant recipients [77, 84, 85]. The length of optimal prophylaxis therapy is unknown, but the length of prophylaxis should depend on risk for reactivation of coccidioidomycosis, with consideration for indefinite therapy in some cases [63].

Cryptococcosis

Although cryptococcal disease is generally thought of as primarily a post-transplant complication, pretransplant infection can also pose problems, especially in liver transplant candidates with cirrhosis. In a multicenter study conducted through the AST Infectious Diseases Community of Practice, 112 patients with cirrhosis and end-stage liver disease with cryptococcosis awaiting liver transplantation were identified, primarily diagnosed by evidence of cryptococcal fungemia on blood culture rather than cryptococcal serum antigen testing; CNS, pulmonary, and peritoneal disease were described [86]. The 90-day mortality rate was 57%, with over half of deaths attributed to cryptococcal disease. The eight patients who survived to transplantation were not delisted due to infection; all patients survived post-transplant with prolonged antifungal therapy. Therefore, although the high mortality rate should be taken into account in evaluation of pretransplant patients with cryptococcosis, especially disseminated disease, this diagnosis should not be viewed as an absolute contraindication to transplantation with effective antifungal therapy and continuation after transplantation for up to 12 months [86, 87]. The mechanism of vulnerability to infection and specifically peritonitis in patients with cirrhosis may be related to complement deficiency and macrophage impairment in cirrhotic ascites [88], in addition to the general immune dysfunction observed in patients with cirrhosis. Risk factors for fungal peritonitis include severity of liver disease and prolonged hospitalization [89]. In a case control study in Taiwan, HIV, chronic liver disease, and receipt of inhibitors of cell-mediated immunity were all found to significantly increase the risk of cryptococcal infection; however, diabetes mellitus

was not found to be a risk factor [90]. Reported close contact with pigeons did demonstrate an association in the single variable but not the multivariate analysis, possibly because of the low number of cases reporting this exposure.

While *Cryptococcus neoformans* is known to be associated with bird droppings but has no specific geographic association, *Cryptococcus gattii* is endemic to eucalyptus growing and other environmental regions in Australia, parts of Africa, the Mediterranean, India, Southeast Asia, Mexico, and Brazil, and has now extended to British Columbia and the US Pacific Northwest [91, 92]. Outdoor activities that may disturb the soil or involve logging or cutting trees may lead to dispersion of *C. gattii* in the air, increasing risk for fungal exposure [93]. However, given the difficulty of establishing clear risk factors for cryptococcal disease in asymptomatic transplant candidates, routine screening for all patients by cryptococcal serum antigen is not recommended [94]. Optimal management of asymptomatic patients with an isolated serum test positive for *Cryptococcus* is unknown, but antifungal treatment or prophylaxis should be considered [93]. Patients with a history of cryptococcal infection should receive at least several months of antifungal therapy and have no ongoing signs of symptoms of cryptococcal disease, ideally with negative culture results prior to transplant. There is no data supporting ongoing monitoring or surveillance with cryptococcal serum antigen testing after clinical resolution of disease [94]. Identification and adequate treatment is important as there is evidence of reactivation of latent infection after transplantation in seropositive patients, presumably due to release of dormant organisms present within a granuloma, generally with earlier post-transplant presentation of disease [95, 96].

Aspergillus and Other Molds

Although unusual as a pretransplant infection, transplant candidates may demonstrate positive cultures, especially respiratory cultures, for *Aspergillus*. There is some evidence from animal models and clinical experience suggesting that *Aspergillus* and other molds including agents of mucormycosis may reactivate after a period of dormancy without clinical symptoms [96]. Pretransplant colonization with *Aspergillus* has long been described as a risk factor for post-lung transplant invasive pulmonary aspergillosis as well as tracheobronchitis [97, 98]. This is a special problem in patients with cystic fibrosis who are often colonized with fungi pretransplantation at an incidence reported as ranging between 8% and 59%, with the predominant type identified as *Aspergillus* sp., although *Scedosporium* sp. and dematiaceous molds have also been described [97, 99]. Other than cystic fibrosis, lung transplant candidates receiving immunosuppression and patients with extensive environmental exposure are also at risk. For transplant programs performing targeted rather than universal prophylaxis after lung transplantation, the isolation of fungi from respiratory cultures prior to transplantation is important data used to direct azole start at the time of transplantation [100]. However, there is not clear evidence supporting antifungal therapy prior to lung transplantation in patients with positive respiratory cultures without evidence of invasive disease. The literature evaluating

impact of positive pulmonary cultures in patients with cystic fibrosis is inconsistent with some studies showing association with decline in pulmonary function and other studies showing no such association [101]. Therefore, many experts recommend only treating patients with cystic fibrosis who meet a certain criteria for symptomatic bronchitis, including failure of symptoms to respond to antibacterial therapy [102]. One mold with geographic association to exposure is *Penicillium marneffei*, which is endemic to Southeast Asia and Northeast Australia [103].

Isolation of mold in pretransplant candidates can guide post-transplant prophylaxis. HSCT candidates should have their medical records reviewed for a history of mold infection during previous chemotherapy, especially patients with a history of prolonged neutropenia. A history of invasive fungal infection significantly increases infection risk post-HSCT [104, 105]. Patients with a history of mold infection should receive secondary prophylaxis with a mold-active antifungal agent. Noncontrast chest CT should also be considered as a screen for previous fungal infection. A study of pretransplant evaluation found that 22% of HSCT candidates had abnormal findings on chest CT, which were primarily lung infiltrates or nodules [106]. Similarly, a history of deep-seated invasive *Candida* disease should also prompt consideration for extended antifungal prophylaxis.

Parasitic Infections

Parasitic infections often have strong geographic associations, emphasizing the importance of obtaining a complete history of birthplace, places of residence, and travel history (Fig. 1).

Chagas Disease

Chagas disease is endemic in Latin America, where 6–seven million people are infected [107]. Transplant candidates with chronic Chagas disease can reactivate the disease in the context of immunosuppression; the risk is highest in the first year after transplantation and subsequently with intensification of immunosuppression. Pretransplant screening in candidates who have resided in or traveled to endemic areas should include information about prolonged stays, residence in rural areas or thatched huts, or low socioeconomic status [103, 108].

Chronic Chagas disease is defined by having a positive epidemiology and serology, using at least two serological methods [107]. Conventional serological techniques are enzyme-linked immunosorbent assay, indirect immunofluorescence, and indirect hemagglutination. In case of inconclusive serology or discordant results, a third test is required. Inconclusive serologic results can be confirmed by polymerase chain reaction (PCR), which is able to detect low-level parasitemia. This screening recommendation applies to both SOT and HSCT candidates, who are also at risk for *T. cruzi* reactivation after immunosuppression. PCR should not be

Fig. 1 Geographic distribution of major parasitic infections seen in transplant recipients

used as a screening test in chronic patients, however, because its sensitivity ranges between 40% and 95% in the chronic phase due to intermittent parasitemia [107].

Schistosomiasis

Schistosomiasis should be considered in any transplant candidate who has resided or traveled to endemic areas with significant freshwater contact [107]. Geographic areas with schistosomiasis include South America, the Caribbean, Africa, the Middle East, and parts of Asia. Transplant candidates from endemic areas should be screened by serologic testing followed by stool examination for those with positive test results [109]. Patients with evidence of active infection can be treated with a single dose of praziquantel prior to transplantation. Serology assays offer high sensitivity for screening, however, antibodies remain detectable for a long period after infection and serology tests do not differentiate between current and past infections [107, 109].

Strongyloidiasis

Strongyloidiasis is an underdiagnosed disease and is endemic in Latin America, including Brazil, Peru, Venezuela, Argentina, and Ecuador, as well as Africa, Asia, Australia, and other areas with inadequate sanitary conditions [107, 108, 110]. Most infected patients are asymptomatic, however immunocompromised patients are at risk of life-threatening disseminated disease in the setting of immunosuppression. Patients who have emigrated from or lived in an endemic area should be screened by serologic testing. As the infection can last for decades, there is no time limit on how long it has been since exposure [107]. Screening in endemic areas should include evaluation for eosinophilia and at least 1 stool specimen for ova and parasites [103]. In nonendemic settings, serology can be used for screening [108]. Candidates testing positive should receive ivermectin prior to SOT or HSCT [107].

Leishmaniasis

Leishmaniasis is a disease transmitted through the bite of infected sandflies, and is predominantly found in tropical and Mediterranean regions. It is a rare disease among transplant recipients [111]. Manifestations may be cutaneous, mucocutaneous, or visceral. Diagnosis is via serology or parasite testing from affected lesions. Patients with active lesions should be treated, while those with a history of infection should be monitored closely for reactivation after initiation of immunosuppression [111, 112].

Malaria

Malaria should be considered in any transplant candidate who has resided or traveled to malaria-endemic areas, which include the tropical areas of sub-Saharan Africa,

Asia, Oceania, and Latin America [108]. Transplant candidates should be screened by epidemiologic history and laboratory testing and treated if there is evidence of active infection [112]. Due to reported cases of recrudescence after transplantation, infected recipients should be monitored clinically and via laboratory testing, ideally PCR, after transplantation [107].

Toxoplasmosis

Toxoplasmosis is a common parasitic infection worldwide, which can be acquired via ingestion of undercooked meat or unwashed vegetables that have been contaminated with oocysts or through contact with the feces of infected cats. Serologic screening for evidence of previous exposure should be performed in all transplant candidates, especially heart transplant and HSCT candidates [112]. Although reactivation of previous infection may occur after the initiation of immunosuppression, serologic testing is also important to identify seronegative patients who are at increased risk of donor-derived infection after receiving organs from seropositive donors, with the highest risk in heart transplant recipients since the parasite encysts in muscle including cardiac muscle [113]. Primary infection of seronegative individuals is another cause of post-transplant infection. Fortunately, the standard trimethoprim-sulfamethoxazole prophylaxis used for PCP prevention has been shown to be effective in preventing reactivation of toxoplasmosis, even in the highest risk situation, donor positive and recipient negative heart transplantation [114, 115]. Reactivation of toxoplasmosis has also been described after HSCT, so antibody testing is useful for patient risk stratification in HSCT candidates [116]. Seropositive HSCT recipients with seronegative stem cell donors are at increased risk.

Viral Infections in the Transplant Candidate

Blood-borne Pathogens

UNOS/OPTN guidelines recommend testing for HIV, hepatitis B (HBV), and hepatitis C (HCV) in all SOT candidates regardless of risk factors. Although specific epidemiologic and geographic evaluation is not necessary to screen for these relatively common infections, it is helpful to be aware of patient risk factors such as sexual activity and intravenous drug use that may increase the risk of infection. Similarly, HSCT candidates should also be screened for HIV, HBV, and HCV [117].

The approach to candidates with HIV is covered elsewhere in this volume, however, it is important to note that pretransplant evaluation of transplant candidates with HIV should include a review of antiretroviral therapy. Use of protease inhibitors and cobiscistat should be avoided whenever possible due to drug–drug interactions with calcineurin inhibitors and other medications. Kidney and liver transplantation in patients with HIV has become increasingly common and is associated with

excellent graft and patient outcomes [118–120]. HIV+ recipients have successfully undergone successful heart and lung transplantation without increased rates of infection, malignancy, or rejection [121–123].

Vaccination of patients who are nonimmune for hepatitis B is an important pretransplantation intervention. The new HBV vaccine Heplisav-B (HepB-CpG) has demonstrated improved vaccination response compared with Engerix [124]. Hepatitis B infection is more common in patients from endemic areas such as Africa, the Middle East, Asia, and Latin America. Patients with active or chronic HBV infection should be treated prior to transplantation according to AASLD guidelines [125].

The general practice for HCV+ abdominal organ transplant candidates has been to withhold treatment for HCV until after transplantation to facilitate receipt of an HCV positive organ; however, a recent retrospective study suggested that control of HCV viremia prior to kidney transplantation was associated with improved outcomes [126]. Candidates for thoracic organ transplantation are generally treated prior to transplantation to minimize adverse outcomes in the setting of generally higher levels of immunosuppression.

Similarly, HSCT candidates should be screened for HBV, HCV, and HIV. Those who test positive for HBV surface antigen or core antibody should receive third-generation antiviral prophylaxis after HSCT. As for SOT candidates, HSCT candidates with active disease should be treated prior to transplantation if possible, and should receive vaccination when feasible if HBV is naive to prevent HBV reactivation after immunosuppression or transmission of disease from donor products [127].

All transplant candidates may benefit from screening for hepatitis A IgG antibody. Patients who are IgG negative should be offered pretransplant vaccination if feasible prior to transplant. Hepatitis A/B combination vaccines can be used in patients who also require hepatitis B immunization.

Cases of hepatitis E virus (HEV) infection have been described in transplant recipients, either as donor-derived infection or as progression of latent infection present prior to transplantation. The presence of infection can be detected in asymptomatic patients using either HEV antigen or PCR testing [128]. Although routine screening is not currently recommended, it should be considered in transplant patients residing in or recently emigrated from the developing world [129].

Endemic Human Herpes Viruses

All HSCT candidates should be tested for herpes simplex virus (HSV) exposure prior to transplantation to identify patients at risk for HSV reactivation [17]. In addition, patient history should be reviewed for history of recurrent or resistant HSV infection in order to guide length and type of prophylaxis. Similarly, varicella zoster virus (VZV) IgG testing should be performed to determine if patients lack protective antibody and therefore need to take special precautions to avoid VZV exposure after transplant. Similarly, cytomegalovirus (CMV) and Epstein-Barr virus (EBV)

antibody status should be evaluated prior to HSCT or SOT to guide post-transplant prophylaxis.

Viral Infections with Geographic Associations

Human Herpesvirus-8 (HHV-8)

HHV-8 exhibits wide variation in incidence by geographic location, with the highest incidence in Africa and the Brazilian Amazon (>50%), followed by the Mediterranean, Eastern Europe, the Caribbean, and the Middle East (5–20% seroprevalence), followed by North American and Asia (<5%) [130]. Rates can also vary within different regions of a single country, with one study demonstrating a two- to threefold difference in incidence in liver transplant recipients depending on geographic region within Spain [131]. HHV-8 is associated with a variety of disease syndromes including Kaposi sarcoma, multicentric Castleman disease, and primary effusion lymphoma.

Increased incidence in men having sex with men (MSM) has been reported in both endemic and nonendemic countries, and it is thought to spread as a sexually transmitted disease given the association with increased rates of other sexually transmitted infections and high-risk sexual behavior as well as multiple partners [130, 132]. No association has been demonstrated with IV drug use, however. Studies of pretransplant rates in liver and kidney candidates in Italy demonstrated a prevalence of 16%, with an additional 11% of patients seroconverting after transplantation [133]. Although development of Kaposi sarcoma is classically associated with HIV, one study from France did not show a significant increase in incidence in liver and kidney transplant recipients with HIV compared with transplant patients without HIV, and disease presentation was not more severe in transplant recipients with HIV [134].

HHV-8 can reactivate with start of immunosuppression in patients previously infected, which has also been described as a donor-derived infection [135]. There are no clear guidelines regarding screening of transplant candidates, and recommendations are complicated by the lack of universal standards for serology or PCR-based laboratory diagnosis [135]. Given that proven prophylaxis regimens in SOT recipients have not been established, the recommendation for monitoring of positive patients after transplantation would primarily be clinical assessment; the role of screening PCR testing for surveillance has not been proven, in part given that an appropriate cutoff for clinically significant positive testing is unknown.

HTLV-1

HTLV-1 is a retrovirus which is also thought to be spread through sexual intercourse, although it can be transmitted from mother to child as well as by blood transfusion or IV drug use [136, 137]. Seroprevalence varies geographically, with highest

seroprevalence in Japan (up to 10%), especially southern Japan, the Caribbean (3–6%), and southern Africa (1–5%), as well as lower levels of incidence in the Middle East, Pacific Oceania, and South America [136, 138]. Pockets of increased incidence may also be seen in regions with concentrations of immigrants from endemic areas. Interestingly, in many countries, prevalence rates have been shown to be higher in hemodialysis patients or in patients receiving transfusions than in healthy controls [137]. Studies of transplant candidates in endemic areas such as Brazil and Japan have demonstrated incidence similar to the general population in that area [136]. The major disease manifestations are adult T cell leukemia or lymphoma and HTLV-1-associated myelopathy, and it does appear that immunosuppression after transplantation is associated with progression of HTLV-1-associated disease in infected transplant recipients, although the typical time to disease is not well described and the overall survival does not differ between infected and uninfected patients [139]. Although official screening recommendations are lacking, it would be reasonable to check HTLV-1 serology on transplant candidates from highly endemic regions, especially if they have been on hemodialysis. Confirmatory testing should be performed with Western blot or NAT testing, as false positive results can occur with ELISA [139]. The role of antiviral therapy to prevent primary infection or reactivation of disease after transplantation is unknown.

Flaviviruses (Arboviruses)

West Nile Virus (WNV)

WNV is a mosquito-borne flavivirus which can cause a wide range of clinical manifestations from mild disease to meningoencephalitis and death [140]. The geographic zone of involvement is large, including Asia, Africa, the Middle East, Europe, the Caribbean, North America, and Latin America, with seasonal activity in temperate zones when levels of infection in the bird reservoir are highest, typically peaking in July through November. Although OPTN/UNOS recommends screening for donors in endemic areas during the season where West Nile virus causes infection, no guidance exists for transplant candidates [1, 141]. Given that within endemic areas rates of seropositivity indicating previous exposure to infection are high, there is likely to be little benefit to testing in an asymptomatic transplant candidate. WNV is generally of more concern as a potential donor-derived infection in endemic areas, as even asymptomatic donors can transmit disease. NAT testing is more specific than serology testing, but may give false negative results depending on the stage of infection [141]. Therefore, only symptomatic patients should be tested as part of a more general diagnostic evaluation for causes of fever or meningoencephalitis; local disease activity and increased mosquito exposure increases risk of infection.

Zika, Chikungunya, and Dengue Viruses

Zika virus (ZIKV) is another viral infection transmitted by mosquitoes that has raised concerns regarding the possibility of donor-derived infection. Other methods of transmission are mother to child, sexual, and via blood transfusion [142]. Infection ranges in severity from mild or asymptomatic to meningoencephalitis or Guillain-Barre syndrome, and notable microcephaly in newborns. Chikungunya (CHIKV) is also a mosquito-borne virus, which has caused disease in Africa and Asia, and now has been found in Latin America [143]. Although able to cause meningoencephalititis and hepatitis, it typically presents as a nonspecific febrile illness with fever, chills, nausea, headache, rash, and sometimes with a chronic inflammatory arthritis. Given a shared mosquito vector and area of distribution, coninfection with dengue virus (DENV) has been reported to occur. Cases of CHIKV infection in transplant recipients has been reported, however the median time after transplantation was 7.5 years, suggesting acute infection rather than reactivation of preexisting disease [143].Transplant donors and candidates with epidemiologic risk factors for exposure and compatible symptoms should be screened for DENV, CHIKV, and ZIKV [142].

Conclusion

Each potential pathogen has its own specific risk factors for pretransplant exposure and post-transplant disease. These factors range from the association of cystic fibrosis and bronchiectasis with chronic bacterial infections such as *Burkholderia* and *Pseudomonas* to specific geographic regions associated with increased risk of endemic fungal infections. Tuberculosis infection is most common in selected countries in the developing world, and many parasitic and arbovirus infections are most common in tropical areas. While some viral infections have specific geographic associations, other viruses are more closely linked to behavior and potential blood-borne exposures, essential to include a careful medical, social, behavioral, and travel history in the evaluation of transplant candidates.

KeyPoints

- Pre-transplant screening is an important intervention to decrease infection risk after transplantation.
- In addition to the medical history, a patient's place of residence, travel history, occupation, exposure to animals and pets, hobbies, prior infections, and other aspects of the social issue are important to review to identify potential issues.
- Pre-transplant exposures that can pose dangers after start of immunosuppression include bacterial, mycobacterial, viral, fungal, and parasitic infections.

Introduction

Transplant tourism and travel posttransplant both play roles in acquisition of infection in solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients. Transplant tourism refers to travel for the purpose of obtaining an organ or tissue transplant outside of a patient's usual country of residence and is often done through commercial means. Travel posttransplant refers to trips abroad taken by SOT and HSCT recipients for the purposes of business, visiting friends and relatives,

or leisure. This chapter discusses both topics separately in order to best address risk of infection and strategies for prevention and treatment accordingly.

Part 1: Transplant Tourism

Introduction

The term "transplant tourism" refers to travel of either the organ donor or recipient for purposes of organ transplantation and often occurs in commercial settings [1]. Numerous international transplant organizations, including the World Health Organization (WHO), the Transplantation Society, and the International Society of Nephrology, have made efforts to decrease the purchase and sale of organs on ethical grounds [2–4], and the practice is illegal in many countries [5]. Nonetheless, these comprise an estimated 10% of SOTs worldwide [6]. Studies have found that outcomes of patients who undergo transplant through commercial means experience decreased allograft and patient survival as well as increased complications including higher rates of rejection and higher rates of infectious complications [7–13]. Although this issue is more prominent and regulations are in place to deter the practice in SOT, transplant tourism also occurs in patients seeking HSCT and stem cell therapies. There is growing concern for stem cell tourism, which involves stem cell therapy for a host of diseases as novel or experimental treatments beyond the traditional use for treatment of hematologic malignancies and disorders [14].

Transplant Tourism and Infectious Complications

Several publications and review papers, including guidelines published by the American Society of Transplantation Infectious Disease Community of Practice (AST Guidelines), highlight the risk of infection that comes with procuring organs through transplant tourism and commercial means [12, 15]. The literature raises concern regarding increased risk across all categories of infection including bacterial, viral, fungal, and parasitic. Differences between endemic rates of infection, antimicrobial resistance patterns, transplant practice, and regulation are all reasons to explain this concern. Pretransplant evaluation and screening of both the donor and recipient as well as routine prophylaxis can vary by country and may not be consistent with the accepted practice, thus potentially increasing the risk of reactivation of latent infection, donor-derived infection, and perioperative or hospital-acquired infection. Furthermore, documentation of transplants that occur in foreign countries, especially for commercial purposes, may not be readily available, therefore making it difficult to provide comprehensive care once the patient returns to his/her resident country.

The body of literature addressing this issue ranges from case reports that outline individual infections acquired through foreign or commercial transplantation to single-center studies looking at outcomes of organ transplants performed

in foreign countries [7, 8, 16, 17] and to review articles and guideline recommendations.

In 2013, Chen and Wilson published a review paper outlining the impact of medical tourism on the field of infectious disease. This paper highlights the magnitude of transplant tourism for both transplant and other purposes on a global scale and provides a useful overview of commonly encountered complications and their impact on healthcare. It raises issues regarding specific infections especially bacterial infections with resistant organisms that can be more common overseas. [18] Given the growing concern for multidrug-resistant organisms (MDRO) and antibiotic resistance worldwide, this is a real concern for patients who have undergone transplant abroad.

Several centers from countries including the United States, Canada, Korea, Australia, and Turkey have looked at rates of infection in patients returning from organ transplantation performed overseas compared to transplants done locally [7, 8, 11, 16, 17]. Prasad et al. have published data on outcomes in patients who underwent renal transplant commercially as compared to those done locally in Toronto, Canada [7, 8]. The first publication reported on 20 patients who received 22 allografts obtained abroad and found increased risk of graft loss and death, and reported 11 patients had serious postoperative infections [7]. The same research group later reported on outcomes of 69 patients who received 72 commercial renal transplants which included infectious complications such as active hepatitis (4 patients), seroconversion of hepatitis B or C (7 patients), pulmonary tuberculosis (2 patients), as well as reduced allograft survival and delayed graft function [8]. Similarly, in a study by Gill et al., 33 patients who underwent transplant abroad were compared to a matched cohort done at the University of California Los Angeles (UCLA) and were found to have a more complex posttransplant course with higher incidence of severe infections [10]. Although the overall rates of infectious complications were similar (52% vs. 48.5%), the severity of infection and the need for hospitalization were greater in those who had transplants abroad. Notably, there were more infections with cytomegalovirus (CMV) in the transplant tourism group as the majority did not receive post-transplant CMV prophylaxis when transplant was done abroad. Finally, in this study, one patient died of donor-derived hepatitis B, which highlights concern regarding screening for infection and donor selection [10].

Studies done outside of North America show similar findings in transplant tourists. An Australian review of recipients of commercial transplants done abroad found patients were at risk of transplant-related HIV infection and new hepatitis [16]. As well, a case series from Turkey reported an increased incidence of malaria, invasive fungal infection, and tuberculosis in 115 patients who had undergone commercial transplants in various countries (including India, Iraq, and Iran) as compared to patients who had undergone transplant locally from living-related donors [17].

Finally, it is important to consider that foreign-born transplant recipients may return to their country of origin for organ transplants [19, 20]. Patients will often

overlook increased infection risk given they are returning home and procedures may occur either during trips for this specific purpose or while they are visiting friends and relatives. These patients are at risk for both reactivation of latent infections and acquisition of new endemic infections; knowledge of the specific infections existing in the transplant region can direct further evaluation [21].

Although less published data exists with regard to the infectious risk involved with stem cell therapy procured through medical tourism and commercial means, professional organizations including the American Society for Transplantation and Cellular Therapy have issued advisory statements on this topic [14, 22]. Concerns from an infection perspective include potential lack of pretransplant screening (both donor and recipient), differences in infection control practices, and possible exposure to multidrug-resistant pathogens and other endemic infections which can vary depending on the center [23]. Patients seeking stem cell therapies through medical tourism or commercial means should be cautioned with regard to these concerns. They should also be made aware that due to differences in healthcare regulations in various countries, stem cell therapies may be experimental or may be offered for novel diseases that have not yet been universally approved; thus, caution with regard to efficacy of treatment as well as other noninfectious complications should be taken into consideration [14, 22, 24].

Conclusion

Experience from transplant centers across the world has shown that there is an increased risk of infection when transplants are done through transplant tourism and in commercial settings. Therefore, identification of patients who have undergone transplant abroad and subsequent evaluation for infection upon their return to local transplant centers is important. This evaluation should include obtaining information regarding transplant process, surgical procedure, and any complications from healthcare received abroad, if possible. It is prudent to perform routine infectious disease screening as per local recommendations that may have been omitted abroad (e.g., CMV, EBV, etc.). Additional screening for endemic infections that could be donor-derived or acquired de novo while abroad based on geographic risk (malaria, strongyloides, tuberculosis, etc.), for blood-borne pathogens (HBV, HCV, and HIV), and for multidrug-resistant organisms is important to thoroughly assess. Treatment of any identified active or latent infection as well as initiation of appropriate prophylaxis as required based on routine practice and screening results will optimize care of these patients.

Key Points

- Despite regulations and laws, 10% of organ transplants occur via commercial practices.
- Patients, both SOT and HSCT, should be discouraged from this practice based on ethical reasons, but should also understand differences in outcomes and increased risk of complications.

- Transplant tourism increases risk of infection, and those patients who have received transplant abroad should be evaluated upon return to their country of residence.
- Special consideration should be paid to endemic infection based on geographic risk and should include resistant bacterial infections, mycobacterial infections, viral infections, fungal infections, and parasitic infections.

Part 2: The Traveling Transplant Recipient

Introduction

An increasing number of solid organ transplants (SOTs) and hematopoietic stem cell transplant (HSCT) are performed each year, thus expanding the population of patients who are immunocompromised posttransplant and hope to re-establish life after transplant in a safe manner. Travel is a major component of this. Studies from the United States, Canada, and Europe have shown that at least one-third of SOT patients travel outside their home country or continent [25–27]. HSCT patients also travel outside their home country; one study showed 44% of post-HSCT patients travel with 32% of patients traveling internationally within 2 years after HSCT [28]. As with any person wishing to travel to destinations with higher infective risk, pre-departure travel medicine evaluation is recommended and is especially important in SOT and HSCT patients who are at higher risk of infection. Unfortunately, not all patients seek or receive travel advice pre-departure [25, 27, 28]. This highlights the importance of ensuring patients are aware to seek advice before planning trips especially to destinations with higher infectious risk and the role of physicians to counsel their patients to do so. The recently published AST Guidelines provide recommendations for traveling SOT recipients and emphasize the importance of addressing travel with patients prior to transplant so they are aware of the need to seek medical advice prior to future travel. [15] Similar guidelines for traveling HSCT recipients are not readily available, but the topic of travel post-HSCT is addressed as part of the American Society for Blood and Marrow Transplantation (ASBMT) Guidelines for Preventing Infectious Complications among Hematopoietic Cell Transplantation Recipients: A Global Perspective [29]. This chapter will outline specific infection that pose risk to SOT and HSCT travelers (Table 2) and ways to mitigate risk during travel, as well as provide a summary of recommendations of key components of the pre-departure travel evaluation.

Risk of Infection While Abroad

Viral Infections

Respiratory Viral Infections

Influenza

Influenza virus is a respiratory virus that is spread through respiratory droplets. Influenza causes respiratory infection that usually present with fever and cough;

however, severe infections leading to respiratory failure and death occur. In fact, the WHO estimates that there are up to five million cases of severe influenza and approximately 500,000 per year globally [30]. Influenza viruses cause infections worldwide and can pose a threat to travelers, especially those with a history of transplant given higher risk of complications due to immunosuppressed state. Transplant recipients are at higher risk of severe infections, complications, and death [31, 32]. Goeijenbier et al. highlight the important considerations for the risk of acquiring influenza during travel including increased human-to-human contact while in transit or at mass gatherings, seasonality of influenza varying between hemispheres, and increased risk by geographic destination [33]. Concern exists during travel as patients transit through airports, on and off planes, trains, and other means of transportation. Proximity to potentially infected people, close spaces, and poor ventilation have all been suspected to increase transmission and attack rates. Seasonality of influenza changes by hemisphere. [34] Flu season falls between May and October in the Southern Hemisphere and between October and May in the Northern Hemisphere. In general, seasonal influenza strains in the Southern Hemisphere precede those seen later in the year in the Northern Hemisphere. Finally, tropical regions especially those located around the equator can have multiple influenza peaks and pose risk of transmission throughout the year. [35] Time of year and destination should be considered to ensure patients are up to date with influenza immunizations. High-risk travelers, such as transplant recipients, may warrant receiving the opposite hemisphere influenza vaccine 2 weeks prior to travel or on arrival at their travel destination [36].

Measles

Measles is a viral illness that infects the respiratory tract and leads to high fevers, upper respiratory tract symptoms, and a diffuse rash. Complications can occur, including encephalitis, and are more common in immunosuppressed patients. The virus is highly contagious and spread through respiratory secretions but can remain in the air or on surfaces for up to 2 hours [37]. Measles remains a common problem in developing countries, and despite immunization programs, there are millions of cases globally, with approximately 110,000 deaths reported in 2017. [37] More recently, measles outbreaks have become a growing global concern. The WHO reports 82,596 people in 47 of 53 countries in Europe had contracted measles in 2018. [38] Smaller outbreaks have also been recently reported across the United States and Canada. Measles vaccination is typically administrated through the combined MMR (measles, mumps, rubella) vaccine. Unfortunately, the MMR vaccine is a live vaccine and contraindicated in SOT recipients due to risk of complications including encephalitis [39–44]. Prior to travel to endemic areas or countries with ongoing outbreaks, evidence of immunity against measles should be evaluated in all SOT recipients to assess for the risk. Some transplant centers will screen and immunize prior to transplantation. For those patients who have not undergone this process pretransplant, immune status should be assessed prior to travel. Patients who were born before 1957, who have had two vaccinations, or who have had

clinical disease are likely protected. Serology (measles IgG) can also be checked. [15] Immune globulin can be considered for short-term protection of nonimmune SOT recipients at high risk for exposure [43].

For HSCT recipients, live attenuated vaccines are generally considered contraindicated until 24 months posttransplant provided the patient is not suffering from graft-versus-host disease (GVHD) and is not on immunosuppressive therapy [29, 42, 45–47]. A typical practice is to perform serology (measles IgG) at this time period to assess if a patient requires measles vaccination, which is generally given as the MMR vaccine. Repeat serology is often checked to ensure seroconversion and a second dose of MMR considered if patient remains seronegative. For those HSCT recipients traveling prior to this time, measles serology (IgG) could be performed early to help with risk assessment and counseling; however, reliability of this as a marker of true protection from measles early posttransplant is controversial. Therefore, risk of measles acquisition during travel should be discussed on an individual basis depending on patient, travel destination and trip itinerary factors.

Middle Eastern Respiratory Syndrome

Middle Eastern respiratory syndrome coronavirus (MERS-CoV) belongs to the family *Coronaviridae*. It was first reported in 2012 and is an emerging coronavirus that causes severe acute respiratory illness [48, 49]. Cases mainly occur in the Middle East, and Saudi Arabia has reported 80% of these. Cases outside in other countries are mostly linked with travel. There have been case reports in SOT [50] and HSCT patients [51]. Transmission is poorly understood, but there is evidence to suggest person-to-person spread as well as increased risk if exposed to dromedary camels. There are no specific methods of prevention recommended for travel; however, travelers should be encouraged to take precautions including proper hand hygiene if they have been in contact with animals [48, 49]. The WHO has identified immunocompromised travels, including SOT recipients, to be at high risk of severe illness from MERS-CoV. As such, SOT recipients should avoid contact with camels and should not consume raw, undercooked, or unpasteurized camel products (i.e., meat and dairy) [48].

Gastrointestinal Viral Infections

Norovirus

Norovirus is a cause of gastroenteritis that is spread through fecal-oral routes, either person-to-person contact or from contaminated foods, mainly raw or undercooked shellfish. Norovirus has been associated as a cause of traveler's diarrhea and is more frequently seen in outbreaks linked to crowded spaces such as cruise ships [52, 53]. While typically norovirus causes a short, self-limited gastroenteritis, transplant patients are at higher risk of complications and can go on to develop chronic norovirus [54]. Prevention involves proper hand hygiene as well as avoidance of raw or undercooked shellfish.

Hepatitis A

Hepatitis A is a frequent cause of food-borne illness and is spread through fecal-oral routes. It is associated with contaminated food and water as well as poor sanitation [55]. Clinical syndromes can range from mild illness to fulminant hepatic failure. Patients who are immunocompromised have higher risk of severe illness, and consequences can be significant.

Geographic distribution is classified as high, medium, or low risk based on endemic rates of infection. The risk of contracting hepatitis A in nonimmune travelers to high-risk areas is estimated at 1 in 1000 per week for those on tourist routes but increases to 1 in 200 for those on more remote itineraries [56].

Transplant recipients traveling to areas with risk of hepatitis A should be protected and should be aware of risk reduction strategies with regard to food and water precautions. [57] Unfortunately, hepatitis A vaccine is less effective in SOT recipients, and studies have shown lower rates of seroconversion [58]. Therefore, when possible, evaluation for hepatitis A serology testing should be done during transplant workup, and nonimmune patients who wish to travel posttransplant should be vaccinated prior to transplant. For HSCT recipients who plan to travel in the future, hepatitis A vaccine can be added to the standard posttransplant immunization schedule.

For those posttransplant patients whose immune status is unknown, hepatitis A serology should be performed. For those nonimmune transplant recipient travelers, two doses of hepatitis A vaccine 6–12 months apart should be given. If the travel departure date does not allow for both doses to be administered, the second dose should still be given upon return in order to confer longer-term protection especially for those repeat travelers. For patients who have already had one dose of vaccine previously, a second dose should be given prior to departure. Finally, for nonimmune transplant recipients who do not have adequate time prior to departure or who are unlikely to respond to immunization, pooled immunoglobulin should be given [45, 59]. Intramuscular pooled immune globulin provides 85–90% protection against hepatitis A [59]. Guidelines are available with regard to administration and dosing specifics [59].

Hepatitis B

Hepatitis B can cause illnesses ranging from an acute hepatitis to a chronic infection that can predispose to cirrhosis, liver failure, and hepatocellular carcinoma. It is transmitted through contact with infected blood or body fluids, and routes of transmission can include maternal-child, sexual contact, unsafe injections, or blood transfusions [60]. Hepatitis B, specifically chronic hepatitis B, affects over 250 million people worldwide with the highest prevalence in the Western Pacific area and Africa. [61] For SOT recipients who were not vaccinated prior to transplant, immunization against hepatitis B before travel is indicated for travelers with higher risk of exposure including those who will be living or traveling in endemic areas for extended periods; those who are likely to need medical care, procedures, or blood products while abroad; and those who anticipate having new sexual partners [15]. Again, if the patient has not been immunized prior to transplant, they can be

immunized prior to departure; however, immune response to the standard hepatitis B vaccine posttransplant is poor. The high-dose vaccination series may be more effective in this population; therefore, immunization with a vaccine containing 40 mcg of hepatitis B surface antigen given in a three- or four-dose schedule is recommended [62]. Anti-HB titers can be measured to assess vaccine efficacy, and a titer of >10 IU/ml is considered protective [42, 62]. Although the need for booster doses is controversial in SOT recipients, they can be considered for high-risk travelers. Hepatitis B vaccination series is typically given over a 6-month span; however, accelerating the schedule to give each vaccine dose 4 weeks apart is possible if travel departure date limits time [15].

For HSCT recipients, hepatitis B vaccine is part of the standard posttransplant immunization schedule [29, 42, 45–47]. Most schedules include a minimum of three doses of hepatitis B vaccine, and anti-HB titers can be measured to assess if booster or repeat vaccine series is required. High-dose vaccine may be more effective in this population.

The combination hepatitis A and B vaccine (such as Twinrix®) is sometimes used for those needing both vaccines; however, the response is often poor in this patient population, and giving the components (A and B) separately is advised for SOT recipients.

Hepatitis E

Hepatitis E is another viral cause of hepatitis that is often self-limiting, but in some cases more severe infections can occur including fulminant hepatitis leading to liver failure, and cases of chronic hepatitis E have been seen in immunocompromised patients. [63] It is spread through fecal-oral route and associated with contaminated drinking water and poor sanitation and rarely has been transmitted through ingestion of infected animals. It is found worldwide but more common in resource-limited countries with the highest prevalence in East and South Asia. [63] There is no specific vaccine for prevention; however, patients should practice food and water precautions and avoid eating raw or undercooked meat products especially in high-risk areas [64].

Polio

Poliovirus is a neurotrophic virus that causes poliomyelitis and can lead to irreversible paralysis. It is spread through fecal-oral transmission, typically person to person, but can also be contracted through contaminated water [65]. Wild-type poliovirus has been eradicated from the Western Hemisphere; however, wild-type virus still exists in regions of sub-Saharan Africa and South Asia, and to this day, Afghanistan, Nigeria, and Pakistan remain endemic countries [66]. On occasion, outbreaks of vaccine-associated poliomyelitis have also occurred.

In efforts to eradicate polio worldwide, the majority of the population has received polio vaccine during childhood immunization series. For HSCT recipients, inactivated polio vaccine is part of the standard posttransplant schedule. Patients typically receive at least three doses and thus should be up to date once they have completed this schedule [29, 42, 45–47]. For adult SOT travelers, this should be

verified, and they should also receive a booster when traveling to endemic areas. [67, 68] For subsequent travel, booster immunization may be prudent for individuals traveling to locations with circulating wild-type polioviruses or polio outbreaks.

Careful attention should be paid to the fact that two forms of the polio vaccine are available: the live oral poliovirus vaccine (OPV) and the injected inactivated poliovirus vaccine (IPV). The oral, live attenuated vaccine is contraindicated in transplant recipients. Also, household contacts of immunocompromised individuals should not receive the OPV as it is possible to spread vaccine strain poliovirus through fecal-oral contact.

Vector-Borne Viral Infections

Yellow Fever

Yellow fever (YF) virus is a flavivirus that can cause hemorrhagic fever with a 20% mortality rate. [69] It is spread through bites from mosquitos, typically the *Aedes* and *Haemagogus* species [70]. As of 2018, 47 countries in South America and Africa either were endemic or had areas of endemicity, with the latest outbreak occurring in Brazil [70].

The yellow fever vaccine (YFV) is an effective vaccine that offers lifelong immunity with one dose [65]. However, it contains a live attenuated viral strain and is contraindicated in SOT recipients. [41, 43, 71–73] Interestingly, a study of 53 SOT patients who received yellow fever vaccine prior to transplantation demonstrated persistence of yellow fever antibodies posttransplant; detectable antibodies persisted after a median duration of 13 years. [74] Therefore, those who plan to travel to or have reasons to potentially need to travel to yellow fever areas should be immunized pre-transplantation. Antibody testing can be done posttransplant to ensure persistent immunity, with a suggested threshold of a YF neutralization test >10 U/l required for travel to high-risk areas. [74]

Those SOT recipients who have not been vaccinated or were vaccinated pre-transplant but do not demonstrate protective antibodies should be advised not to travel to endemic regions. They should not receive the yellow fever vaccine post-transplant. If avoiding travel is not possible, they should not go in peak season. [43, 75]

For HSCT recipients, data is limited. As per the *Guidelines: Vaccination of hematopoietic cell transplant recipients*, the risk-benefit of yellow fever vaccine should be considered [45]. Since it is a live attenuated vaccine, patients should be >24 months posttransplant with no active GVHD and off immunosuppressive therapy [45]. A retrospective study of 21 post-allogeneic (allo)-HSCT recipients immunized with yellow fever vaccine, a median of 39 [21–86] months post-transplant, reported no side effects [76]. Thus, this vaccine could be considered for long-term survivors of HSCT who are traveling to high-risk areas, and consultation with travel medicine expert familiar with immunocompromised patient would be advised.

When yellow fever vaccine has not been given, patients should travel with a yellow fever vaccine waiver letter stating the contraindication to vaccination.

Patients should be counseled to present this letter when entering countries that require proof of yellow fever vaccine and are generally acceptable to most governments.

Family members of immunosuppressed patients may receive yellow fever vaccine.

Japanese Encephalitis

Japanese encephalitis (JE) virus of the genus *Flavivirus* is an arbovirus that causes encephalitis. It causes up to 10,000 deaths annually in Asia and can lead to long-term neuropsychiatric sequelae in survivors [77, 78]. JE is transmitted by mosquitoes (*Culex* species) and is the most common vaccine-preventable encephalitis in Asia [78]. It is more common in rural and agricultural areas specifically those with significant irrigation such as rice paddies. Peak seasons occur in the summer and fall, but can vary based on rain patterns [78].

Immunization against Japanese encephalitis with two doses of inactivated JE vaccine can be considered for individuals with intense rural travel in areas of Asia endemic for JE, especially during periods of increased transmission [78, 79]. It is recommended for travelers with trips planned for longer than 1 month or with plans for extensive rural travel in endemic areas [80]. Although vaccine efficacy data in SOT and HSCT recipients is limited, inactivated JE vaccine is recommended in transplant recipients for the same indications. A booster dose should be given for re-exposure or continued JE risk if the primary series was administered $\geq$1 year previously. [77–79] Some JE vaccines available in Asia contain live virus; these are contraindicated in SOT recipients and those post-HSCT who do not meet LAV criteria. Patients should be aware they should not receive such vaccines [15].

Dengue, Chikungunya, and Zika

Dengue, chikungunya, and Zika are all arboviruses or arthropod-borne viruses transmitted by mosquitos, most commonly the *Aedes aegypti*. Although dengue is the most common mosquito-borne virus, increasing cases of chikungunya and Zika are being seen in tropical and subtropical regions [81–83]. They can all pose a risk to immunocompromised hosts including traveling transplant recipients [84]. To date, no vaccines currently exist to prevent these viral illnesses, and patients should be counseled on mosquito protection.

Dengue virus is of the genus *Flavivirus*. It typically causes a self-limited flu-like illness, but serious complications including dengue hemorrhagic fever and dengue shock syndrome can be fatal. Patients who have previously suffered from or been exposed to dengue fever are at increased risk of serious complications such as dengue hemorrhagic fever or dengue shock syndrome during a second infection. This is especially concerning in immunocompromised hosts [81]. Clinical course and outcomes in SOT recipients may be similar to that of immunocompetent patients, [85, 86] but studies have raised concern for worse outcomes including an increased risk of dengue shock syndrome leading to death as well as graft dysfunction. [87, 88] Limited data exists regarding dengue in HSCT patients, although case

series of post-HSCT recipients suggests prolonged viremia in this patient population [89, 90].

Chikungunya is of the *Alphavirus* genus. It presents with some unique symptoms which helps to distinguish it from other arboviruses. Febrile illness with abrupt fevers, maculopapular rash, and arthralgias are characteristic. The disease is typically self-limited, but literature does report that SOT recipients can develop chronic polyarthritis from this viral infection [81, 91].

Zika is another *Flavivirus*. It was first reported in Uganda, and there have been outbreaks in Africa, Asia, the Americas, and the Pacific. Most recently, in 2015, Brazil reported association between Zika, pregnancy, and microcephaly. Since then, Zika has spread throughout the Americas prompting travel recommendations for women who are or may wish to become pregnant and those interested in preventing sexual transmission of Zika [92, 93]. In adult patients, it presents as a non-specific viral illness but has been linked to Guillain-Barré syndrome (GBS). Data is limited in transplant recipients, and further studies are needed to appreciate the impact on this patient population [81, 90, 94, 95].

Rabies

Rabies (*Rhabdoviridae*, genus *Lyssavirus*) is a neurotropic virus that causes acute encephalomyelitis. The WHO reports 59,000 deaths per year from rabies, with most cases occurring in Africa and Asia. Rabies is transmitted through the saliva from infected animal bites [96]. All mammals are susceptible to the virus, with most common being terrestrial carnivores and bats [96]. The majority of human cases occur from transmission via dog bites in endemic areas, but wild animals including bats worldwide are of concern [96, 97]. All travelers should be counseled regarding the risk of animal bites while abroad, especially in rabies-endemic countries, and in general should avoid contact with free-roaming and wild animals. Pre-exposure rabies vaccine can be given pre-departure to select patients with high risk of exposure. For example, it may be considered in long-term travelers to endemic areas, individuals expecting significant animal exposure, and individuals who plan to be in remote areas without access to medical care [15, 96].

In the event of an animal bite while traveling, all transplant recipient should seek medical care. For those with rabies exposure or potential rabies exposure, patients should receive postexposure prophylaxis. This involved thorough and immediate cleansing of the wound with soap and water. Those who have not previously been immunized require human rabies immune globulin (HRIG) injected into the wound directly with the remainder given intramuscularly and postexposure prophylaxis with multidose vaccine regimen [97]. Those who have received pre-exposure prophylaxis require two more doses of the vaccine, but do not require HRIG. Since SOT recipients may not mount adequate antibody responses to the rabies vaccine, some experts recommend administration of HRIG after all at-risk exposures [80, 97, 98].

Bacterial Infections

Salmonella enterica Serovar Typhi

Salmonella enterica serovar Typhi is a bacterial infection that causes typhoid fever. It affects up to 20 million people and leads to 160,000 related deaths worldwide each year [99]. *Salmonella typhi* is spread through contaminated food and water and infects the gastrointestinal tract. Typhoid fever classically presents with systemic illness including high fevers, abdominal pain, and altered bowel movements. Some patients will develop blood stream infections. SOT recipients are at risk of severe complications [100].

Treatment for *Salmonella typhi* involves antibiotic therapy; typically, fluoroquinolones have been used, but with increasing resistance especially in South and Southeast Asia, alternatives may be needed. If possibility of resistance is high, third-generation cephalosporins are favored [101].

Given the risk of severe illness, immunization is recommended for travel to endemic areas. Two vaccines are available. The oral live attenuated vaccine is contraindicated in immunocompromised patients. Transplant recipients should receive the injectable polysaccharide vaccine. This should be given at least 2 weeks prior to departure and repeated every 2 years for ongoing travel or future trips to endemic areas. Travelers should be counseled that the immune response to this vaccine may be suboptimal. Travelers should be counseled about food and water precautions.

Vibrio cholerae

Vibrio cholerae is a gram-negative bacillus that infects the intestinal tract; infections in humans are most often caused by serogroups O1 and O139 which are the toxigenic strains. It is most often acquired from contaminated water but has also been associated with fish and shellfish consumption. Person-to-person transmission is possible but rare. It is generally associated with poor sanitation. *Vibrio cholera* is endemic in approximately 50 countries worldwide, mainly in Africa and South and Southeast Asia. It is often associated with natural disasters. For example, more recently, it has been seen more frequently in the Caribbean with a large outbreak in Haiti associated with the 2010 earthquake. Cholera presents as watery diarrhea, and when severe or if left untreated, it can cause severe fluid loss and life-threatening dehydration [102].

The mainstay of treatment is rehydration. In most countries, doxycycline is the first-line antibiotic, but patterns of resistance are emerging, and antibiotic susceptibility testing on the specimen is recommended.

Prevention of infection in travelers is mainly through food and water precautions as well as proper hand hygiene. Three inactivated oral cholera vaccines exist and include the inactivated, oral travelers' diarrhea and cholera vaccine (Dukoral®). This vaccine offers protection against *Vibrio cholera* serogroup O1 [103, 104]. In general, this vaccine is not recommended routinely for travelers, but physicians may wish to consider it on an individual basis for those at high risk of exposure. [105–107] It is

administered in two doses 1 week apart with a booster every 2 years if ongoing travel [103]. It is not available within the United States, but is available in other countries such as Canada. Within the United States, the oral cholera vaccine (Vaxchora®) is a live vaccine; it is not recommended for transplant recipients as safety and efficacy have not been established in immunocompromised patients.

Enterotoxigenic *Escherichia coli* (ETEC)

Traveler's diarrhea is the most common travel-related illness. Bacterial pathogens are the most common cause, accounting for up to 90% of cases [108]. The enterotoxigenic strain of *E. coli* or ETEC is the most common cause of traveler's diarrhea. Highest-risk areas include Asia, the Middle East, Africa, Mexico, and Central and South America [109]. The route of spread is fecal-oral and mainly is acquired through contaminated food or water. Clinical presentation involves acute watery diarrhea that can become severe. The mainstay of treatment involves rehydration. Antibiotics that can be used include fluoroquinolones and macrolides; therefore, many travelers will travel with antibiotics on hand to be started based on physician instructions depending on severity and duration of traveler's diarrhea. Prevention mainly entails food and water precautions as well as proper hand hygiene. The inactivated, oral travelers' diarrhea and cholera vaccine (Dukoral®) has not shown sufficient evidence to support reliable protection against travelers' diarrhea caused by enterotoxigenic *E. coli* [103, 104].

Neisseria meningitidis

Neisseria meningitidis is an encapsulated, gram-negative diplococcus spread person to person through aerosolized droplets or secretions. There are eight main serovars that cause invasive infections in humans. Clinical disease includes meningitis, bacteremia, and shock with high case fatality rates (5–15%). Suspected infections require prompt evaluation, diagnosis, and treatment; typically beta-lactam antibiotics such as penicillin or ceftriaxone are recommended.

Immunization against meningococcal disease is recommended for travelers to endemic areas, such as the "meningitis belt" of sub-Saharan Africa, and for those traveling to Saudi Arabia for the Muslim pilgrimages of *hajj* or *umra*, where proof of vaccination is required [110]. SOT recipients traveling to areas of risk should receive two doses of the conjugated quadrivalent vaccine (MenACWY) prior to departure with booster repeated every 5 years. For HSCT recipients, quadrivalent meningococcal disease may be part of the standard posttransplant schedule as per country recommendations [29, 42, 45–47]. HSCT recipients who are not vaccinated and traveling to areas of risk should be immunized prior to departure. The conjugated vaccine protects against serotypes A, C, W, and Y; traditionally serotype A was of most concern for travelers, but more recently outbreaks with C and W have been seen [110]. Separate serogroup B meningococcal vaccines (MenBV) are now also available and can be considered in transplant recipients. This vaccine is not yet generally recommended for travel [110], but should be considered for transplant recipients traveling to endemic areas [80].

Streptococcus pneumoniae

Streptococcus pneumoniae is a gram-positive coccus, and infection with this bacterium causes clinical presentations such as pneumonia, bacteremia, and meningitis. It is one of the most common causes of community-acquired pneumonia worldwide. Developing countries have higher incidence [111]. Treatment of infection involves antibiotic therapy with beta-lactam or macrolide; the antibiotic choice, route, and duration depend on diagnosis and severity of the illness. For prevention, two pneumococcal vaccines are available, and transplant recipients should be up to date prior to travel if these have not been administered within the past 5 years. SOT recipients should have received at least one dose of the conjugated pneumococcal vaccine (Prevnar®13, PCV13) followed by the polysaccharide pneumococcal vaccine (Pneumovax®23, PPSV23) [42, 44]. HSCT recipients should complete pneumococcal vaccines as part of the standard posttransplant schedule, receiving multiple doses of the conjugated vaccine and finishing with the polysaccharide [29, 42, 45–47].

Clostridium tetani

Clostridium tetani is an anaerobic gram-positive bacillus that causes tetanus. It is distributed worldwide in the environment, but is more common in rural areas [112]. It is transmitted through contact with broken skin barrier, often occurring during an injury. Tetanus causes acute spasms and muscle rigidity, often starting locally but can become generalized and lead to death. Treatment involves wound care, tetanus immune globulin, antibiotic therapy typically with metronidazole, tetanus toxoid vaccine, and supportive management. Infection can be prevented through immunization, which is universally recommended. Although tetanus is rare among travelers, all transplant recipients should have a tetanus booster if they are not up to date before traveling. Patients can be immunized with combination vaccine for tetanus, diphtheria, and acellular pertussis (Tdap) [42].

Corynebacterium diphtheriae

Corynebacterium diphtheriae causes diphtheria; most commonly respiratory diphtheria can cause inflammation of pseudomembranes which can lead to fatal airway obstruction. Mortality occurs in 5–10% of cases. It is transmitted person to person through droplets. In tropical countries, cutaneous diphtheria can occur through direct skin contact. Diphtheria continues to be endemic in many countries worldwide with outbreaks occurring. It is more common in resource-poor regions. Treatment requires diphtheria antitoxin and antibiotic therapy, usually penicillin or macrolides. Diphtheria toxoid vaccine is universally recommended, and travelers, including transplant recipients, should be up to date. A booster should be administered prior to travel to endemic areas or those with outbreaks if patients were last vaccinated more than 10 years previously. Patients can be immunized with combination vaccine for tetanus, diphtheria, and acellular pertussis (Tdap) [42].

Bordetella pertussis

Bordetella pertussis is a gram-negative aerobic bacillus that causes pertussis or more casually known as whooping cough. It is highly communicable with transmission

via respiratory droplets. Unfortunately, worldwide incidence of pertussis is on the rise, with 90% of pertussis occurring in developing countries. Treatment is with antibiotic therapy with macrolides, specifically erythromycin, recommended first line. [113] All travelers including transplant recipients should be protected [114]. Patients can be immunized with combination vaccine for tetanus, diphtheria, and acellular pertussis (Tdap) [42].

Mycobacterial Infections

Mycobacterium tuberculosis

Mycobacterium tuberculosis is an acid-fast bacillus that causes tuberculosis (TB). It is transmitted person to person through airborne particles. TB can lead to both active, pulmonary and extrapulmonary, and latent infections. In 2017, the WHO reported an estimated ten million new cases of TB and 1.6 million deaths [115]. Immunocompromised patients, including transplant recipients, are at higher risk of TB. In these patients, most cases are felt to be reactivation of latent infection from prior exposure; however, new infection can be acquired posttransplant with higher risk in endemic countries. Clinical manifestation of TB in SOT recipients can present differently, and mortality rates are high [116]. Treatment of active TB involves multidrug regimen with careful consideration for interactions with immunosuppressive therapy.

Although there are no specific recommendations for prevention of TB exposure in travelers, transplant recipients should be cognizant of risk while traveling in endemic areas for prolonged periods of time or if their itinerary involves high-risk exposure. For example, use of an appropriate mask (fitted N95) for those working or volunteering in high-risk healthcare settings in endemic regions should be considered [15]. If there is concern for TB exposure while abroad, a post-travel tuberculosis skin tests with the purified protein derivative (PPD) or an interferon-gamma release assay may be helpful; however it should be noted that immunocompromised patients are at risk of false-negative tests. TB screening in asymptomatic patients should only be done if there is a known exposure to active tuberculosis infection or if there has been prolonged exposure in a high-risk environment such as working or volunteering in a healthcare setting in an endemic area [117]. The bacillus Calmette-Guérin (BCG) vaccine is a live attenuated strain of *M. bovis* and is contraindicated in transplant recipients due to risk of disseminated BCG infection.

Fungal Infections

SOT and HSCT recipients are at higher risk for fungal infection compared to the immunocompetent population. Although this risk is universal and not limited to travel exposures, certain fungal infections are known to be linked to geographic areas. [118, 119] Transmission or acquisition of infection is generally through environmental exposures and most commonly through inhalation or cutaneous inoculation. Clinical presentation is variable and depends on organ system involved, but can include pulmonary disease, cutaneous disease, rhino-orbital-cerebral disease, and disseminated infection among others. Optimal antifungal therapy depends on the

fungal species responsible for infection, and surgical excision or debridement should be considered when appropriate or necessary for source control. Prevention revolves around avoidance of high-risk environmental exposures.

Certain geographic areas pose higher risk of endemic fungal infections. In 2002, Ericsson et al. published a review of fungal infections among returning travelers that had been reported through the GeoSentinel network [120]. This study reported up to 0.5% monthly morbidity of illness in returning travelers was due to fungal infection and specifically review cases due to histoplasmosis, coccidioidomycosis, and penicilliosis (now talaromycosis). In 2013, Lortholary et al. reviewed the published literature of fungal infections in immunocompromised travelers [121]. Endemic fungal infections, including histoplasmosis, blastomycosis, and coccidioidomycosis in North America, paracoccidioidomycosis in South America, and talaromycosis due to *Talaromyces* (formerly *Penicillium*) *marneffei* infection in Southeast Asia, can be acquired during travel [21, 80, 119–124]. More details on the geographic distribution of these endemic fungal infections are summarized in Table 1.

Transplant recipients should be counseled to be diligent with regard to avoiding high-risk exposures for respiratory exposures such as visiting caves (spelunking). If exposures cannot be avoided, surgical masks can be worn to reduce risk of inhalational exposure. Other fungal infections can be transmitted through direct skin inoculation from the environment; thus gloves or skin covering can be donned to minimize direct skin inoculation.

Parasitic Infections

A wide variety of parasites exist worldwide and are generally classified as helminths, protozoa, and ectoparasites. They can cause infection of the blood, tissue, and intestinal tract in human hosts. In SOT recipients, parasite infections can occur through reactivation, donor-derived acquisition, or de novo acquisition, especially in patients who live or spend prolonged periods of time in endemic areas. A Canadian study found 29% of 3,528 returning travelers, and new immigrants had parasitic infection [125]. Travelers who were visiting friends and relatives (VFR) seemed to be at high risk. With increasing travel among SOT recipients, the incidence of parasitic infections in returning travelers is expected to grow [126] (Tables 3 and 4).

Vector-Borne Parasite Infections

Vectors, mainly insects, can spread parasite infections to human hosts. These include through mosquitos (*Plasmodium* spp.), sand flies (*Leishmania* spp.), triatomine bugs or tsetse flies (*Trypanosoma* spp.), and ticks (*Babesia* spp.) [127].

Plasmodium Species

Five species of *Plasmodium*, including *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*, cause malaria. Malaria remains a large global health problem with most recent estimates of 219 million infections in 87 countries and 435,000 deaths worldwide [128]. It is transmitted through mosquitos (female *Anopheles*). Malaria is an acute febrile illness that can quickly progress to severe illness and death if left

Table 1 Geographic distribution of endemic fungal infections

Fungal infection	Geographic distribution
Blastomycosis	
Blastomyces dermatitidis	Midwestern, South Central, and Southeastern United States and Canada (especially Ohio and Mississippi Rivers, the Great Lakes, Saint Lawrence River, and Northern Ontario)
Coccidioidomycosis	
Coccidioides immitis ***Coccidioides posadasii***	Southwestern United States (Arizona, California, Nevada, New Mexico, Texas, Utah), Mexico, and Central and South America
Cryptococcosis	
Cryptococcus gattii	Pacific Northwest United States (Washington, Oregon) and Canada (British Columbia and Vancouver Island), Australia, Papua New Guinea Also seen in parts of Africa, Asia, Europe, Mexico, and South America
Histoplasmosis	
Histoplasma capsulatum	Worldwide especially river valleys in the United States (Ohio and Mississippi Rivers), Canada (Ontario, Quebec especially Saint Lawrence River) Also seen in Central and South America, Africa, Asia, and Australia
Paracoccidioides	
Paracoccidioides brasiliensis	Central and South America (Brazil, Venezuela, Colombia, and Argentina)
Talaromycosis	
Talaromyces marneffei	Southeast Asia, southern China, eastern India

untreated. Like all travelers to endemic areas, transplant recipients are at risk. Treatment involves prompt diagnosis and administration of antimalarials; the choice and route depend on causative species, area of acquisition along with known resistance patterns, level of parasitemia, and severity of illness. Supportive care and close monitoring are especially important in severe disease.

Patients traveling to malaria areas should be provided prophylaxis prior to departure and be counseled on insect protection including use of bed nets. Transplant recipients should be provided prophylaxis against malaria as per routine recommendations based on area of travel and resistance patterns, but careful attention needs to be paid to drug interactions with immunosuppressive therapy [129]. The *Center for Disease Control (CDC) Yellow Book* among other resources provides country-specific guidelines and patient-related considerations for selecting a prophylactic agent [130]. The AST Guidelines provide additional information including a summary of antimalarial interactions with common medications taken by SOT recipients including calcineurin inhibitors, mTOR inhibitors, and/or trimethoprim-sulfamethoxazole [15], some of which are also by HSCT recipients. This information has been adapted from several references and summarized in Table 5.

Table 3 Recommendations for vaccination for solid organ transplant travelers [15], 44, 72]

Vaccine	Recommendations for adults
Routine immunizations	
Parenteral influenza	Yearly Should be considered prior to travel for patients traveling to opposite hemisphere during flu season
Pneumococcal conjugated and polysaccharide	Recommended; booster after 5 years
Tetanus/diphtheria	Recommended; booster every 10 years
Pertussis	Recommended in combination with tetanus and diphtheria (Tdap) once
Measles, mumps, and rubella (MMR)[a]	Contraindicated If serostatus or immunization history is unknown, perform serology prior to travel to areas of outbreak
Varicella[a]	Contraindicated
Travel immunizations	
Hepatitis A	Recommended when indicated
Hepatitis B	Recommended when indicated
Meningococcal conjugate	Recommended when indicated
Meningococcal serogroup B	Recommended when indicated
Inactivated polio vaccine (IPV)	Recommended when indicated
Rabies	Recommended when indicated
Japanese encephalitis (inactivated)	Recommended when indicated
Cholera vaccine	Recommended when indicated; non-live available in Canada and elsewhere; live vaccine contraindicated
Typhim Vi	Recommended when indicated
S. typhi Ty21a[a]	Contraindicated
Oral polio vaccine (OPV)[a]	Contraindicated in patients and family/household members
Bacillus Calmette-Guérin (BCG)[a]	Contraindicated
Yellow fever vaccine (YFV)[a]	Contraindicated

Adapted from the Centers for Disease Control and Prevention "Recommended Adult Immunization Schedule — United States, 2018," [114] "Advising Travelers with Specific Needs: The Immunocompromised Traveler" [43] in Centers for Disease Control and Prevention's "Health Information for International Travel," "Guidelines for vaccination of solid organ transplant candidates and recipients" [44], and the AST Guidelines [15]

[a]*Live attenuated*

Leishmania Species

Leishmania species cause protozoan infection known as leishmaniasis that can be classified as cutaneous, mucocutaneous, or visceral. An estimated one million new cases occur globally each year [131]. Visceral leishmaniasis most often occurs in

Table 4 Recommendations for vaccination for hematopoietic stem cell transplant travelers

Vaccine	Recommendations for adults
Routine immunizations	
Parenteral influenza	Yearly Should be considered prior to travel for patients traveling to opposite hemisphere during flu season
Pneumococcal conjugated and polysaccharide	Recommended as part of post-transplant immunization series; booster after 5 years
Tetanus/diphtheria	Recommended as part of post-transplant immunization series; booster every 10 years
Pertussis	Recommended as part of post-transplant immunization series
Hepatitis B	Recommended as part of post-transplant immunization series
Inactivated polio vaccine (IPV)	Recommended as part of post-transplant immunization series
Meningococcal conjugate	Recommended as part of post-transplant immunization series
Measles, mumps, and rubella (MMR)[a]	Typically given if serology indicates nonimmune at 24 months post-transplant if patient meets criteria to receive live attenuated vaccine (LAV)[b]
Varicella[a]	Typically given if serology indicates nonimmune at 24 months post-transplant if patient meets criteria to receive live attenuated vaccine (LAV)[b]
Travel immunizations	
Hepatitis A	Recommended when indicated
Meningococcal serogroup B	Recommended when indicated
Rabies	Recommended when indicated
Japanese encephalitis (inactivated)	Recommended when indicated
Cholera vaccine	Recommended when indicated; non-live available in Canada and elsewhere; live vaccine contraindicated
Typhim Vi	Recommended when indicated
S. typhi Ty21a[a]	Contraindicated; an inactivated vaccine exists and is recommended for these patients
Oral polio vaccine (OPV)[a]	Contraindicated; an inactivated vaccine exists and is recommended for these patients
Bacillus Calmette-Guérin (BCG)[a]	Contraindicated
Yellow fever vaccine (YFV)[a]	Contraindicated, however, may be considered if indicated if patient is 24 months post-transplant and meets criteria to receive live attenuated vaccine (LAV)[b]

Adapted from the Centers for Disease Control and Prevention "Recommended Adult Immunization Schedule — United States, 2018," [114] "Advising Travelers with Specific Needs: The Immunocompromised Traveler" [43] in Centers for Disease Control and Prevention's "Health Information for International Travel," and ASBMT: Guidelines for Preventing Infectious Complications among Hematopoietic Cell Transplantation Recipients: A Global Perspective [29]

[a] *Live attenuated*

[b] *Criteria to receive LAV: ≥ 24 months post-HSCT, no active GVHD, no immunosuppressive therapy*

Table 5 Travel-related medications, adult dosages, duration, and drug interactions

	Dose	Duration	Change for reduced GFR	Interactions with calcineurin inhibitors (CNI): tacrolimus and cyclosporine	Interactions with mTOR inhibitors: sirolimus, everolimus
Travelers' diarrhea treatment					
Ciprofloxacin	500 mg bid	For 3–7 days	Yes	May cause QT prolongation when used in combination May ↑CNI levels (cyclosporine)	
Levofloxacin	500 mg daily	For 3–7 days	Yes	May cause QT prolongation when used in combination May ↑CNI levels (cyclosporine)	
Azithromycin	500 mg daily	For 3–7 days	Use caution if CrCl<10 mL/minute	May ↑CNI levels	May ↑ levels
Malaria prophylaxis					
Atovaquone-proguanil	Atovaquone/ proguanil 250 mg/ 100 mg daily	Start 1–2 days prior to entering a malaria-endemic area, continue throughout the stay and for 7 days after leaving malarial area	No dose adjustment for mild to moderate renal impairment; avoid if severe renal impairment occurs (CrCl <30 ml/min)	No significant interactions	
Mefloquine	250 mg weekly	Begin 2 weeks before, arrival in endemic area, continuing weekly during travel and for	No	Can interact with tacrolimus to prolong QT	Everolimus may increase mefloquine levels

		4 weeks after leaving malarial area			
Doxycycline	100 mg daily	Start 1–2 days prior to entering a malaria-endemic area, continue throughout the stay and for 28 days after leaving malarial area	No	No significant interactions	
Chloroquine	500 mg/week (300 mg base)	Begin 1–2 weeks prior to exposure; continue for 4 weeks after leaving malarial area	Administer 50% of dose if CrCl<10 mL/minute	May ↑ cyclosporine levels Can interact with tacrolimus to prolong QT	May ↑ cyclosporine levels Can interact with tacrolimus to prolong QT
Hydroxychloroquine	400 mg/week	Begin 1–2 weeks prior to exposure; continue for 4 weeks after leaving malarial area	No, but may need to consider reduction	May ↑ cyclosporine levels	
Primaquine	52.6 mg/daily (30 mg base)	Begin 1–2 days before exposure; continue for 7 days after leaving malarial area	No	May ↑ cyclosporine levels Can interact with tacrolimus to prolong QT	

Adapted from Chap. 3 "Malaria" in the Centers for Disease Control and Prevention's Yellow Book [130], the AST Guidelines [15], Lexi-Comp®Lexi-Drugs, and Lexi-Comp® Drug Interactions

Brazil, Southeast Asia, and East Africa, whereas cutaneous leishmaniasis is more common in the Mediterranean Basin, Middle East, and Central Asia [131]. Transmission is through sandfly bites. Immunocompromised patients, including SOT recipients, are at higher risk of developing disease and more severe infection [132]. Treatment requires prompt diagnosis and treatment, with options including amphotericin B, pentavalent antimonials, miltefosine, and paromymycin [132]. Although rare, travelers can be exposed when visiting endemic regions. Transplant recipients should take precautions to prevent sandfly bites including use of protective clothing, insect repellent, and treated bed nets and minimize activities during dusk hours [82, 133].

Trypanosoma Species

Trypanosoma species are protozoan parasites that cause two specific disease entities.

In Africa, *Trypanosoma brucei* is transmitted through the tsetse fly and causes African trypanosomiasis or sleeping sickness. Fortunately, due to control efforts, the WHO reports a significant drop in the number of cases and is targeting elimination by 2020 [134]. Therefore, this is unlikely to pose a significant risk to travelers; however, transplant recipients should still take precautions to avoid tsetse fly bites while traveling to endemic areas.

Of more significant concern, in the Americas, *Trypanosoma cruzi* is transmitted through feces of triatomine insects and causes American trypanosomiasis or Chagas disease. It can also be transmitted through blood transfusions and organ transplantation. It is endemic in Mexico and Central and South America. The WHO reports an estimated seven million people worldwide are infected [135]. The disease can cause an acute phase and chronic phase, with the chronic phase leading to cardiomyopathy and disease involving the gastrointestinal tract and nervous system [135, 136]. Treatment requires trypanocidal therapy with benznidazole [136]. The risk of acquiring de novo infection can occur while traveling; however, the incidence of this occurrence is thought to be quite low. Nonetheless, transplant recipients should take precautions to minimize exposure to triatomine bugs by avoiding sleeping in thatched, mud, or adobe housing, by avoiding consumption of products that may have been contaminated with insect feces, and by being cautious of blood transfusions in endemic areas [136, 137].

Babesia Species

Babesia species are protozoan parasites which are transmitted through bites by *Ixodes* ticks. Cases have been reported worldwide; however, they are seen mostly in North America and Europe. Areas of high risk within North America include the Northeast and Midwest United States. Clinical infection can range from asymptomatic to flu-like illness to hemolytic anemia and thrombocytopenia. SOT recipients are at higher risk of severe and fatal infection even with proper treatment [138]. Other immunocompromised patients, including HSCT recipients and especially patients with asplenia, can also have more severe disease and are at risk for prolonged or refractory infection [139, 140]. Treatment consists of combination therapy with atovaquone plus azithromycin or clindamycin plus quinine; duration

of therapy may need to be extended in transplant recipients. In some patients, exchange transfusion may be indicated. Transplant recipients traveling to endemic areas, especially those with plans for significant outdoor activities, should take steps to prevent tick exposure including wearing long sleeves and using insect repellent (DEET). Tick checks should be performed on a regular basis [127].

Environmentally Transmitted Parasite Infections

Parasites can be transmitted through penetration of the skin during environmental exposures such as direct contact with soil or water. These parasites include hookworm (*Ancylostoma duodenale* and *Necator americanus*), *Strongyloides stercoralis*, and *Schistosoma* species.

Strongyloides stercoralis

Strongyloides stercoralis is a helminth or worm. Upwards of 100 million people worldwide are infected. It is found mainly in tropical and subtropical regions but has been reported in temperate climates as well. It is acquired by direct contact with contaminated soil. It can lead to asymptomatic infection or can cause strongyloidiasis affecting the intestinal tract, lungs, and skin. Patients with immunocompromising conditions, including SOT and HSCT recipients, are at higher risk of severe disease including hyperinfection syndrome and disseminated strongyloidiasis. This can lead to critical illness including shock and multi-organ failure with high rates of mortality. Treatment is with ivermectin, and duration depends on the type and severity of infection. Albendazole is an alternative. The risk for short-term travel is low but can increase with prolonged time spent in endemic areas or participating in activities that would increase exposure. Transplant recipients should wear appropriate footwear/shoes while in endemic areas especially if walking in areas that could be contaminated with human feces [141, 142].

Schistosoma Species

Schistosoma spp. are helminths that cause schistosomiasis. Species vary between geographic regions, and clinical syndrome can depend on which species is involved. The majority of the cases occur in Africa, and most common species include *S. mansoni* and *S. haematobium*. Other affected areas include the Middle East (*S. haematobium*) and Asia (*S. japonicum*, *S. mekongi*). Travelers often acquire infection in sub-Saharan Africa. Exposure is through freshwater in endemic areas with infection acquired when swimming, bathing, or wading in contaminated water. Clinical presentation of acute infection, known as Katayama syndrome, consists of fever, headache, diarrhea, and respiratory symptoms. Chronic disease can develop and depends on the type of species causing the infection with *S. mansoni* and *S. japonicum*, whereas *S. haematobium* affects the urinary tract. Treatment is with praziquantel. Travelers to endemic areas should avoid freshwater exposures including swimming, bathing, wading, water adventure sports, etc. [142, 143]

Ingested Parasitic Infections

Parasite infections can be acquired through ingestion of contaminated food or water or accidental ingestion of contaminated dirt/soil. These parasites include amebiasis (*Entamoeba* spp.), cryptosporidiosis (*Cryptosporidium* spp.), cyclosporiasis (*Cyclospora cayetanensis*), fascioliasis (*Fasciola* spp.), giardiasis (*Giardia intestinalis*), taeniasis (*Taenia* spp.), and toxoplasmosis (*Toxoplasma gondii*) among others. Geographic distribution, syndromes, and treatments are infection specific, and more information can be found in Chap. 3 of the *CDC Yellow Book* [144] and in the AST Guidelines on Parasitic Infections in Solid Organ Transplantation [126]. Generally speaking, for all of these parasitic infections, prevention centers around precautions to prevent food- and water-borne illnesses. Transplant recipients traveling to endemic areas or areas with poor sanitation should avoid eating raw or undercooked meats and fish and raw fruits and vegetables that they cannot peel themselves and should ensure safe drinking water. They should not drink from freshwater sources such as lakes, rivers, and streams.

Pre-departure Infectious Disease Evaluation and Recommendations

SOT and HSCT recipients who plan to travel should seek advice from a travel medicine specialist. All transplant recipients should be counseled on the importance of safe travel posttransplant and value of pre-departure assessment; this should be included as part of their pretransplant education and teaching.

SOT recipients should be advised not to travel to high-risk areas during times of increased immunosuppression such as the first year posttransplant or after treatment for rejection. [43, 80, 145] Recommendations for timing of travel post-HSCT depend on the type of transplant. Allo-HSCT recipients should be advised not to travel to high-risk areas for the first 6–12 months posttransplant or if on treatment for graft-versus-host disease (GVHD) with immunosuppressive therapy, whereas autologous (auto)-HSCT recipients may be able to travel as soon as 3–6 months posttransplant [146]. All patients should consult with their transplant physician(s) to ensure it is safe to travel as decisions should be made on an individual basis. Although patients may be out of the highest-risk period, it is important to note the post-HSCT immunization schedule is generally not completed until 24 months posttransplant date. Thus, this should be taken into consideration when determining timing of travel posttransplant and when providing recommendations for minimizing the risk of infection while traveling.

Infectious risk depends on the travel itinerary by both destination and type of travel, and recommendations for prevention of infection will vary accordingly. Important elements of the pre-departure evaluation include review of past medical history, current medications, and travel itinerary including destinations, accommodation type, and potential exposures; counseling on risk reduction strategies; counseling on when and where to seek medical attention should they fall ill while away; administration of recommended vaccinations; and prescribing of prophylactic medications. Patients should verify travel insurance coverage prior to departure.

Finally, a review of important items in the form of a packing list may also be helpful for travelers. Examples of such lists can be found in the *CDC Yellow Book* and the AST Guidelines [15, 147].

Vaccine Recommendations

Patients should be advised to seek pre-travel advice early when planning trips as full vaccine series may require several months prior to departure. Passive immunization with immune globulin can be considered for urgent travel situations. When possible, if patients indicate plans to travel after SOT, travel-related vaccines can be considered pretransplant. This is especially important if there is a need for live attenuated vaccines which are contraindicated posttransplant. SOT recipients should be up to date with their routine immunizations as immunocompromised individuals are at risk of common infections both at home and abroad. Recommendations are available through the AST Guidelines, the CDC, and other publications on routine immunizations in SOT recipients. [44, 114, 148, 149] More specific information regarding travel-related vaccines in immunocompromised individuals can be found in the *Yellow Book* [43] and other publications including recommendations for SOT recipients who travel specifically [15, 72, 80, 148, 150, 151]. Recommended immunizations have been summarized based on these recommendations in Table 3. Patients should travel with their immunization records as well as a waiver for yellow fever immunization indicating contraindication.

Recommended immunizations for HSCT recipients differ from those recommended for SOT. Typically, HSCT patients receive extensive immunization schedule posttransplant as it is believed their previous immunity to vaccine-preventable diseases (VPDs) may have been eliminated during the transplant process. Although post-HSCT immunization schedules differ between allo- and auto-HSCT recipients, both take approximately 18 months to complete and typically finish around 24 months posttransplant [42, 45, 47, 146, 152]. The last immunizations in these series are the live attenuated vaccines, including measles, mumps, and rubella (MMR) and varicella. For those patients who plan to travel once deemed safe to do so, common travel-related vaccines, such as hepatitis A, can be built into the standard immunization schedule. Specific travel-related vaccines should be considered on an individual basis and take into consideration the destination and trip itinerary [29, 47]. Recommended immunizations have been summarized in Table 4.

Risk Reduction of Non-vaccine-Preventable Infections

Education and counseling of patients prior to departure plays an important role in minimizing risk during travel. The AST Guidelines provide further information and helpful summary tables on important travel-related topics for SOT [15]. Similarly, the ASBMT Guidelines provide information for HSCT patients [29]. Basic infectious precautions including hand hygiene, avoiding sick contacts, and use of procedure mask while in transit (e.g., airplanes) or participating in high-risk activities should be reviewed.

Prevention of Food-Borne Illnesses and Diarrhea

Diarrhea is the most common illness of travelers, especially in travelers to low-resource countries. Although, in general, many episodes can be mild and self-limited, travelers' diarrhea can lead to complications and can even be life-threatening. Transplant recipients should be instructed on appropriate food and water precautions [105, 153–155]. They should avoid beverages that contain local water or ice and only drink boiled or bottled water. Other high-risk food and drink including unpasteurized dairy products, raw meats and fish, and undercooked foods should be avoided. Consumption of fruits and vegetables should be restricted to those they can peel themselves. All travelers should carry appropriate antibiotics for self-treatment of traveler's diarrhea. The choice of antibiotic depends on local resistance patterns of enteric pathogens, [105, 106, 156] and interactions with immunosuppressive agents should be taken into consideration (Table 5). Patients should be counseled on when to seek medical attention, such as non-resolving diarrhea, fever, or bloody stools.

Respiratory Infections

Respiratory infections are the second most common infection affecting travelers [56]. High-risk periods of travel include while in transit through public spaces such as airports or while on airplanes. Masks may be helpful in preventing respiratory infections. Active outbreaks of respiratory infections may warrant deferring travel.

Insect Protection

Travelers to areas endemic for mosquito- and tick-borne diseases should be counseled about minimizing insect bites. Strategies including use of repellents containing DEET (N,N-diethyl-3-methylbenzamide), protective clothing with long sleeves, and permethrin-impregnated clothing and bed nets should be considered [43, 105]. Efforts should be made to choose accommodation with air conditioning and screens.

Environmental Exposures

Infections that exist in the environment can pose a threat and include those that transmit via direct contact and those that transmit via respiratory particles or spores.

Water and soil exposure can pose a risk of infections through direct contact. Travelers should avoid swimming or bathing in freshwater when traveling in areas endemic for *Schistosoma* and should always wear footwear when in regions endemic for *Strongyloides stercoralis* [82].

Exposure to endemic fungal infections occurs through inhalation of spores found in the environment. Transplant recipients should avoid activities that place them at higher risk of exposure, and use of procedural masks may help prevent acquisition of infection.

Blood-Borne Pathogens

Travelers should avoid contact with non-sterile needles, syringes, and other medical equipment. If travel is planned to regions where healthcare settings may not be reliable, travelers should consider a first aid kit equipped with sterile needles, syringes, and sutures in case required while abroad.

Sexually Transmitted Infections (STI)

Travelers may be more likely to engage in sexual activity with new partners, counseling should be provided with regard to safe sex practices, and patients should be encouraged to have STI screening performed upon return home should they engage with new partners while abroad.

Post-travel Evaluation

Transplant recipients should contact their transplant center and be evaluated following return from travel if they develop new symptoms of infection. Workup and investigations will depend on evaluation of symptoms and timing of onset, as well as travel history with specific attention paid to destinations, activities, and exposures. In general, travelers who are well on return do not need to be seen after foreign travel. However, if they have been in high-risk situations or have a known or potential exposure to infection, then evaluation for necessary screening should be pursued. Examples of such may include working or volunteering in a healthcare setting, exposure to blood-borne pathogen, new sexual partner(s), etc.

Conclusion

Travel is an important component of many people's lives, whether it is for business, visiting friends and relatives, or leisure purposes. In 2017, the United Nations World Travel Organization documented 1.326 billion international tourist arrivals worldwide [157]. This number is expected to continue to increase. Among those traveling to international destinations include transplant recipients, who are immunosuppressed and at increased risk of infection. Transplant recipients should be counseled on the importance of pre-departure travel assessment when planning trips abroad, especially to areas of higher infection risk. They should seek medical advice before departure, and risk mitigation will depend on destination(s) and trip itineraries and should be tailored to the patients taking into consideration time since transplant, type of transplant, and immunosuppressive therapy.

Key Points

- Importance of safe travel should be discussed during the pretransplant evaluation.
- All transplant recipients should be seen by a travel medicine specialist prior to travel to regions with higher rates of infection.
- SOT patients should not travel to areas with higher infection risk during the first year posttransplant and/or during times of increased immunosuppression.
- HSCT patients should not travel to areas with higher infection risk during the first 3–12 months posttransplant depending on the transplant type and/or during times of increased immunosuppression and/or presence of GVHD.
- Travel recommendations, immunizations, and prophylaxis depend on destination and itinerary. Country-specific recommendations should be followed.

- Vaccine-preventable illnesses:
  - Patients should be up to date with routine immunizations:
    - Travel-related immunizations depend on travel destination.
  - Live vaccines are *contraindicated* in SOT recipients.
  - Live vaccines are contraindicated in HSCT recipients until 24 months post-transplant, no active GVHD, and they are no longer taking immunosuppressive therapy:
    - Patients traveling to countries with yellow fever immunization requirements should travel with an official waiver.
- Prophylaxis:
  - Necessary prophylaxis should be assessed by trip destination and itinerary.
  - One of the most important and common infections that requires prophylaxis when traveling is malaria.
    - Malaria prophylaxis should be based on country-specific guidelines.
    - Assess for drug interactions with immunosuppressant agents.
- Counseling:
  - Topics including prevention of food- and water-borne illness, respiratory infections, insect-borne illnesses, blood-borne infections, and sexually transmitted infections should be covered during the pre-travel visit.
- Patients should travel with adequate supply of medications (especially immunosuppressants) and copies of prescriptions.
- Patients should be aware of transplant centers at which they could seek medical attention if they become ill while away.
- Patients should have adequate travel medical insurance.
- Patients should be aware to seek medical attention if they develop signs and symptoms of infection upon return home after travel.

Introduction

In order to minimize a solid organ transplant (SOT) recipient's risk for infection and injury, it is important to anticipate the risks post-transplantation inherent in routine and not so routine activities of daily living. It is invaluable to orient potential SOT recipients to these risks, as often leading up to transplant they may likely experience debilitation due to chronic illness, yet after SOT can go on to live healthy, fruitful lives with increased exposures and risks. Potential transplant recipients should update their vaccinations, with a particular eye toward ensuring live virus vaccines are prioritized. Education should commence regarding the importance of food and water safety after transplant so recipients may plan accordingly. While often pet ownership is beneficial due to the animal-human bonding, the risks of such

ownership due to animal exposure require careful discussion and planning to minimize potential exposure to zoonotic pathogens post-transplant. Additionally, realistic expectations should be set with regard to travel, occupational environment, and participation in recreational activities. Incorporating such counseling and planning routinely into pre- and post-transplant visits can empower SOT recipients and assure their knowledge of both the risks inherent to everyday living and the best strategies to mitigate such risks.

Pre-transplant Evaluation

Ensuring optimal health after solid organ transplant (SOT) mandates conscious preparation pre-transplantation. Part of this preparation should involve evaluation of home environment including water supply, potential future travel, returning to work, hobbies, and other social activities. Table 1 lists the topic areas that should be part of the pre-transplant evaluation in order to address areas that should be identified, improved upon, and planned for subsequent to transplant.

The pre-transplant evaluation can assist with identifying other potential risks to the SOT recipient including the vaccination status and philosophy of their household contacts. The CDC's Morbidity and Mortality Weekly Report from January 2018 to May 2019 reported on outbreaks of hepatitis A, hepatitis B, measles, and mumps, reinforcing the need to optimize community protection against vaccine-preventable illness, especially for those living with immunocompromised hosts [1–4]. Counseling the SOT recipient pre-transplant hopefully ensures an open dialogue for assessment of the acquisition of new lifestyle infectious risks allowing for continued intervention post-transplant.

Vaccination

As discussed above, optimization of a SOT recipient's vaccine status is ideal in order to prevent morbidity and mortality post-transplant both in everyday life and in planning for potential travel. Preferably, this is initiated pre-transplant and should be reassessed post-transplant with the patient to verify vaccine statuses are staying current. The CDC Advisory Committee on Immunization Practices (ACIP) updates recommendations regarding routine and special vaccinations for adults at least yearly and is located at www.cdc.gov/vaccines/schedules/hcp/imz/adult.html. It is important to review vaccination status frequently of the SOT recipient to ensure updated completeness. In addition, see ▶ Chap. 12, "Vaccination Strategies in Solid Organ and Stem Cell Transplant" for a more complete review of this topic specific to the SOT recipient. Likewise, the American Society of Transplantation published guidelines in 2019 updating general principals and use of specific vaccines in solid organ transplant recipients [5]. Although use of live vaccines is contraindicated in adult SOT recipients post-transplant, significant indirect benefit of live virus vaccination of household contacts can be achieved [6]. Aside from potential risk of transmission of live attenuated influenza vaccine (LAIV), smallpox vaccine, and oral polio vaccines, there is no concern for transmission of live virus vaccines from vaccinated household contacts to their immunocompromised contacts [6]. Smallpox vaccine is no longer routine, and most countries have switched or are switching to the inactivated polio vaccine [7]. In 2019, the World Health Organization (WHO) unveiled a new strategic plan to face multiple global health challenges, including "vaccine hesitancy" – the reluctance to vaccinate despite the availability of vaccines. This is particularly relevant for an immunocompromised host who benefits from "herd immunity" and is at increased risk for the acquisition of vaccine-preventable diseases in the current climate where illnesses such as measles have seen a 30% increase globally [8]. Moreover, within developed countries such as the United States, authors have identified a strong association between vaccine refusal and vaccine-preventable disease outbreaks such as measles and pertussis [9].

Everyday Living Strategies

As the American Society of Transplantation (AST) notes, even after the immediate post-transplant period, the risk of infection remains for the SOT recipient for as long as they are immunocompromised, with periods of enhanced susceptibility [10]. As most pathogens are acquired via direct contact via hands, ingestion, or inhalation, frequent handwashing and avoidance of those with respiratory illnesses are essential ways to minimize acquisition of infectious pathogens [10]. There have been numerous studies performed to evaluate the effect of handwashing in decreasing gastrointestinal and respiratory illnesses. One meta-analysis evaluated the efficacy of different methods of hand hygiene interventions in the prevention of illness and found that education combined with handwashing with antibacterial soap decreased gastrointestinal illness by 50% [11]. In this same analysis, the utilization of

benzalkonium chloride-based hand sanitizers prevented 40% of respiratory illnesses [11]. As well outlined in the AST recommendations for safe living after transplantation and summarized in Table 2, frequent handwashing is strongly recommended but especially after certain activities/exposures. While the WHO and CDC recommend that alcohol-based hand sanitizers (ABHS) not be used on visibly soiled hands, the lack of readily available soap and water in some situations could impede clean hands. As such, investigators at Stanford University investigated the efficacy of ABHS against experimentally soiled hands with dirt, cooking oil, or both after inoculation with 10^7 *E. coli.* They observed that despite participants feeling that their soiled hands were less clean than their unsoiled hands, the ABHS reduced the levels of *E. coli* as well on clean or soiled hands [12]. While noting that laboratory conditions may not entirely reflect everyday life, these data support the use of ABHS as a reasonable temporizing substitute in select circumstances to handwashing until access to soap and water is attained. Practically, in everyday life, ABHS could be utilized while out in public places such as retail locations, recreational facilities, or places of religious worship until proper handwashing can be employed. Similar to recognizing where hand hygiene practices are most important, attention to risks inherent in other everyday activities is imperative to reducing risk for acquisition of infections. As summarized in Table 2, the AST provides guidance on the types of activities to avoid. Certain occupations may require planning in advance of transplantation especially in cases where occupational exposures are inherent and serious consideration given to modification or discontinuation of such employment. In particular, occupations such as farming, bird breeding, construction involving excavation and demolition, landscaping, and arboriculture place SOT recipients at risk for inhalational exposure to fungal infections such as histoplasmosis, coccidioidomycosis, blastomycosis, aspergillosis, and cryptococcosis [13]. Subsequent to transplant if recipients must remain employed in these fields, precautionary measures including N95 particulate respirators and personal protective equipment including non-vented goggles, gloves, and coveralls should be utilized [14]. Exposure to herbivores such as horses can result in *Rhodococcus* infections, which can be

Table 2 Ways to reduce risk of infection from every day activities.

Employ hand washing after	Avoid
Eating or Preparing food	Close contact with persons with respiratory viruses
Changing diapers (if not unavoidable)	Prolonged contact with crowded areas
Touching plants or dirt	Tobacco and Marjuana smoking
Using/cleaning the restroom	Visiting areas with increased risk of exposure to tuberculosis (prisons, homeless shelters, certain healthcare facilities)
Touching animals	Construction areas/areas of excavation
Touching items in contact with animal or human bodily fluids (litter boses/tissues)	Areas with possible exposure to fungal spores: caves, bird cages/coops, soil aerosols via mulching
Collecting or deposing of garbage	Self-piercing, tatooing or needle sharing
Going outdoors or to a public place	
Adapted from [10]	

complicated to diagnose and manage in SOT recipients [15]. Relatedly, recipients should be discouraged from engaging in such activities for leisure.

Akin to avoiding inhalation of decayed vegetation in soil through leisure activities or as part of an occupation, SOT recipients should be counseled against smoking, vaping, and ingestion of cannabis plant-based materials, "medical" or otherwise. This is particularly relevant nowadays with the legalization of recreational marijuana in many regions [16]. Investigators have evaluated the microbiome of cannabis samples obtained from marijuana dispensaries. These samples grew *Pseudomonas aeruginosa* in up to 12% of samples, *Aspergillus fumigatus* in 12% of samples, as well as numerous other Gram-negative bacteria known to be capable of necrotizing lung infections such as *Klebsiella* as well as other fungi and molds such as *Mucor* and *Cryptococcus* in smaller overall amounts [17, 18]. While it's not clear that the presence of such organisms is associated with actual infection, there are several cases in the literature of *Pseudomonas aeruginosa* [19] and *Aspergillus* [20] inhaled via either "bongs," water pipes, or vaping causing necrotizing lung infections and some of these in less immunocompromised hosts than the SOT recipient. There have been few studies evaluating the effect of sterilization to alleviate or abrogate this risk. Some experts recommend heat treatment of dried marijuana leaves to kill mold spores. The SOT recipient should be aware of potential drug interactions with their transplant medications and a higher risk of graft loss due to rejection in those who use cannabis products [21]. Thus, there is no way to safely recommend or approve of the utilization of cannabis plant-based materials in the SOT recipient due to the unquantifiable risk of infection with opportunistic pathogens. Manufactured "edibles" may be a safer alternative as far as decreasing the infection risk, although these products have not yet been adequately studied.

Activities of Leisure

Strategies listed above as recommendations about modifying employment also apply to leisure activities. As outlined, because of the fungi inherent in soil, landscaping and gardening need to be approached with caution. Recreational water exposure-related illnesses can be significant. There have been increasingly recognized *Cryptosporidium* outbreaks, now the leading cause of swimming pool-associated diarrheal illness [22]. SOT recipients should be counseled that chlorine can kill many infectious pathogens but some (especially *Cryptosporidium)* can persist in spite of chlorination. Thus, they should avoid getting water in their mouths and noses when swimming in lakes, ponds, oceans, rivers, and swimming pools [22]. The CDC in 2018 reported 140 separate outbreaks of illness associated with non-treated recreational water from 2000 to 2014 and 493 outbreaks from treated recreational water from the same time period [23, 24]; Table 3 lists the major pathogen causes and the frequency of each in the reported outbreaks. Not surprisingly, the peak incidence of outbreaks in treated and non-treated water is the summer months but with a relatively steady number of outbreaks in treated water all year round [23, 24]. Hot tubs have

Table 3 Recreational water-associated outbreaks: Major pathogen causes and the frequency of each in the reported outbreaks associated with both treated and untreated recreational water from 2000 to 2014. (Data from the CDC [23, 24])

Recreational water associated outbreaks		
Etiology	Treated water	Untreated water
Bacteria	26%	31%
	E. coli>*Shigella*>*Leptospirosis*	*Legionella*>*Pseudomonas*>*Shigella*
Parasite	45%	18%
	Cryptosporidium>Giardia	Cryptosporidium>Avian Schistomiasis>Naegleria fowleri
Virus	3%	16%
	Norovirus	Norovirus
Toxin	4%	4%
	Chlorine	Algae blooms
Unidentified	22%	26%

been associated with *Pseudomonas* and other pathogens (including mycobacteria) and should be avoid after transplant.

Activities including body piercing, tattooing, and pedicures have been associated with acquisition of infections, especially non-tuberculous *Mycobacterium* (NTM). Body piercing can lead to blood-borne infections (especially hepatitis C), although cellulitis is more common and can lead to bacteremia (even endocarditis), Ludwig's angina, Fournier's gangrene, and sepsis or toxic shock [25]. Tattoo ink contaminated with *Mycobacterium chelonae* has caused an outbreak of cutaneous NTM infection in immunocompetent hosts in multiple US states in 2012 [26]. Cutaneous mold infections have also been reported after tattooing in the SOT recipient [27]. There have been several outbreaks of rapid-growing *Mycobacterium* spp. associated with whirlpool footbaths in mostly immunocompetent individuals with one case of fatal cutaneous *Mycobacterium chelonae* in a relatively immunocompromised host [28–30]. The authors of that report caution about pedicures in the setting of open wounds or skin trauma. Additionally, the source of the mycobacteria was felt to be the drains associated with the footbaths with recommendations for salons to utilize a 10% bleach solution to adequately disinfect such drains [28, 29]. As such, SOT recipients should be cautioned of such risk and advised to avoid whirlpool footbaths especially if the integrity of the cleaning cannot be assured.

Sexual Health

Sexual health concerns in the SOT recipients likely exist pre-transplant and based on scant studies in the literature exist post-transplant [31]. One study in liver transplant recipients found that about 25% of men and women experienced sexual health

concerns pre-transplant that increased to 51% and 40%, respectively, post-transplant [31]. Most of the concerns are related to sexual function, desire, and dyspareunia. Transplant clinicians may become the primary physician many SOT recipients see after transplant and candid discussion about sex (especially safer sex for those not in monogamous relationships) may be important to ensure avoidance of sexually transmitted infections (STI). There have been reports of HIV acquisition through sex after transplantation [32]. In addition, acquisition of other STIs such as syphilis has been described as well. Due to low infectious doses, inadvertent consumption of fecal material during sexual activities involving oral-anal and unprotected genital-anal contact can lead to human to human transmission of *Shigella, Giardia*, and *Entamoeba histolytica* [33]. Counseling should therefore be provided about avoidance of such sexual practices post-SOT to minimize risk of sexually transmitted enteritis. While most transplant recipients will be adequately vaccinated for hepatitis B prior to transplant and thus protected against sexual transmission, SOT recipients should be counseled about other viral infections such as CMV, HSV, and EBV and their enhanced susceptibility if seronegative prior to transplant and avoidance of sex with partners who may be manifesting symptoms of such infections. Testing provided in sexual health clinics may be useful for those entering longer-term relationships. Sexual activity when pursued safely can be fulfilling and infectious risk can be minimized.

Food and Water Safety

Access to safe water is essential after SOT because the most common causes of water-associated disease outbreaks due to private water sources (i.e., private wells) per the CDC as of 2010 are hepatitis A, *Giardia, Campylobacter, Shigella, E. coli, Cryptosporidium, Salmonella,* and *Yersinia enterocolitica* [34]. As such, assessment of water sources prior to solid organ transplant can assist recipients with advance planning especially if they have a private water source associated with their home. Municipal water supplies in most regions where transplants are done would be safe, both well chlorinated and tested as the provision of safe water both in the United States and internationally is a defining characteristic of a developed country [35]. In the United States, the Safe Drinking Water Act of 1994 enacted many state- and federal-level controls governing municipal water supplies [36]. Groundwater supplies half the US's water supply and can become easily contaminated. Further, it is estimated that over 13 million US households rely on private wells [37]. Ensuring patients are aware to be cognizant of water use after intense rainstorms is extremely important as in the event of extreme weather especially significant rainfall; groundwater may contaminate private wells increasing risk for infectious pathogens. In addition, in certain highly populated areas, common sewer overflow during times of extreme precipitation can dump untreated overflow into drinking water sources, and in such areas, there has been association with GI illnesses after such events [38]. Thus, SOT recipients should

be instructed to attend to boil water advisories after both periods of significant storms and any disruption in usual water supply to prevent ingestion of potentially contaminated drinking water. More concerning, in addition to the issues related to contaminated water, studies have found contamination of drinks obtained from beverage dispensers such as soda fountains with coliform bacteria [39]. Because of this, SOT recipients should be cautioned to avoid such sources for consumption. Finally, many SOT recipients may choose bottled water instead of using tap or boiled water. The FDA does regulate bottled water as a packaged food. Unless bottled water is distilled, filtered through a 1 micron unit, or treated with ozonation or reverse osmosis, organisms such as *Cryptosporidium* can persist [40]. According to the Centers for Disease Control and Prevention, 48 million persons get sick, 128,000 are hospitalized, and 3,000 die from foodborne infection and illness in the United States each year [41]. In the United Kingdom, the Government National Food Survey collects population-based food consumption data and can estimate the incidence and effect of foodborne infection; data collected from 1996 to 2000 estimated 1,724,315 cases of indigenously acquired foodborne infection with 4% of these being attributable to human transmission through food handlers [42]. Infection attributed to ingestion of chicken accounted for 30% of the foodborne illnesses likely accounting for the *Campylobacter* and nontyphoidal *Salmonella* cases. Not surprisingly, *Listeria monocytogenes* and *E. coli* 0157: H7, while only accounting for 0.1% of all cases of foodborne illness, unfortunately accounted for 15% of the deaths [42]. Authors from the CDC in the United States have published data compiled from surveillance from 2000 to 2008 and population data as of 2006 estimating the incidence of foodborne illness [43]. It was necessary to perform some modeling, and the types of potential pathogens may be underreported due to data being extrapolated from laboratory surveillance and not due to active disease surveillance [43]. The authors found that in the United States, similar to the UK data, norovirus caused the most illnesses; nontyphoidal *Salmonella* spp., norovirus, *Campylobacter* spp., and *T. gondii* caused the most hospitalizations; and nontyphoidal *Salmonella* spp., *T. gondii*, *L. monocytogenes*, and norovirus caused the most deaths [43]. These data are particularly important when counseling the SOT recipient due to their enhanced susceptibility to severe or persistent infections with pathogens such as *Listeria monocytogenes* and norovirus, respectively. In preparation for SOT and after transplantation, recipients should be educated about the risk of illness due to foodborne infections. The US Federal Drug Administration (FDA) with the US Department of Agriculture and the US Department of Health and Human Services have a published guide available from 2006 and updated in 2011 that it is downloadable from the FDA's website that outlines safe handling of food, safer food choices if eating outside of home, temperature and hygiene guidance, as well as a list of the most common foodborne pathogens and associated foods and the most common symptoms of illness with such pathogens [44]. In addition, this guide is available in both English and Spanish and contains resources with instructions on procedures if foodborne illness is suspected and tip lines to contact with questions. Consideration should be given to providing such a guide to

recipients in addition to verbal instructions provided by transplant team members especially nutritionists. Further reinforcing food and water safety as a part of ongoing post-transplant care can ensure such issues are not minimized or lose their importance as the time increases from receipt of an organ transplant.

Animal and Insect Precautions

As the human population expands with increasing contact with animals and the environment and as the One Health Initiative purports, an integrative effort of multiple disciplines working locally, nationally, and globally is necessary to ensure the health and preservation of all [45]. One Health is working to survey infections in domestic and wild animals as others have reported that approximately 75% of newly reported human infections have emerged from animal reservoirs [46]. This is of particular importance in the field of solid organ transplantation as zoonotic infections have become additionally recognized and reported [47]. In addition, trends are emerging where exotic or unconventional pets are being captured locally or imported, and with these unconventional pets, unusual diseases such as salmonellosis, tularemia, monkeypox, LCMV, and yersiniosis are being transmitted to their human owners [48]. In addition, there have been several reports of pet store-acquired birds leading to psittacosis [49]. As such, ownership of exotic pets should be discouraged, and this should be discussed pre-transplant and reiterated subsequently.

Dogs, cats, and fish are generally acceptable pets for SOT recipients. When possible, adopting older animals may be preferable as there may be fewer bites and scratches. Transplant recipients should not change kitty litter, nor should they wash fish tanks. In general, other animals are not recommended. All pet animals should receive routine veterinary care. Attention should be provided to pet's diet, avoiding raw meat or eggs and discouraging consumption of toilet or other non-potable water [47]. The CDC provides guidance entitled "Healthy Pets, Healthy People" that offers helpful information and instruction for both SOT recipients and care providers about the care of domestic animals and avoidance of certain animals as pets and in their natural environments [50].

When addressing zoonoses, it is imperative to also address vector-borne illness, as animals may serve as the reservoirs for such diseases for which humans become infected. Some domestic animals may provide a means for vectors such as ticks to access humans, i.e., a dog that brings a tick from outdoors into a human's bed when sleeping with its owner. There are cases in the literature of SOT recipients with infections due to vector-borne infections such as babesiosis, anaplasmosis, and West Nile virus but little about the overall incidence [51, 52]. Regardless, the clinical courses reported are typically more severe than in non-SOT hosts; thus, avoidance of insect bites through the use of DEET application, clothing, avoidance, etc. should be routinely practiced. In addition, if traveling to malaria-endemic regions, SOT recipients should be prescribed malaria prophylaxis and advised about bed netting in addition to the other measures advocated for daily living [51].

Travel Advice

Pre-transplant counseling about future travel is essential and may be of particular importance to the foreign-born SOT recipient. Although only 13% of the US population is foreign-born, 37% of international travelers from the United States list visiting friends and relatives (VFR) as their reason for travel [53]. Furthermore, in a large travel clinic study in Canada from 2001, two thirds of the SOT recipient travelers surveyed were foreign-born [54]. Additionally, when foreign-born SOT travelers are VFRs, they experience higher risk for acquisition of travel-associated infections most often due to lack of awareness, potential last minute travel (i.e., returning for family illness or death), travel for longer duration, and living a local lifestyle with exposure to less safe food and water and mosquito netting [53]. Pre-transplant evaluation of foreign-born SOT recipients allows for updating routine vaccines, ensuring immunity to vaccine-preventable illnesses, and assessing need for live vaccines such as MMR, varicella, and yellow fever prior to immunosuppression. Furthermore, for any SOT recipient, education regarding safe eventual travel can be initiated and advice given around seeking future pre-travel counseling visits. Good habits with regard to food and water safety should continue to be followed, with emphasis placed on not eating street food or raw fruits or vegetables that can't be peeled. In addition, routine vaccinations such as influenza vaccine should be updated, and consideration for non-live travel vaccines such as inactivated polio, typhoid vaccine, meningococcal vaccine, and hepatitis A vaccine should be made depending on the area of travel. For those traveling to yellow fever regions, they should be supplied with a Yellow Card stating that they cannot undergo yellow fever vaccination given their immunosuppression. The CDC recommends that several key education points be discussed with immunocompromised travelers: developing an illness contingency plan with an identified clinic/hospital; bringing extra medications in case of travel delay; avoiding procuring medications during travel due to risk of counterfeit; use of sun protection; vigilant food and water precautions; and travel with a health kit [55]. In addition to these measures, travel to high-risk destinations should be postponed until at least a year after transplantation [55]. Malaria chemoprophylaxis should be prescribed for SOT recipient travelers to endemic areas [55]. Strict mosquito and other insect precautions should be emphasized as diseases like dengue, Zika, chikungunya, Chagas, and leishmaniasis can cause major illness in immunocompromised hosts [56]. While such extensive travel counseling may be perceived as excessive especially by those foreign-born who are traveling to visit friends and relatives, such measures should be planned for and discussed pre-transplant and emphasized subsequent to receipt of organ transplantation.

Conclusion

The benefits of longevity by virtue of organ transplantation need to be closely protected by education before, during, and after transplantation about potential infectious risks and measures to mitigate such exposures. Additionally, SOT

recipients cannot stand alone in their efforts toward modifying their risks. Household contacts should be considered and advice offered toward moderating their contribution to risk by encouraging updating their vaccines and encouraging them to assume responsibility of daily tasks/chores that should be avoided by SOT recipients such as direct animal care and gardening. Additionally, while many activities are still able to be enjoyed after transplant such as career activities, travel, and recreation, careful preparation should be employed and reiterated by care providers to mitigate any infectious risks inherent in such activities and implement risk reduction behaviors if such activities are embarked upon. A longitudinal preventative health strategy based on the topics addressed here can assist with maintenance of health and avoidance of infection and its associated morbidity and mortality.

Key Points

- Safe living after solid organ transplant (SOT) involves preparation pre-transplant.
- Vaccine status evaluation should be continually reassessed for the SOT recipient and household contacts before and after transplant.
- Avoidance of environmental pathogens is ideal, but if it cannot be avoided, then personal protective equipment should be consistently used.
- Guidance exists and should be made readily available to the SOT recipient about food and water safety to minimize risk for foodborne illness.
- Animal-human bonding may be beneficial but certain animals as pets engender greater risk than others and such ownership should be avoided.

Introduction to Vaccination in Transplant Recipients

Patients who have undergone solid organ transplant (SOT) or hematopoietic stem cell transplant (HSCT) are at a higher risk than the general population of contracting a vaccine-preventable illness, by virtue of their immunosuppressed state. It follows

that vaccination in the transplant patient is an important strategy in mitigating the risk of infectious complications and mortality post-transplant. Given the significant differences in immunogenicity post-SOT and HSCT, the optimal strategy for vaccination in each of these two populations differs.

Recipients of SOT are chronically at risk of infections due to their lifelong use of immunosuppressive medications. The ideal strategy regarding vaccination in the SOT population is to ensure the patient is up-to-date on their immunizations *prior* to the transplant occurring. There are two important principles that govern this recommendation. First, live vaccines are generally contraindicated once a patient has undergone SOT, given the risk of enhanced viral replication in the immunosuppressed patient [1, 2]. Thus, when possible it is important to ensure all live vaccines are administered $\geq$4 weeks prior to transplantation. Second, while inactivated vaccines are generally considered safe in the SOT population [3–5], it is well-known that the immune response to vaccines in this population can be dampened by the use of immunosuppressive medications. Therefore, administration of all recommended vaccines prior to transplant is ideal. In certain situations, however, there may not be enough time to fully immunize a patient prior to undergoing SOT, or certain vaccines might require annual or booster doses in the future. In these cases, careful timing of vaccination post-transplant is critical. Guidelines generally recommend administration of inactivated vaccines begins 3–6 months following organ transplantation, with certain exceptions [6]. This is to avoid vaccinating soon after receipt of induction immunosuppression or while on high doses of immunosuppressive medications that can impair T- and B-cell responses and thus hinder the ability to mount an appropriate immunogenic response. In the absence of graft rejection or other complications, immunosuppression has generally been tapered to maintenance doses by 3–6 months post-transplantation, making immunization more ideal after this time period.

The basic principle behind HSCT involves eliminating disease using cytotoxic therapy in conjunction with immune replacement using a donor's or one's own disease-free stem cells. By way of this process, much of the transplant recipient's immunity to specific pathogens is lost. Thus, in this population, regardless of a patient's vaccination history prior to HSCT, all or most immunizations must be readministered in a carefully timed schedule following HSCT. However, in contrast to SOT patients who require lifelong immunosuppression, HSCT recipients are expected to eventually reconstitute their immune system. It can take up to 3 months before B- and T-cell counts begin to recover post-HSCT. B-cell count recovery can be further delayed in patients who receive rituximab post-transplant. Counts generally recover to a level acceptable enough to mount an immune response to vaccines by 6–12 months following HSCT, barring any complications such as graft-versus-host disease (GvHD) or graft rejection [7]. Thus, in usual circumstances, guidelines recommend the reintroduction of inactivated vaccines 6–12 months following HSCT [7]. Given HSCT patients are expected not to require lifelong immunosuppression, there is no lifelong contraindication to live vaccines as there is in the SOT population. At 24 months post-HSCT, a patient is generally considered immunocompetent again, provided there has been no history of GvHD or other issues requiring

prolonged immunosuppressive therapy. Thus, guidelines suggest administration of live vaccines is safe starting at 24 months post-HSCT, as long as the patient is free of GvHD and is off all immunosuppressive medications [7]. Although the process of immune recovery differs between autologous and allogeneic HSCT recipients, guidelines recommend the same vaccination schedule should apply for all HSCT recipients, regardless of type [7].

In summary, timing of vaccination following SOT and HSCT is critical in order to maximize immune response and safety post-transplant. A general outline of optimal timing of immunizations in SOT and HSCT recipients is presented in Tables 1 and 2, respectively. Unless otherwise specified, vaccination *prior* to SOT and/or HSCT is recommended in accordance with guidelines for the general population. Details and exceptions pertaining to each vaccine will be discussed further in the text that follows.

Specific Vaccine Recommendations

Vaccination Against Influenza

Influenza remains a major public health concern, and each year contributes significantly to morbidity and mortality in the general population. It is well-known that the risks associated with influenza are even higher in certain vulnerable populations, including in those who have undergone SOT or HSCT. For example, progression to lower respiratory tract infection or pneumonia is reportedly more common in transplant recipients than in the general population, with the incidence of influenza pneumonia ranging from 22.1 to 32.5% [8–11]. Vaccination against influenza is associated with lower viral loads at the onset of influenza infection, lower incidence of progression to pneumonia, and a lower rate of ICU admission [8]. Transplant recipients may still be at risk of developing infection secondary to influenza due to reduced immunogenicity of the vaccine as compared to the general population; however, in this subset of patients who do develop disease despite vaccination, disease severity is significantly reduced. Thus, annual vaccination against influenza is strongly recommended in both the SOT and HSCT populations [6, 7, 12].

There are two main types of influenza vaccine available: the live attenuated influenza vaccine (LAIV) and the inactivated influenza vaccine (IIV). The LAIV is contraindicated in transplant recipients given the theoretical risk of viral replication following its administration. The IIV is currently available either as a trivalent (containing three virus strains) or quadrivalent (containing four virus strains) formulation. Among these, the trivalent vaccine has been best studied in the transplant population and is available in standard-dose, high-dose, and adjuvanted formulations. Specific recommendations with respect to influenza vaccination in both the SOT and HSCT populations will be discussed below.

Recommendations in SOT. As previously mentioned, administration of inactivated vaccines is generally recommended to begin 3–6 months post-transplant in the SOT population [6]. However, given the significant risks associated with

Table 1 Recommended timing of vaccination in SOT patients

Vaccine	Recommended schedule
Influenza	Inactivated vaccine recommended annually beginning as early as 1 month post-SOT depending on timing of transplant relative to timing of local influenza season
Streptococcus pneumoniae	Recommended as a three-dose schedule: Conjugated vaccine followed by polysaccharide vaccine ≥8 weeks later, followed by polysaccharide booster vaccine 5 years later[a]
Neisseria meningitidis	Recommended in accordance with guidelines for the general population, except in certain high-risk scenarios
Haemophilus influenzae B	Recommended in accordance with guidelines for the general population
Tetanus, diphtheria, pertussis	Recommended in accordance with guidelines for the general population
Hepatitis B	Recommended as a three-dose schedule ideally at time 0, 1, and 6 months; alternatively may be administered as an accelerated schedule at time 0, 1, and 2 months or time 0, 7, and 21–28 days with a booster dose at 1 year
	Recommended in non-immune patients pre-transplant, but can also be administered beginning 3–6 months post-transplant; consider administration of high-dose rather than standard-dose vaccine in patients with end-stage kidney or liver disease
Hepatitis A	Recommended as a two-dose schedule given prior to liver transplant in non-immune candidates; if unable to administer prior to transplant, can administer post-transplant beginning at 3–6 months
	In all other organ transplant candidates/recipients, vaccination is recommended only if exposure risk is high (e.g., travel, lifestyle factors) as is recommended in the general population[b]
Human papillomavirus	Recommended as a three-dose schedule of quadrivalent or nonavalent vaccine at time 0, 2, and 6 months ideally prior to transplant; if unable to complete series prior to transplant, immunization can occur post-transplant beginning at 3–6 months
	Recommended for men and women up to age 45
Varicella	One dose of live attenuated viral vaccine is recommended to be given ≥4 weeks prior to transplant in non-immune patients, followed by a second dose if seroconversion has not occurred after one dose[c]
	Contraindicated post-transplant in adult patients
Herpes zoster	VZV-seropositive patients ≥ age 50 can receive one dose of live attenuated vaccine ≥4 weeks prior to transplant; alternatively vaccination with inactivated recombinant subunit vaccine can be administered as a two-dose schedule ≥8 weeks apart beginning 3–6 months post-SOT
	Live attenuated zoster vaccine is contraindicated post-SOT
Measles, mumps, rubella	One dose of live attenuated viral vaccine is recommended in non-immune patients ≥4 weeks prior to SOT, followed by a second dose if seroconversion has not occurred after one dose
	Contraindicated post-transplant in adult patients

[a]This is the recommendation in pneumococcal vaccine-naïve patients; see Table 3 for recommendations in other scenarios

[b]Given current outbreak of hepatitis A virus in the United States, consider vaccination of all non-immune transplant candidates

[c]This recommendation is based on guidelines published by the American Society of Transplantation; guidelines by the Infectious Diseases Society of America suggest administration of two doses of varicella vaccine in non-immune transplant candidates, with each dose 4 weeks apart.

Table 2 Recommended timing of vaccination in HSCT patients

Vaccine	Recommended schedule
Influenza	Inactivated vaccine recommended annually beginning as early as 3 months post-HSCT depending on timing of transplant relative to timing of local influenza season
Streptococcus pneumoniae	Recommended as a three-dose schedule of conjugated vaccine beginning at 3–6 months post-HSCT with each dose administered 1 month apart, followed by one dose of polysaccharide vaccine at 12 months post-HSCT in those without GvHD; in those with GvHD, a fourth dose of conjugated vaccine can be administered instead
Neisseria meningitidis	Recommended as a two-dose schedule of quadrivalent conjugated vaccine beginning at 6 months post-HSCT in those aged 11–18 years; one booster dose at age 16–18 when the first dose was given between 11 and 15 years of age
Haemophilus influenzae B	Recommended as a three-dose schedule of conjugated vaccine beginning at 6–12 months post-HSCT
Tetanus, diphtheria, pertussis	Recommended as a three-dose schedule of full-dose diphtheria toxoid vaccine beginning 6–12 months post-HSCT
Hepatitis B	Recommended as a three-dose schedule in non-immune patients beginning at 6–12 months post-HSCT at time 0, 1, and 6 months
Hepatitis A	Recommended in accordance with guidelines for the general population
Human papillomavirus	Recommended in accordance with guidelines for the general population
Varicella	Recommended as a two-dose schedule given $\geq$4 weeks apart starting $\geq$2 years following HSCT in non-immune patients as long as patient is off all immunosuppressive therapies with no evidence of active GvHD
Herpes zoster	Live attenuated vaccine is contraindicated post-HSCT. There is not enough data to recommend use of inactivated recombinant subunit vaccine post-HSCT; if eligible, vaccination should occur in accordance with recommendations for the general population prior to transplant
Measles, mumps, rubella	One dose of live attenuated viral vaccine is recommended in non-immune patients beginning at $\geq$2 years post-HSCT, as long as the patient is off all immunosuppression, and there is no evidence of active GvHD

development of influenza infection in this population, vaccination against influenza specifically is recommended as early as 1 month post-SOT if the timing of transplant coincides with influenza season [6, 12, 13]. Anecdotal concerns have been raised about the potential for triggering organ rejection with early administration of influenza vaccine post-SOT; however, several studies that have looked at the development of HLA alloantibodies and rejection rates post-vaccination have refuted this finding [3, 4, 14, 15].

Regarding immunogenicity of the influenza vaccine, studies report seroprotection and seroconversion rates between 15% and 93% with use of the trivalent IIV in the SOT population [16]. This varying response rate depends on a number of factors, including type of transplant, timing from transplant, and type and intensity of immunosuppression. Given the overall suboptimal response to influenza vaccination in SOT recipients, numerous methods have been studied in

an attempt to increase immunogenicity to the vaccine in this population. For example, a randomized controlled trial (RCT) comparing a high-dose intradermal influenza vaccine to the standard-dose trivalent intramuscular vaccine revealed no significant difference in response rates to the two vaccines in SOT patients [14]. In fact, similar to the standard-dose trivalent vaccine, response rates to the high-dose intradermal vaccine remained quite a bit lower in the SOT population than those observed in the immunocompetent population [14, 17]. Another trial compared MF59-adjuvanted IIV to non-adjuvanted IIV in a cohort of SOT patients [18]. Both vaccines elicited similar seroprotection and seroconversion rates in the overall cohort. However, a subgroup analysis found that the group aged 18–65 appeared to respond significantly better to the adjuvanted vaccine. A recent RCT examined the efficacy of one dose of IIV as compared to a booster strategy whereby two doses were administered 5 weeks apart [19]. In the per-protocol analysis, short-term seroconversion rates to all three vaccine strains were significantly higher in the group who received a booster dose of vaccine; this result was not, however, demonstrated in the modified intention to treat analysis. Most promising is the recent evidence examining the immunogenicity of a high-dose trivalent IIV, containing four times the dose of each antigen as the standard-dose vaccine (60 μg vs. 15 μg). In the general population, the high-dose inactivated influenza vaccine is approved for use in patients ≥65 years of age. Recent data in the SOT population suggest significantly higher seroconversion rates with use of the high-dose trivalent IIV as compared to the standard-dose vaccine [20]. Anecdotally, some transplant centers are now suggesting administration of the high-dose trivalent IIV for all solid organ transplant recipients ≥18 years of age.

Recommendations in HSCT. Influenza infection in the HSCT population can carry with it an even higher mortality risk than that of the SOT population [8]. Thus, although the general recommendations for administration of inactivated vaccines suggest beginning at 6–12 months post-HSCT, influenza vaccination presents an exception. Guidelines recommend influenza vaccination as early as 3–4 months after HSCT, depending on the timing of transplant in relation to influenza season [7, 12, 21]. Because immune reconstitution usually occurs earlier in autologous than allogeneic HSCT recipients, it is possible that earlier administration of influenza vaccine in autologous recipients might produce an effective immune response; however, there are no specific data confirming this. Similar to the SOT population, it is important to strike a balance between early protection of the individual against influenza infection through vaccination and vaccinating at a point where the immune system has shown some signs of recovery, so as to elicit a greater immunogenic response.

Safety of the influenza vaccine has not been a major concern in the HSCT population. However, immunogenicity of the standard-dose trivalent IIV has been shown to be lower in the HSCT population as compared to the general population [22]. Response rates to seasonal influenza vaccine are greater as the interval between HSCT and vaccination increases, with rates approaching those of immunocompetent individuals at around 2 years post-transplantation [23]. In

addition to time from transplant, other factors associated with a lower vaccine response rate include lymphopenia, hypogammaglobulinemia, GvHD, type and intensity of immunosuppression, and the use of rituximab [22–26]. Various strategies have been trialed in order to improve influenza vaccine immunogenicity in the HSCT population. An RCT comparing an adjuvanted trivalent IIV with the non-adjuvanted trivalent IIV showed similar vaccine response rates between groups [24]. Another RCT comparing one versus two standard doses of influenza vaccine given 4 weeks apart revealed no significant increase in the immunogenic response following receipt of the second vaccine [27]. Overall, the use of granulocyte-macrophage colony-stimulating factor along with influenza vaccination in HSCT recipients has not been shown to increase response rates, although, in patients vaccinated at <1 year post-HSCT, and in allogeneic HSCT recipients, a higher response rate to the influenza B antigen was demonstrated [28]. In a study evaluating the effectiveness of HSCT donor or recipient pre-transplant vaccination, pre-transplant recipient vaccination resulted in protective titers up until day 60 post-transplant [29]. Finally, an RCT evaluating the high-dose trivalent IIV as compared to the standard-dose trivalent IIV in the HSCT population resulted in greater immunogenicity against influenza in those who received the high-dose vaccine [30]. Thus, use of high-dose IIV may be the optimal strategy for protection against influenza in the HSCT population, although the data are derived from small numbers of patients and not yet incorporated into guidelines [7, 21].

Vaccination Against Pneumococcal Disease

Pneumococcal disease, or infection secondary to *Streptococcus pneumoniae*, is a vaccine-preventable illness that can cause invasive disease in the form of bacteremia, pneumonia, or meningitis. It causes significant disease in the immunocompetent population, but the risk of invasive pneumococcal disease is much higher in both SOT and HSCT recipients [31, 32].

One of the major virulence factors used by *S. pneumoniae* is its capsular polysaccharide, which plays an important role in the prevention of phagocytosis, and complement activation. To date there have been over 92 serotypes of *S. pneumoniae* identified, differing from each other on the basis of antigenic variations in their capsular polysaccharides. There are two main pneumococcal vaccines available. The 23-valent pneumococcal polysaccharide vaccine (PPSV-23) has coverage against 23 serotypes of *S. pneumoniae*, whereas the 13-valent pneumococcal conjugate vaccine (PCV-13) covers 13 serotypes of *S. pneumoniae*. Guidelines recommend SOT and HSCT recipients receive both vaccines as each has its own advantages [6, 12, 21]. Protein-conjugated vaccines such as PCV-13 typically provide greater immunogenicity. They do so by inducing a T-cell-dependent immune response that leads to the formation of memory B-cells conferring long-term protection. In turn, polysaccharide vaccines such as PPSV-23 typically result in a poor memory B-cell response; however, the advantage of the PPSV-23 vaccine is that it

includes a broader range of pneumococcal serotypes (23 vs. 13 serotypes). The specific recommendations with respect to vaccination against pneumococcal disease for SOT and HSCT recipients will be discussed in detail below.

Recommendations in SOT. Studies have shown the risk of contracting invasive pneumococcal disease in the SOT population is as high as 13–41 times that of the general population, depending on the transplanted organ [33]. In a 10-year prospective population-based surveillance study performed in order to better understand the epidemiology of invasive pneumococcal disease in the SOT population, it was found that 85.0% of invasive pneumococcal infections in SOT recipients were due to a serotype included in PPSV-23 [31]. In this study only 23.8% of SOT recipients who developed invasive pneumococcal disease had been vaccinated using PPSV-23 within the past 5 years. These data further confirm the importance of immunization against pneumococcal disease in the SOT population. Despite this fact, pneumococcal vaccination rates among SOT recipients have been reported to be as low as 40% [34].

In the SOT population, studies have not demonstrated an increased immunogenic response to conjugated pneumococcal vaccination as compared to the polysaccharide vaccine [34, 35]. In an RCT designed to evaluate the immunogenicity of a conjugated as compared to a polysaccharide pneumococcal vaccine in 60 kidney transplant recipients, overall antibody titers were similar between groups at 8 weeks post-vaccination, although they were greater for serotype 23F in the conjugated vaccine group [34]. In a long-term follow-up of this study, it was noted that antibody titers for both groups declined significantly and were similar to baseline titers after 3 years [35]. More recently, in a prospective cohort study examining kidney transplant recipients immunized with PCV-13, 27% of patients seroconverted to 0 serotypes, 58% to 1–8 serotypes, and 16% to $\geq$9 serotypes [36]. As an alternate solution, experts have suggested a prime-boost strategy may improve vaccine immunogenicity in SOT patients, whereby the conjugated pneumococcal vaccine is given initially followed by a boost with the polysaccharide vaccine a minimum of 8 weeks later. An RCT designed to evaluate this method in adult liver transplant recipients revealed no significant immunogenicity benefit of the prime-boost strategy as compared to those receiving a single dose of "unprimed" polysaccharide vaccine [37]. Similarly, an RCT performed in adult renal transplant recipients revealed no significant difference in immune response with use of the prime-boost strategy as compared to the group that received two doses of polysaccharide vaccine 1 year apart [38]. There are prospective data in the pediatric SOT population to suggest that boosting with one dose of polysaccharide vaccine following completion of a primary series with conjugated vaccine enhances the immunogenic response in heart and liver transplant recipients; however, this has not yet been demonstrated in the adult SOT population [39]. Nevertheless, the Advisory Committee on Immunization Practices (ACIP) does recommend use of the prime-boost strategy for pneumococcal vaccination in immunocompromised hosts, including in adult SOT recipients [40]. This recommendation is also reflected in the most current guidelines regarding vaccination in SOT recipients [6, 12]. Additionally, given antibody titers are known to wane post-vaccination of the SOT recipient, guidelines also recommend

Table 3 Timing of PCV-13 and PPSV-23 vaccination in SOT recipients

Previous doses of pneumococcal vaccine	Recommended vaccination schedule
No previous pneumococcal vaccine	PCV-13 followed by PPSV-23 ≥8 weeks later, followed by PPSV-23 booster 5 years later
Previous PPSV-23	Wait ≥1 year prior to giving PCV-13 followed by PPSV-23 ≥8 weeks later (as long as 5 years has elapsed since previous PPSV-23 dose)
Previous PCV-13	Wait ≥8 weeks prior to giving PPSV-23 followed by PPSV-23 booster 5 years later

a booster dose of PPSV-23 5 years after receipt of the first dose [6, 40]. Table 3 outlines specific recommendations regarding timing of each vaccine in relation to one another in a number of different scenarios.

Recommendations in HSCT. HSCT recipients are at high risk of developing invasive pneumococcal disease; studies have shown the incidence is as high as 30.2 times that of the general population [41]. The risk appears to be higher in allogeneic than autologous HSCT recipients, and among allogeneic HSCT recipients, the risk is highest in those with chronic GvHD [42]. In the allogeneic HSCT population, this increased risk can be attributed in part to impaired reactivity to polysaccharide antigens, IgG2 deficiency, and decreased production of *S. pneumoniae*-specific opsonizing antibodies, which are all important in the regulation of pneumococcal infection. Chronic GvHD impairs immune reconstitution and requires treatment with immunosuppressive medications, further impairing the host's immune response. Although some HSCT patients may have been vaccinated against pneumococcal disease prior to transplantation, there is a gradual loss of acquired immunity that occurs after HSCT. Thus, re-vaccination post-HSCT is an important strategy in order to mitigate the risk of invasive pneumococcal disease.

A retrospective study examining the epidemiology of invasive pneumococcal disease in hematology patients in France revealed that 84% of serotypes causing disease would have been covered by PCV-13 and 92% by PPSV-23 [43]. Another study examining epidemiology of invasive pneumococcal disease in HSCT recipients in Toronto, Canada, revealed that 100% of serotypes causing disease would have been covered by PPSV-23 [41]. In this study, only 21.4% of HSCT recipients who developed invasive pneumococcal disease had been vaccinated in the past 5 years. Vaccination with PPSV-23 alone has been shown to result in protective antibody responses in as few as 19% of HSCT recipients after 2 years [44]. In an RCT comparing HSCT donor and recipient vaccination with polysaccharide vaccine as compared to donor and recipient vaccination with conjugated vaccine, where donors were vaccinated prior to stem cell harvest, and recipients 6 months post-HSCT, immunization with conjugated vaccine was found to be more immunogenic than vaccination with polysaccharide vaccine [45]. Knowing that a significant proportion of infections secondary to *S. pneumoniae* occurs within the first year post-HSCT, Cordonnier et al. performed an RCT examining early versus late immunization with conjugated pneumococcal vaccine in allogeneic HSCT

recipients. The results suggested that vaccination with three doses of conjugated pneumococcal vaccine beginning at 3 months post-HSCT was non-inferior to vaccination beginning at 9 months post-HSCT when measuring antibody titers 1 month after completion of the three-dose series [46]. However, at 24 months post-HSCT, response rates were significantly higher in the late vaccination group, suggesting faster waning of antibody titers in the early vaccination group. Additionally, the effect of a booster dose of PPSV-23 following the primary series was greater in the late vaccination group. Interestingly, of the patients who did not respond at all to three doses of conjugated vaccine, 41% appeared to respond to the antigens in the conjugated vaccine after receiving a booster dose of PPSV-23. Additionally, PPSV-23 vaccination as a booster following a primary vaccination series with conjugated pneumococcal vaccine has been shown to confer protection against additional antigens not found in the conjugated formulation [47]. Finally, in a study examining allogeneic HSCT recipients age $\geq$2 years, three doses of PCV-13 administered 1 month apart, beginning at 3–6 months post-HSCT, resulted in protective antibody responses [48]. An additional fourth dose of PCV-13 elicited antibody levels similar to those achieved with a single dose of PCV-13 in immunocompetent individuals.

With all of the available literature, current guidelines suggest administration of three doses of PCV-13 to HSCT recipients, beginning at 3–6 months post-transplantation. At 12 months post-HSCT, a dose of PPSV-23 is recommended provided the patient does not have chronic GvHD. In those with GvHD, given the known poor immunogenic response to PPSV-23 in this population, a fourth dose of PCV-13 is recommended at the 12-month mark instead [12, 21].

Vaccination Against Meningococcal Disease

Meningococcal disease, or infection secondary to *Neisseria meningitidis*, most commonly manifests as a form of bacterial meningitis, pneumonia, or bacteremia. The most common serotypes causing disease in humans are serogroups B, A, C, Y, and W-135. Surveillance data reported by the Centers for Disease Control and Prevention (CDC) suggest that in the United States, serogroup B is by far the most common cause of meningococcal disease in children $\leq$5 years of age, whereas in individuals $\geq$11 years old, most meningococcal disease is caused by serotypes C, Y, and W-135 [49]. Serotype A tends to be associated with travel, for example, to areas of sub-Saharan Africa where it remains endemic. Inactivated quadrivalent meningococcal vaccines cover serotypes A, C, Y, and W-135. They are available as either polysaccharide (MPSV-4) or conjugated (MCV-4) vaccines. Immunization against serotype B occurs via a multicomponent inactivated vaccine (4CMenB). Meningococcal vaccination is a routine component of the childhood vaccination series. Re-immunization is routinely recommended post-HSCT in patients 11–18 years of age [12]. In adult HSCT recipients, as well as in the SOT population, there is no evidence that the risk of meningococcal disease is greater than that of the general population; therefore, meningococcal vaccine is generally only recommended under specific

circumstances. The detailed recommendations pertaining to meningococcal vaccination in the SOT and HSCT populations will be discussed below.

Recommendations in SOT. Meningococcal vaccination is recommended as part of routine immunization schedules as dictated by each country's national guidelines. In the SOT population, there are no additional recommendations for vaccination against *N. meningitidis* [6, 12]. If a patient has already received routine childhood meningococcal vaccination, additional vaccination post-transplant is done only for certain high-risk scenarios. Such scenarios include travel to the meningitis belt of sub-Saharan Africa or to Saudi Arabia during the Hajj or Umrah pilgrimage [50]. Following SOT, patients may be functionally or anatomically asplenic (e.g., if splenectomy occurs as part of the transplant surgery). In these cases, guidelines recommend re-vaccination against meningococcal disease [6]. Receipt of the monoclonal antibody eculizumab presents another high-risk scenario for development of invasive meningococcal disease. Eculizumab has been used for treatment of recurrent atypical hemolytic-uremic syndrome in renal transplant recipients or for prevention of graft rejection in renal and heart transplant recipients. Its mechanism of action includes binding to C5 causing inhibition of the terminal complement pathway, placing the recipient at a one to two thousand-fold increased risk of developing meningococcal disease [51]. The ACIP recommends simultaneous immunization with MCV-4 as well as 4CMenB prior to eculizumab use [52]. The first dose of meningococcal vaccine should be given a minimum of 2 weeks prior to receipt of eculizumab. Development of meningococcal disease after eculizumab treatment, however, has been reported in the SOT population despite prior immunization against *N. meningitidis* [53]. In fact, the literature suggests suboptimal immune responses to both MPSV-4 and MCV-4 in adult SOT recipients [54]. Adequate response rates were reached in 40% of patients with MPSV-4 and 50% of patients with MCV-4. Further research is needed in order to determine optimal strategies for meningococcal vaccination in SOT recipients at high risk of disease.

Recommendations in HSCT. Routine re-vaccination against meningococcal disease is recommended in post-HSCT recipients aged 11–18 years. For adult HSCT recipients, guidelines suggest vaccination in accordance with guidelines for the general population [7, 12, 21]. However, in the scenario where an adult HSCT recipient is deemed to be functionally asplenic, re-vaccination should be considered. Currently there are no comparative studies evaluating the immunogenicity of MPSV-4 and MCV-4 in the HSCT population. However, extrapolating from the data on pneumococcal vaccination as well as the known mechanisms of action of these vaccine formulations, it is assumed that greater immunogenicity is achieved with the conjugated rather than polysaccharide vaccine. The literature suggests that 52% of allogeneic HSCT recipients who received a single dose of MCV-4 either showed no immunogenic response or showed a response to only one of the four antigens in the vaccine [55]. The most common antigen for which there was a response was serogroup A, which is the least common to cause disease in North America (although it is important in sub-Saharan Africa and the Middle East). This limited immunogenicity was seen despite the fact that median time to immunization was 2.34 years post-allogeneic HSCT. Interestingly, response to vaccination was not affected by

age, time from transplant, or history of GvHD. When a second or booster vaccine was given at a median of 8.9 months following the first vaccine, response was significantly better with 81.2% of patients responding to at least three serogroups. Thus, guidelines suggest administration of two doses of MCV-4 beginning at 6 months post-HSCT in patients aged 11–18 years or in those with other specific risk factors for invasive meningococcal disease [12]. A booster dose is recommended at age 16–18 when the first dose was received between the ages of 11 and 15. Duration of antibody response following meningococcal vaccination is unknown in this population; thus, it is unclear whether further booster doses would be of benefit. Vaccination with 4CMenB is recommended in accordance with each individual country's recommendations and in the setting of an outbreak.

Vaccination Against Hepatitis B Virus

Transplant patients are at increased risk of transmission of hepatitis B virus (HBV) via a number of different mechanisms. HBV in the transplant patient can be donor-derived or, rarely, can be transmitted via nosocomial outbreak. The normal modes of transmission including via sexual transmission, via needle sharing, and via shared products such as razors also apply to the transplant population. There are several vaccine formulations and dosage strengths available for immunization against HBV. Single-antigen formulations are available containing either 10 μg, 20 μg, or 40 μg of HBV surface antigen protein/mL. The 40 μg dose is considered high-dose and is recommended in certain populations who do not respond adequately to standard-dose HBV vaccine. Recently another 20 μg formulation of the HBV vaccine using a novel adjuvant (HepB-CpG) was approved for use in adults aged $\geq$18 years; however, it has not yet been studied in the transplant population [56]. Detailed recommendations regarding HBV vaccine in SOT and HSCT recipients will be discussed below.

Recommendations in SOT. Donor-derived HBV can be contracted by a solid organ transplant recipient via receipt of an organ from an HBV surface antigen or core antibody-positive donor [57]. HBV core antibody-positive donors are now being knowingly used as a strategy to increase the donor pool. Building immunity to HBV prior to transplant significantly reduces the risk of transmission post-transplant, most notably in the liver transplant population where transmission risk is high [58]. All SOT candidates should be evaluated for immunity to HBV as part of their pre-transplant work-up, by measurement of HBV surface antibody titers. Ideally, if found to be non-immune, the HBV vaccination series will be administered prior to transplantation [6, 12]. Typically, this is administered over a 6-month schedule at 0, 1, and 6 months. If transplantation occurs in the interim, the third dose may be given starting at 3–6 months post-transplant. If time is quite limited prior to SOT, an accelerated schedule can be followed (e.g., 0, 1, and 2 months or 0, 7, and 21–28 days with a booster dose at 1 year), although there have been no comparative studies evaluating responses in SOT recipients using an accelerated schedule as compared to the standard of care. This strategy, however, is still

preferred to the alternative option of vaccinating post-transplant, given immunogenicity after SOT is known to be quite low [59, 60]. In certain populations, when the HBV vaccine series is to be given prior to transplantation, high-dose HBV vaccine is recommended over standard-dose [12]. Specifically, high-dose HBV vaccine is recommended in patients with end-stage renal disease on hemodialysis and can be considered in patients with end-stage liver disease, as these populations are known to respond particularly poorly to standard-dose HBV vaccine [61, 62]. Further study is needed to determine the true benefit of high-dose HBV vaccine in these populations, as well as whether high-dose vaccine might improve vaccine efficacy in the post-SOT population.

Following completion of the HBV vaccination series, whether pre- or post-transplant, HBV surface antibody titers should be checked to ensure immunity [6, 13]. If immunity has not been achieved following a three-dose standard vaccination series, re-vaccination with a high-dose series can be attempted, although there is no available literature evaluating the benefit of this strategy. If and when immunity is achieved following HBV vaccination, experts recommend serial monitoring of HBV surface antibody titers to ensure immunity does not wane [6, 13]. Although in the immunocompetent population a three-dose HBV series is thought to confer lifelong immunity even if antibody titers wane, it is unclear whether this is the case in the post-SOT patient. Thus, in this population, if titers fall below the protective threshold, re-vaccination is recommended [13]. How often titers should be checked following demonstration of an adequate response to the HBV vaccine series differs depending on a patient's individual risk of HBV exposure, for example, based on their country of residence or subsequent travel plans to an endemic area.

If concurrent vaccination with hepatitis A virus (HAV) is required, vaccination can occur using a combined HAV/HBV vaccine, which contains 20 μg of HBV surface antigen protein/mL (see specific recommendations regarding HAV vaccination in the section entitled "Vaccination Against Hepatitis A Virus").

Recommendations in HSCT. Similar to the SOT population, HBV can be donor-derived in allogeneic HSCT through the use of HBV surface antigen or core antibody-positive grafts [63]. Guidelines recommend vaccination against HBV in the non-immune HSCT candidate if their donor is known to be surface antigen or core antibody-positive [21]. Regardless of immune status prior to HSCT, given the decline of HSCT recipient immunity post-transplant from vaccinations given pre-transplant, re-vaccination against HBV is generally recommended to occur beginning at 6–12 months post-HSCT [7, 12, 21]. Standard doses of vaccine are recommended for administration using a 0-, 1-, and 6-month schedule. Interestingly, there is evidence to suggest that donor vaccination against HBV allows transfer of immunity to HSCT recipients for some time after transplant [64]. However, due to logistical and ethical issues, donor vaccination is not recommended as part of the guidelines [7, 12]. In a review of 292 non-HBV-immune allogeneic HSCT recipients vaccinated against HBV using a standard 3-dose schedule post-transplant, only 59% of adult patients developed protective titers [65]. Risk factors for a decreased response included age >18 years and a history of chronic GvHD. Given the immunogenicity of the vaccine appears to be significantly lower post-HSCT than

in the general population, it is recommended to measure HBV surface antibody titers following completion of the HBV vaccination series to check for immunity [12]. In the event that protective titers have not been attained post-vaccination, strategies to consider might include re-vaccination or vaccination using high-dose HBV vaccine, although there is no literature evaluating the efficacy of high-dose vaccine in this population. If protective titers have been achieved, experts would recommend serial monitoring of HBV surface antibody titers as immunity is known to wane in this population [65].

In the HSCT population, if concurrent HAV vaccination is indicated, a combined HAV/HBV vaccine can be administered (see specific recommendations regarding HAV vaccination in the section entitled "Vaccination Against Hepatitis A Virus").

Vaccination Against Hepatitis A Virus

In the transplant population, vaccination against HAV is most often considered in relation to travel or in other high-risk situations. However, there are a few specific situations in which HAV vaccination is recommended regardless of the risk of exposure, which will be discussed below. The HAV vaccine is available either as a single-antigen formulation administered over a two-dose schedule or as a combined formulation with HBV administered over a three-dose schedule, as the latter contains a lower dose of HAV-specific antigen.

Recommendations in SOT. HAV vaccine is recommended in SOT candidates at high risk of HAV exposure, as determined by future travel plans, country of residence, occupational risk, or other lifestyle risk factors [6]. In liver transplant candidates, however, routine HAV vaccination is recommended for all those who are non-immune. This is largely based on the ACIP recommendation for all patients with chronic liver disease to be vaccinated against HAV given the knowledge that this population is at increased risk of fulminant liver failure and death if infected with HAV [66]. Given that liver transplant patients are at ongoing risk of developing chronic liver disease secondary to rejection, recurrence of pre-transplant disease, or other post-transplant complications, the same recommendations have been applied to this population. Vaccination can be given as a standard two-dose series or a three-dose series if being administered as a combination vaccine with HBV.

A prospective study of adult post-liver transplant patients in which non-immune patients were vaccinated against HAV at $\geq$1 year post-transplant revealed a response rate of 26% 7 months after the initial dose of vaccine [67]. This was compared to 98% of historical controls with chronic liver disease who had responded to the vaccine at 7 months. Thus, greater response rates are likely to be achieved with vaccination prior to transplant whenever possible. Immunity has been shown to wane after transplant; however, current guidelines recommend monitoring of HAV antibody titers only in the setting of ongoing risk of exposure, such as before travel to a high-risk area [6, 68]. Given poor overall response rates in transplant patients and waning immunity to HAV vaccine post-transplant, further studies are needed to determine the optimal strategy for HAV protection in this population.

Recommendations in HSCT. There are no specific recommendations for HAV vaccination in the HSCT population. Guidelines recommend using HAV vaccination in this population the same way one would in the general population, for example, vaccinating in the case of planned travel to an endemic area for HAV, or based on other high-risk exposures [7, 21]. There have been no specific data on the immunogenicity of HAV vaccine in HSCT recipients, but it is likely that immunogenicity post-transplant would be lower than that of a healthy adult, as has been shown in the SOT population.

Vaccination Against Human Papillomavirus

There are over 180 types of human papillomavirus (HPV) that have been identified to date. HPV can cause two main groups of disease: cutaneous warts and lesions of the mucosal or genital surfaces (including genital and anal warts and cancers of the genital and anal tracts). HPV viral types 1, 2, and 4 are the most common types implicated in cutaneous warts, whereas viral types 6 and 11 account for most cases of genital warts. Viral types 16 and 18 cause the majority of HPV-related anogenital cancers and are considered high-risk oncogenic types. Viral types 31, 33, 45, 52, and 58 are also often implicated in cases of anogenital cancer.

Currently there are three formulations of inactivated HPV vaccine available. The bivalent vaccine (HPV-2) protects against types 16 and 18. The quadrivalent vaccine (HPV-4) protects against types 6, 11, 16, and 18. More recently, a nonavalent vaccine (HPV-9) was developed, which protects against types 6, 11, 16, 18, 31, 33, 45, 52, and 58. In the general population, HPV vaccination is recommended up to the age of 45 in females and 26 in males. The HPV-2 vaccine is approved for use in women only, but HPV-4 and HPV-9 are recommended for both men and women. If administered in healthy persons $\geq$ age 15, HPV-4 and HPV-9 are generally recommended using a three-dose schedule at 0, 2, and 6 months. HPV-2 is also recommended on a three-dose schedule when the series is started at age 15 or later, however at 0, 1, and 6 months. In immunocompetent children aged 9–14 years, a two-dose schedule at 0 and 6 months has been approved for all three vaccine formulations. Specific recommendations with respect to HPV vaccination in SOT and HSCT recipients will be discussed below.

Recommendations in SOT. Solid organ transplant recipients have a 2.2–20.3-fold risk of developing an HPV-related cancer as compared to the general population, depending on the site of the cancer [69]. When reviewing 187,649 SOT recipients in the United States, Madeleine et al. found a 2.2-fold increased risk of HPV-related invasive oropharyngeal cancer as compared to the general population, and a 20.3-fold increased risk of in situ vulvar cancer related to HPV. All other HPV-related anogenital cancers were also found to be much higher risk in SOT recipients aside from invasive cervical cancer which was found to occur at an incidence similar to that of the general population. The risk of developing HPV-related cancer increased with time from transplant, as well as with the number of transplants a given patient had received. This suggests the risk may be correlated with cumulative

duration of exposure to immunosuppressive agents. The results of this study highlight the importance of HPV vaccination in all eligible SOT recipients.

The immunogenicity of HPV-4 was examined in a prospective cohort study of 50 adult SOT recipients aged 18–35 [70]. Patients were a minimum of 3 months post-transplant, and all were on stable immunosuppressive regimens. Each patient received three doses of HPV-4 on a 0-, 2-, and 6-month schedule. Immunogenicity at 1 month post-completion of the vaccination series was measured, and the results revealed a response rate of 52.6–68.4% depending on the HPV type being measured. This is significantly lower than what has been demonstrated in healthy vaccine recipients [71]. In this study, vaccine response was greater as the time from transplant increased, and lower in lung as compared to kidney recipients [70]. At 6 months post-vaccine series completion, antibody titers to each viral type waned significantly overall, although they remained within protective levels. In another study, a three-dose series of HPV-4 was administered to liver and kidney transplant recipients aged 9–17 years, starting at 6 months post-transplant [72]. In this study, a 100% seroconversion rate to all four vaccine types was noted, although only eight patients completed the full vaccine series and underwent serological testing. A third study examining HPV-4 response rates in kidney transplant recipients aged 9–21 reported rates similar to those demonstrated by Kumar et al. in those aged 18–35 [70, 73]. Thus, further studies are needed to determine whether the strength of immune response to HPV vaccine is affected by age.

Guidelines recommend vaccination of all eligible SOT recipients between the ages of 9 and 45 against HPV using the HPV-4 or HPV-9 vaccine in a three-dose schedule [6]. This recommendation applies to SOT recipients aged 9–14 as well, despite the approved two-dose schedule in immunocompetent patients of this age group. Thus far there have been no studies regarding the immunogenicity of the HPV-9 vaccine in SOT recipients; however, the ACIP recommends it be added to HPV-2 and HPV-4 as a third option with broader coverage, including in the immunocompromised population [74]. Ideally, given the reduced immunogenicity to HPV vaccination post-transplant, the three-dose series should be given prior to transplant. If, however, the series is not complete or has not been started prior to transplant, vaccination can resume or begin at 3–6 months post-transplant [6]. At this time, it is unclear whether there is any benefit in vaccinating patients above age 45 against HPV in the SOT population.

Recommendations in HSCT. Current guidelines do not suggest any specific recommendations for HPV vaccination post-HSCT aside from those that exist for the general population [7, 12]. There is a clinical trial ongoing in order to examine the immunogenicity of HPV-9 in allogeneic stem cell transplant recipients, but as of yet there has been no published data on the use of any of the available HPV vaccines in this population (NCT03023631). This is an area of needed research, as HSCT recipients are known to have a high rate of HPV-related genital disease [75]. Similar to other vaccines, it is possible that immunity from pre-transplant vaccination against HPV may wane following HSCT; thus, further studies are also needed to determine whether re-vaccination post-HSCT would be beneficial and safe.

Vaccination Against Varicella Zoster Virus

Varicella zoster virus (VZV) is the causative agent of both primary varicella (chicken pox) and herpes zoster (shingles). Chicken pox is the primary manifestation of VZV, usually occurring in childhood. In the immunocompetent host, chicken pox is generally a benign infection, but in the immunocompromised host, it can be disseminated and life-threatening. Shingles typically occurs later in life, as a consequence of reactivation of latent VZV. Again, infection in the immunocompromised host can be much more severe than it is in the healthy patient. Thus, vaccination against VZV is an important consideration in both SOT and HSCT patients. All patients should be assessed for immunity against VZV prior to transplant, which would determine whether or not a patient is immune from either previous varicella infection or previous immunization. Once this information is available, a decision can be made regarding whether the transplant candidate requires vaccination against both varicella and herpes zoster, which are covered using two different vaccines. The specific details regarding vaccination against varicella and herpes zoster in both SOT and HSCT patients will be discussed below.

Vaccination against primary varicella

Varicella vaccine is a live attenuated viral vaccine. Vaccination against varicella protects not only against primary varicella but also against herpes zoster. The risk of developing herpes zoster has shown a trend toward being lower in those immunized with varicella vaccine as compared to those who have been previously infected with wild-type varicella virus [76]. Once the varicella vaccine became licensed in the United States in 1995, it was added as a routine childhood immunization in order to prevent primary varicella infection. In immunocompetent children, vaccine efficacy is reported to be between 80% and 85% against all varicella disease and greater than 95% against severe disease [77]. Varicella in the immunocompromised host can cause serious complications, including central nervous system disease, pneumonia, secondary bacterial infections, or even death. Furthermore, mortality is much higher for adults with varicella than it is for children [78]. Thus, vaccination against varicella is extremely important in the adult transplant population. Transplant candidates might already be immune from primary varicella infection or previous vaccination. It is important to be aware of any transplant candidate's immune status against VZV prior to transplantation.

Recommendations in SOT

Being a live attenuated viral vaccine, immunization with varicella vaccine is generally contraindicated post-SOT. Thus, if an adult SOT candidate is found to be non-immune to VZV, vaccination is recommended with one dose of varicella vaccine prior to transplant [6]. Post-vaccination, SOT candidates should be re-checked for immunity. If seroconversion has not occurred, guidelines would suggest re-immunizing with one more dose of varicella vaccine prior to transplantation, if time permits [6]. Alternatively, provided there is adequate time prior to transplantation, some guidelines would suggest administration of two doses of varicella vaccine in

non-immune transplant candidates, with each vaccine given a minimum of 4 weeks apart [12]. Safe administration of the vaccine requires that the patient is not on any immunosuppressive therapy and the vaccine is given ≥4 weeks prior to transplantation. The rationale for waiting at least 4 weeks after varicella vaccination prior to undergoing intense immunosuppression is to take into account the clearance of vaccine-induced viremia. If transplant is urgent, a decision will have to be made regarding whether or not it is possible to hold transplant for 4 weeks to allow for varicella vaccination. If there is not adequate time for vaccination prior to transplant, current guidelines would suggest using preventative measures other than vaccination, for example, postexposure prophylaxis in the case of an exposure to VZV post-transplant [6].

There are some data in the pediatric population to suggest that varicella vaccination in the post-transplant setting is safe and immunogenic [79, 80]. In one study, VZV-seronegative pediatric liver transplant recipients were immunized against VZV and monitored for development of varicella disease, as well as response to the vaccine [79]. All patients were ≥1 year post-transplant, with no episodes of acute rejection within the prior 2 months, were on low doses of immunosuppressive therapy, and had a total lymphocyte count ≥750 cells/μL at the time of immunization. A small proportion of children developed a vesicular rash within 8 weeks of vaccination, which may have represented attenuated varicella infection, but all lesions remained isolated and resolved spontaneously within 48 hours without antiviral treatment. This is a known adverse effect of the vaccine in immunocompetent recipients as well. Over 4 years of follow-up, there were no identified cases of varicella disease in these vaccinated patients. This suggests that in a very specific subset of pediatric patients, varicella vaccination may be considered post-SOT. However, no such studies have been completed in adult SOT recipients. In fact, cases of disseminated varicella after inadvertent varicella vaccination in adult post-SOT patients have been reported [81, 82]. Thus, until further study can be done to examine the safety of varicella vaccine in the adult SOT population, the recommendation remains to avoid the use of this live vaccine in adult SOT recipients [6, 12].

Recommendations in HSCT

Following HSCT, patients are at high risk of developing disseminated varicella infection if exposed, even in the setting of previous immunity from natural infection [83]. This likely relates to waning immunity post-HSCT. Thus, re-vaccination post-HSCT is an important strategy in mitigating the risk of recurrent varicella infection. Varicella vaccine in the HSCT recipient follows the general guidelines with respect to live vaccine administration in this population; it is considered safe once a patient is ≥2 years post-HSCT, off all immunosuppressive therapies, and without evidence of active GvHD [7, 12]. However, data on the epidemiology of varicella infection post-HSCT suggest that the majority of cases present within 1 year of transplantation and during this time period mortality secondary to varicella is the highest [83]. In this study, those at highest risk of infection were those who had received allogeneic HSCT or those with acute or chronic GvHD. There are no clear data as to whether or

not pre-transplant vaccination or donor vaccination might help reduce this risk of serious varicella infection in the first year post-HSCT.

Varicella vaccine safety and immunogenicity in adult autologous HSCT recipients was examined using a two-dose schedule with 8 weeks between doses, starting within 6 months post-HSCT [84]. Vaccine response was elicited in only 1 of 19 patients examined after the second dose of vaccine, suggesting the immune system was not yet mature enough to mount an appropriate response this soon after HSCT. The vaccine was noted to be relatively safe, however, with only two patients developing a varicella-like rash, which is not unexpected with this vaccine. There are no similar studies in adult allogeneic HSCT recipients.

Thus, with the lack of available immunogenicity and safety data in adult HSCT recipients, varicella vaccine is recommended in accordance with the recommendations for other live vaccines in this population, when all of the following criteria are met: $\geq$2 years since HSCT, no immunosuppressive use, and no evidence of GvHD [7, 12]. Two doses of vaccine are recommended, a minimum of 4 weeks apart, mimicking the schedule suggested in routine childhood immunization [12]. In addition, patients receiving varicella vaccine must not be on prophylactic anti-herpes viral therapy or immune globulin therapy as many post-HSCT recipients are, because these treatments are known to interfere with vaccine efficacy [12]. Guidelines recommend waiting at least 3 months post-administration of immune globulin prior to administering the vaccine [12, 85].

Vaccination against herpes zoster

Shingles or herpes zoster occurs as a result of reactivation of latent VZV, acquired from primary varicella infection. Therefore, VZV-seronegative persons who have never been exposed should not require vaccination against herpes zoster. VZV-seropositive persons who have acquired immunity from previous varicella infection have a risk of developing shingles later in life and thus should be vaccinated. It is unclear if herpes zoster vaccine is required in those who have immunity from previous varicella immunization *without* a history of natural varicella infection.

Herpes zoster can cause disseminated disease and significant postherpetic neuralgia (PHN) post-transplant [83]. Thus, vaccination against herpes zoster in the transplant patient is an important consideration. There are two main vaccine formulations available. Initially, the only option was a live attenuated zoster vaccine (LZV). In 2017, an inactivated adjuvanted recombinant subunit zoster vaccine (RZV) became widely available. Both vaccines are approved for use in immunocompetent adults $\geq$ age 50 to prevent shingles. Only one dose of LZV is required, whereas RZV is given as a two-dose schedule, separated by a minimum of 8 weeks. The major difference between the two vaccines in the immunocompetent population is with respect to efficacy. LZV has been found to reduce the incidence of herpes zoster by 51.3%, whereas RZV has been estimated to be 97% and 91.3% efficacious in adults up to the age of 70 and those above 70 years of age, respectively [86–88]. Similarly, LZV is 67% efficacious in preventing PHN, whereas RZV has been found to prevent PHN in 88.8–91.2% of cases [86–88]. LZV has been contraindicated in both SOT and HSCT recipients given that the vaccine contains ~14-fold greater

plaque-forming units of live virus than varicella vaccine [7, 12]. Therefore, a theoretical benefit of RZV in the transplant population is the fact that it is an inactivated vaccine and thus does not share the same risks of viral replication in the immunocompromised population. The specific recommendations with respect to vaccination against herpes zoster in the SOT and HSCT populations will be discussed below.

Recommendations in SOT

The crude incidence of herpes zoster in the SOT population has been reported to be as high as 5.7–21.3% depending on the organ transplanted, the type of immunosuppression, and the type of antiviral prophylaxis used [89–93]. The risk of herpes zoster infection in SOT recipients is anywhere from three- to tenfold higher than that of the general population [92, 93]. Thus, clear guidance on the optimal vaccination strategy in this patient population is needed.

Until recently, guidelines regarding vaccination against herpes zoster in the SOT population included guidance on the use of LZV only. As mentioned, given LZV is a live vaccine, its use is contraindicated post-SOT, given the risk of disseminated disease due to viral replication [6, 12]. In the SOT candidate, LZV can be administered to VZV-seropositive individuals $\geq$ age 50. There are preliminary data to suggest the use of LZV in renal transplant candidates with ESRD resulted in a boost in VZV titers equal to that of gender- and age-matched controls; however, it is unclear whether this provides any clinical benefit in prevention of herpes zoster post-transplant [91]. Additionally, it is unclear whether or not the vaccine is useful in patients less than 50 years of age. In a recent phase I RCT comparing safety and immunogenicity of LZV compared to placebo in renal transplant candidates $\geq$ age 18, Miller et al. demonstrated antibody responses in this population were similar to those seen in immunocompetent individuals $\geq$ age 50 [94]. The vaccine was safe with no herpes zoster-related adverse effects, even in patients who were transplanted within 30 days post-receipt of LZV. Interestingly, although antibody responses waned by 6 months post-immunization, there was no significant difference in titers between those who had been transplanted in that period and those who were still awaiting transplant. This is the first study to demonstrate immunogenicity of LZV in the pre-transplant population (including in patients $<$50 years of age), with antibody titers remaining in the protective range even post-SOT with up to 4 years of follow-up. Lastly, in the event that an organ transplant candidate has had previous herpes zoster, LZV can be still be given as long as 1 year has passed since the time of the active infection, with the intention of preventing further episodes; however, again there are no data to support the use of LZV beyond prevention of a first episode of shingles [6].

Vink et al. performed an RCT examining the safety and immunogenicity of RZV in adult renal transplant recipients [95]. Study participants were administered a two-dose series of RZV or placebo beginning at 4–18 months post-transplant. Results demonstrated that RZV was immunogenic in this population, with responses persisting through 1 year post-vaccination. The vaccine appeared safe, and there was no significant difference in graft rejection rates between arms. While these data

are promising, efficacy as well as longer-term immunogenicity data are needed. There is also a clinical trial ongoing with the goal of assessing the immunogenicity of RZV post-lung transplantation (NCT03493776). Despite limited data, RZV is being used at some centers for pre- and post-SOT patients who meet the indications for the vaccine in the general population (e.g., age ≥50 years, VZV seropositive). Extrapolating from recommendations regarding other inactivated vaccines in this population, if RZV is to be used post-transplant, immunization should occur a minimum of 3 months after the date of transplantation. As in the general population, RZV should be administered using a two-dose schedule separated by at least 8 weeks. If a patient has previously received LZV, in the general population, it is reasonable to administer RZV as long as at least 1 year has elapsed since LZV was given; this rule could potentially be applied to the SOT population as well. RZV has shown high efficacy against shingles in the immunocompetent population; thus, further safety and immunogenicity data in SOT candidates and recipients are needed.

Recommendations in HSCT

Herpes zoster in the HSCT population is associated with significant morbidity and mortality [83]. Guidelines with respect to vaccination against herpes zoster in this population were published prior to the availability of RZV. As mentioned above, LZV has not been recommended for use in HSCT patients, even if ≥2 years post-transplant, on no immunosuppression, and with no evidence of GvHD [7, 12]. This is in contrast to the recommendations with respect to varicella vaccination in this population. There are data published on the use of LZV in allogeneic and autologous HSCT recipients >2 years post-transplantation, with 98.2% of patients experiencing no adverse events after receiving LZV [96]. Two patients did develop a herpes zoster-like rash; however, there was no determination as to whether the rashes were due to wild-type or vaccine virus. Both patients required treatment with antivirals. Following the first 42 days post-vaccination, there were no reported cases of VZV reactivation, although median follow-up was only 9.5 months. Thus, further study is needed to determine the safety as well as immunogenicity of LZV in the HSCT population.

The safety and immunogenicity of RZV has been studied in autologous HSCT recipients [97]. Stadtmauer et al. performed a phase I/II RCT comparing RZV with placebo in autologous HSCT patients ≥ age 18. The vaccine was well-tolerated when administered starting at days 50–70 post-transplant, whether it was given on a two- or three-dose schedule. Cellular and humoral responses to the vaccine were strong using both schedules and persisted for up to 1 year after the last vaccine dose. These results are encouraging, yet specific guidance with respect to the use of RZV in the HSCT population has not yet been published. Currently, a phase III efficacy trial is underway in the autologous HSCT population (NCT01610414). As of yet, the vaccine has not been studied in the allogeneic HSCT population.

Recently, results of a randomized, placebo-controlled, phase III trial were published examining the efficacy and safety of an investigational herpes zoster vaccine inactivated by gamma irradiation in autologous HSCT recipients ≥ age 18 [98]. Patients received four doses of vaccine or placebo; the first dose was

administered 5–60 days before transplant, and the remaining doses were administered at approximately 30, 60, and 90 days post-transplant. A significantly higher proportion of patients in the placebo group developed herpes zoster. The estimated vaccine efficacy was 63.8%. The vaccine also appeared to reduce the severity of herpes zoster infection and its complications in those who did develop disease. The proportion of patients with serious adverse events was similar across both groups. The results of this trial are important not only in that they demonstrate promising results for a new vaccine against herpes zoster in HSCT recipients, but also because they show that vaccination during the highest period of immunosuppression post-HSCT can be effective. As of now it is unclear what role this vaccine formulation will play in immunization of the post-transplant patient.

Vaccination Against Measles, Mumps, and Rubella

Measles, mumps, and rubella (MMR) are all viral infections generally causing disease in childhood. Rubella also becomes important in pregnancy, as congenital infection can result from viral transmission to the fetus. In the immunosuppressed adult, measles infection can cause significant morbidity and mortality related to complications of pneumonia, acute encephalitis, and/or subacute sclerosing panencephalitis. Vaccination against MMR generally occurs via a combination live attenuated viral vaccine. In immunocompetent children, vaccination is recommended after the age of 12 months, followed by a booster dose several years later. Thus, adult patients can either be immune to MMR via natural infection or from previous vaccination. Given the constraints with respect to administration of live vaccines following transplant, it is important to know a patient's immune status prior to transplant. Specifically, measurement of measles antibody titers is important given outbreaks of measles continue to occur. Knowledge of immunity against rubella becomes more important in female transplant candidates who wish to become pregnant in the future.

Recommendations in SOT. MMR vaccine is contraindicated post-SOT; thus, if a patient is found to be non-immune, vaccination should occur prior to transplantation if possible [6]. In adults, one dose of vaccine is recommended followed by repeat testing to assess for seroconversion. If seroconversion has not occurred, a second dose can be administered, time-permitting. Similar to other live attenuated vaccines, vaccination against MMR must occur $\geq$4 weeks prior to transplantation in order to avoid giving immunosuppression during the period of viral replication. Preliminary data in very small groups of patients suggest that the use of MMR vaccine post-SOT in pediatric patients might be safe [99–101]. More recently, Pittet et al. demonstrated a strong seroresponse after administration of 1–3 doses of MMR vaccine to 44 pediatric liver transplant recipients $\geq$1 year post-transplant [102]. All patients were minimally immunosuppressed. Adverse events did occur post-vaccine that may have been attributable to viral replication; however, the presence of measles RNA was not confirmed microbiologically in any case, and for each patient, symptoms improved within days. This further suggests live vaccine administration to a carefully selected

subset of pediatric SOT recipients may be safe. As of yet there have been no studies regarding the safety of MMR vaccination after SOT in adult patients.

Recommendations in HSCT. Guidelines suggest vaccination against MMR in non-immune HSCT recipients in accordance with recommendations for all other live vaccines in this population: once the patient is ≥2 years post-transplant, off all immunosuppression, and without evidence of GvHD [12]. Seroconversion after MMR vaccine in this setting has been reported at 77%, 64%, and 75% for measles, mumps, and rubella, respectively, when studied in patients across the age spectrum [103]. Pre-transplant immunity to measles has been shown to wane beginning at 1 year post-HSCT, so re-immunization in the setting of previous vaccination or natural infection is important [104]. Early vaccination using one dose of MMR vaccine between 9 and 18 months post-HSCT resulted in no major safety issues despite the majority of patients still being on immunosuppressive therapy [105]. However, given many patients maintain immunity to measles in the first year post-transplant, administration of another dose of vaccine prior to waning of immunity resulted in a suboptimal vaccine response. Thus, early vaccination should be reserved for use in an outbreak setting. Additionally, MMR vaccine should be delayed a minimum of 3 months post-receipt of immune globulin for any indication [12, 85].

Other Routine Vaccines

Evidence is scarce regarding vaccination against *Haemophilus influenzae* serotype B (HiB) as well as for the use of diphtheria-tetanus-pertussis vaccine in adult transplant recipients. In SOT patients the recommendation is simply to vaccinate in accordance with immunization guidelines for the general population (e.g., tetanus booster every 10 years, etc.) [12]. In HSCT recipients, conjugated HiB vaccine is recommended using a three-dose schedule beginning at 6–12 months post-HSCT. Similarly, combination diphtheria-tetanus-pertussis vaccination with the use of vaccine containing full-dose diphtheria toxoid (e.g., DTaP) is recommended using a three-dose schedule beginning at 6–12 months post-transplant [7, 12].

Special Considerations in Vaccination of the Transplant Recipient

Other Specifics Regarding Vaccine Timing

Receipt of intravenous immunoglobulin (IVIg) and other blood products can interfere with the ability to mount an immune response to live vaccines. Thus, in both the SOT and HSCT populations, it is recommended to avoid MMR and varicella vaccines for 3–11 months post-receipt of IVIg or other blood products, depending on the type of blood product or dose of immunoglobulin replacement being administered [12, 85]. Rituximab is an anti-CD20 monoclonal antibody that may be used in the hematology setting depending on the underlying disease, or in the SOT

population for antibody-mediated rejection. Due to its B-cell-depleting properties, rituximab can significantly impair vaccine responses post-HSCT. Thus, guidelines recommend delaying vaccination for at least 6 months after the last dose of rituximab was received [21]. The same likely applies with receipt of other anti-B-cell monoclonal antibodies.

Two live vaccines can be administered on the same day; however, if they are *not* administered on the same day, guidelines suggest waiting 4 weeks in between each vaccine in order to maximize vaccine responsiveness [85]. Additionally, live vaccines can interfere with responses to tuberculin skin testing (TST). A TST can be implanted on the same day as live vaccine administration; however, if *not* done on the same day, guidelines suggest waiting a minimum of 4 weeks after vaccine administration prior to implantation of a TST [85].

Travel Vaccines

Transplant recipients should seek guidance from their physicians prior to travel for specific recommendations regarding travel safety. Depending on the patient's vaccination/immune status and the area of intended travel, the need for vaccination against HBV, HAV, and meningococcal disease should be routinely assessed (see recommendations with respect to administration of each vaccine in previous sections). If vaccination against *Salmonella typhi* is indicated, administration of the intramuscular, rather than oral formulation is recommended, as the oral formulation is a live attenuated vaccine. Rabies vaccine should be considered, especially if travel will include close animal contact. Vaccination against Japanese encephalitis using inactivated vaccine is recommended if travel to an endemic area will exceed 4 weeks' duration. Oral polio vaccine is contraindicated in the transplant recipient given the increased risk of vaccine-associated paralytic poliomyelitis from viral replication. If vaccination against poliovirus is indicated, inactivated vaccine can be given instead. Similarly, vaccination against tuberculosis with live attenuated bacillus Calmette-Guérin (BCG) vaccine is contraindicated in transplant recipients due to the risk of disseminated mycobacterial disease.

Live attenuated yellow fever vaccine is generally contraindicated due to the increased risk of severe vaccine-related complications, including viscerotropic or neurotropic disease. Certain countries require proof of yellow fever vaccine before entry into that country is permitted; in select cases a waiver can be issued to the transplant recipient exempting them from this requirement. However, transplant patients should be discouraged from travel to endemic countries at times of year in which there is a high risk of exposure [6]. Newer retrospective data regarding yellow fever vaccine in allogeneic HSCT recipients has become available, suggesting administration of the vaccine was safe in patients $\geq$2 years post-HSCT [106]. In this study, patients had been off all immunosuppressive therapies for a median of 33 months, and none had active GvHD at the time of vaccination. The vaccine was found to be efficacious overall when administered in this fashion. Patients who had been vaccinated prior to HSCT were also reviewed. In the majority of situations

where both donor and recipient had been vaccinated against yellow fever prior to transplant, immunity persisted at a median of 8.6 years of follow-up. Thus, in very select cases, yellow fever vaccine may be considered in HSCT recipients at ≥2 years post-transplant after withdrawal of immunosuppression in accordance with other recommendations regarding live vaccine administration in this population. A small series of 19 SOT patients who received inadvertent administration of yellow fever vaccine did not report any serious adverse events; however, not enough data are available to safely make a routine recommendation in this population [107].

Immunization of Household Contacts

In addition to immunization of the transplant recipient his or herself, ensuring household and close contacts (including pets) are fully vaccinated is an important strategy when it comes to maintaining the health of a transplant recipient. Specifically, annual influenza vaccine in all close contacts of a transplant patient is recommended [6, 7]. Preferably, a form of IIV should be used in household contacts of a transplant recipient. However, if LAIV must be used, the ACIP would recommend avoidance of contact with the vaccine recipient for up to 7 days [108].

In addition to influenza vaccine, household contacts should have all routine immunizations in accordance with their specific jurisdiction's recommendations. Receipt of all inactivated vaccines and almost all live attenuated viral vaccines in household contacts and pets is safe for the transplant recipient and in fact should be done in order to further protect these patients from exposure to vaccine-preventable illnesses [6, 7]. Exceptions to this include small pox and oral polio vaccines which should be avoided in household contacts of transplant recipients due to the risk of transmission of live virus to the immunocompromised host. If oral polio vaccine is inadvertently administered to a household contact of a transplant recipient, the ACIP recommends avoidance of close contact for 4–6 weeks [109]. If this is not possible, rigorous hand hygiene techniques should be employed after any contact with the vaccine recipient's feces, and contact with saliva should be avoided. This should continue for 4–6 weeks as maximum excretion of vaccine virus occurs within 4 weeks of receipt of oral polio vaccine. Rotavirus vaccine is not contraindicated in household contacts of transplant recipients. Precautions including frequent handwashing, specifically after diaper changes, are recommended following vaccine administration to a household contact, however, as viral antigen can be detected in the stool up to 15–30 days post-vaccination depending on the formulation used [110, 111].

Conclusion

Adult transplant recipients are at high risk of developing serious vaccine-preventable illnesses in light of their heavily immunosuppressed state. Vaccination in the post-transplant recipient is an important strategy in order to mitigate this risk. Timing of

vaccination in this population is critical and must take into account the desire to provide early protection against vaccine-preventable illnesses while maximizing immune response and safety. Given the reduced immunogenicity to vaccines in the post-transplant population, ongoing development of newer vaccination strategies in this highly-vulnerable group of patients should be a continued area of focus in order to promote healthier living and decrease mortality post-transplant.

Key Points

- Vaccination in patients undergoing SOT or HSCT is an important strategy in mitigating the risk of serious infection post-transplant.
- Careful timing of vaccination in the SOT and HSCT candidate or recipient is critical in order to provide early protection against vaccine-preventable illnesses while maximizing the potential for an adequate and safe immune response.
- Research regarding vaccination in the transplant patient has come a long way, but this is still an area of much needed attention in order to determine optimal vaccine strategies in this population.

Introduction

Infections due to multidrug-resistant organisms (MDROs) after transplantation are associated with high morbidity and mortality despite advances in the transplant field. Multidrug-resistant organisms in the solid organ transplant context may be donor-derived, especially from donors with hepatitis C viremia or from donors who have received narrow-spectrum gram-negative antibiotics [1]. More commonly, multidrug-resistant organisms that lead to invasive infections arise from the recipient in the pre- and post-transplant setting. Perioperative antibiotic regimens that are tailored to cover for donor pathogens and recipient pre-transplant MDROs are often necessary through organ transplantation [2]. In recent years, the top six causative organisms found to have increasing resistance to antibiotics have been grouped together under the acronym ESKAPE: *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* species [3]. Herein we will describe the epidemiology, pre-transplant evaluation, diagnosis, and treatment of these multidrug-resistant organisms (MDROs) in both solid organ transplant (SOT) and hematopoietic stem cell transplantation (HSCT).

Vancomycin-Resistant *Enterococcus*

Enterococci are facultative gram-positive cocci that are found as commensal organisms of the normal human intestinal tract [4]. However, in the 1970s, likely due to selective antibiotic pressure, enterococci evolved into a frequent cause of hospital-acquired infection via a number of virulence factors, including those that permit adhesion and biofilm formation [5, 6]. Two species of enterococci typically cause infection, *E. faecium* and *E. faecalis* [4]. Enterococci have several intrinsic resistance mechanisms to antibiotics [7]. Vancomycin-resistant enterococci (VRE) were first reported in 1986 in France [8]. Since that time, VRE have been named a serious public health threat by the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) [9].

VRE colonization typically precedes infection [8]. Serial examination of the intestinal microbiota of HSCT recipients suggests that intestinal domination of VRE species precedes bacteremia [10]. Host and environmental risk factors are associated with VRE colonization. For example, immunosuppressing conditions like SOT, HSCT, hematologic malignancy, critical illness, renal dysfunction, and diabetes all predispose an individual for VRE colonization [11, 12]. VRE colonization has also been associated with prior receipt of antimicrobials [12]. Mouse models suggest that antibiotic elimination of commensal microbiota downregulates innate

immune-protective mechanisms to directly facilitate VRE colonization [13]. As an intra-abdominal microorganism, VRE infection in the pre-transplant setting often manifests as intra-abdominal infections such as spontaneous bacterial peritonitis or biliary tract infections in patients with end-stage liver disease; urinary tract infections, particularly catheter-associated infections; bloodstream infections; and less frequently endocarditis [7]. Here we review the epidemiology, clinical implications, and management of VRE colonization or infection as they pertain to pre-transplant evaluation of candidates for solid organ or bone marrow transplantation.

Disease Epidemiology

Solid Organ Transplant

A recent meta-analysis of VRE colonization and infection pre- and post-solid organ transplantation demonstrated that 11.9% of patients have pre-transplant VRE colonization [10]. Of note, the majority of the studies that composed this meta-analysis were from patients with end-stage liver disease who went on to receive liver transplantation. One of these studies was a single-center prospective study of liver transplant recipients which documented a 13% frequency of VRE colonization pre-transplant in this population [14]. This study also performed a multivariate analysis to analyze risk factors for VRE acquisition and found that risk factors for pre-transplant VRE colonization included prior hospitalization, prior procedures like paracentesis or ERCP, and receipt of an anti-anaerobic antibiotic.

VRE colonization has also been studied in patients with end-stage renal disease (ESRD) on dialysis [15]. A meta-analysis underscored the limitations in these studies with poor patient enrollment from dialysis centers in the majority of studies, variable follow-up of patients after VRE colonization, and variable reporting of antibiotic receipt in the dialysis patients under study. Nevertheless the meta-analysis found a pooled prevalence of 6.2% dialysis patients were colonized with VRE. The meta-analysis also reported associations between receipt of antibiotics, particularly vancomycin, and recent hospitalization as significant risk factors for the acquisition of VRE in the dialysis patient population.

The epidemiology of VRE colonization in patients with end-stage lung or heart disease has not been systematically studied. VRE colonization leading to VRE infection and bacteremia has been documented in individuals on left ventricular assist devices as a bridge to heart transplantation [7]. Additionally, VRE acquisition rate for patients who have been hospitalized in intensive care units has been documented to be 8.8% (95% CI 6.9–11.0) [16]. Thus, we can extrapolate that a significant proportion of patients with end-stage lung or heart disease who are frequently hospitalized in acute care settings are at risk for VRE colonization.

In the context of SOT, VRE colonization of the recipient prior to transplant is typically of greatest concern. Although there is a theoretical risk of transmission of

donor microbiota, including multidrug-resistant organisms to the recipient, this kind of transmission has not been systematically studied. However, a recent report does document the presence of a VRE strain from donor to recipient with a high degree of microbiologic similarity suggesting that donor-derived VRE transmission to recipient is possible [17]. These data underscore the importance of timely communication of donor culture results to transplant centers and warrant further investigation into the microbiota shifts after organ transplantation.

Bone Marrow Transplant

Bone marrow transplantation for hematologic malignancy usually occurs after a period of induction and consolidation chemotherapy for an acute hematologic malignant process. Thus, the incidence of VRE colonization among patients with an acute hematologic malignancy reflects the pre-bone marrow transplant burden. VRE colonization among patients with a hematologic malignancy has been reported to be as high as 24% (95% CI, 16%–34%) [16]. Risk factors for VRE colonization in this patient population include prior vancomycin and prior hospitalization in the past 3 months [16].

Clinical Impact in Transplant

Pre-transplant VRE colonization has been associated with the development of VRE bacteremia in the context of both SOT and HSCT. Here we review the clinical implications of VRE colonization pre-transplant on post-transplant outcomes.

Solid Organ Transplant

As VRE is an intra-abdominal commensal, the clinical consequences of pre-transplant VRE colonization have been studied best in the context of intra-abdominal SOT. For example, single-center prospective evaluation of VRE colonization in liver transplant patients identified 13% rate of VRE colonization in waitlist candidates [14]. Of these, 44% underwent liver transplantation and 32% developed VRE infection after transplantation. In contrast, among the 87% of individuals who were not VRE colonized prior to transplant, only 18% developed VRE infection after liver transplantation [14]. Of note, this study did not assess whether the genome of the pre-transplant VRE-colonizing strain was identical to the post-transplant infecting VRE strain. A study of VRE-colonized liver transplant candidates and recipients reported a significantly increased risk of death within 1 year of VRE colonization, and although this analysis was not restricted to the pre-transplant candidate specifically, half of the VRE colonization subjects in this study were identified and followed in the pre-transplant setting [18]. Collectively, these data underscore the negative consequences of pre-transplant VRE colonization on post-transplant outcomes.

Bone Marrow Transplant

Several studies have examined the relationship between pre-HSCT VRE colonization and post-HSCT VRE bacteremia and mortality [19–23]. In general, these studies associated VRE bacteremia after HSCT with high mortality. However, these studies had conflicting results regarding the relationship between pre-transplant VRE colonization and VRE bacteremia because they differed in the classification of pre-transplant VRE colonization either at time of stem cell transplant or prior to stem cell transplant as well as in the classification of VRE bacteremia pre-stem cell engraftment or post-stem cell engraftment. A more recent examination of the relationship between VRE colonization and hematopoietic stem cell transplant outcomes was designed to distinguish between subjects with VRE colonization at various timepoints prior to stem cell transplant and subjects who went on to develop VRE bacteremia at various timepoints after stem cell transplant [24]. This single-center study prospectively examined 161 patients with acute leukemia, 109 of whom underwent subsequent stem cell transplantation. The study documented that VRE colonization during treatment for acute leukemia was predictive of VRE colonization at the time of stem cell transplant. Molecular analysis performed on a subgroup of patients showed that 10/22 subjects had the same VRE-colonizing strain pre-transplant and at the time of transplant. VRE colonization prior to stem cell transplant was associated with pre-engraftment and post-engraftment VRE bacteremia as well as greater healthcare costs. Among subjects who were VRE colonized prior to transplant but did not have a positive VRE rectal swab culture at the time of transplant, none developed VRE colonization after stem cell transplantation. Thus, these recent data suggest that pre-transplant VRE colonization, particularly on the day of transplant, is predictive of subsequent VRE bacteremia after transplant.

Disease Diagnostics and Clinical Evaluation

Vancomycin binds to the D-alanine-D-alanine (D-ala-D-ala) residues of the enterococcal peptidoglcycan cell wall to exert its antimicrobial activity [25]. Various gene clusters termed *vanA*, *vanB*, *vanC*, *vanD*, *vanE*, *vanG*, *vanL*, *vanM*, and *vanN* alter the D-ala-D-ala residues of the enterococcal cell wall to prevent binding of vancomycin and thereby mediate resistance [25]. These gene clusters differ from one another according to constitutive versus inducible expression as well as structural arrangement and amino acid sequence [25].

The Clinical and Laboratory Standards Institute (CLSI) defines vancomycin-resistant enterococci as exhibiting a minimum inhibitory concentration or MIC to vancomycin of $\geq$ 32 ug/mL [26]. Tests to determine vancomycin resistance from infected sites require growth of the isolate and subsequent detection of vancomycin resistance using agar screens, disk diffusion screens, or broth microdilution screens. The latter can be automated using a VITEK system [26]. These methods have drawbacks including the required organism growth, user interpretation of results,

and inability to detect isolates with low-level resistance or inducible resistance to vancomycin.

Screening for VRE colonization is performed on sample obtained from rectal swabs. This material is typically plated onto chromogenic agar plates, which have a high sensitivity and specificity for VRE and can differentiate between *E. faecalis* and *E. faecium* species according to colony pigment [27, 28]. However, a rectal swab culture-based approach to determine VRE colonization has limitations, chiefly because other intestinal flora are also cultured from these swabs and may cause false-negative assays.

To overcome the limitations of culture-based VRE detection, molecular-based assays for VRE identification have been developed [29, 30]. These methods use PCR-based testing of the enterococcal genome to detect vancomycin resistance genes described above. Such molecular-based testing has the advantage of providing faster results than culture-based assays. However, false-positive results may occur because vancomycin resistance genes, vanA and vanB, may be present in anaerobic commensals [31]. To minimize false-positive molecular-based assays, two-tier approaches that utilize initial molecular-based testing followed by confirmatory culture results have been suggested [30]. Finally, serial 16s RNA sequencing of the intestinal microbiota to identify VRE strain in the overall microbiota composition may play a role in future early diagnosis of VRE colonization [32].

Management

Prevention

As discussed above, VRE colonization is often preceded by hospitalization. Transmission of VRE in the healthcare setting may occur from contaminated environmental sources as VRE can exist as a fomite, from direct contact with colonized healthcare workers, or from contaminated medical equipment [33]. These transmission events suggest VRE infection control measures to prevent VRE transmission may be important. Such measures include antimicrobial stewardship, rectal VRE surveillance swab cultures, strict hand-washing, staff education, intensive environmental cleaning, and contact isolation [7]. Although these measures have been recommended routinely in various national guidelines, the efficacy of these measures to prevent VRE transmission has not yet been convincingly demonstrated in randomized trials or cohort analyses [34, 35]. Contact precautions have been linked to certain adverse patient outcomes like fewer bedside visits and physical examinations [36]. Certain tertiary care centers have documented successful discontinuation of contact precautions for VRE with associated cost savings [37]. Expert guidance for the discontinuation of contact precautions for VRE is available; however, these guidelines do not pertain to individuals in the pre-transplant or post-transplant setting [38].

Currently, there are no approved vaccines that prevent the colonization of VRE. There are immunogenic antigens on the enterococcal cell wall that could be the basis

of for future vaccine design. One of these antigens, glycosylated lipoteichoic acid (LTA), provides passive immunity in a rabbit model of VRE infection [39, 40].

Decolonization

Screening for VRE in the pre-transplant setting is not routinely recommended unless there is an ongoing outbreak [41]. VRE colonization is often persistent and patients can become spontaneously decolonized and recolonized [42]. Although several antibiotic regimens have been tried to effect VRE decolonization, these have been variably successful. Fecal transplantation is a modality used to treat *Clostridioides difficile* and has been shown to eradicate VRE colonization in a case series [43]. Selective commensal species have been shown to eradicate VRE intestinal carriage in mouse models [44]. Thus, fecal transplantation may be a promising mechanism to eliminate VRE carriage, but this needs to be systematically studied across a variety of patient populations.

Treatment

Outside of infective endocarditis [45], published guidelines for the treatment duration or selection of antimicrobial agents for VRE infection do not exist. Expert opinion indicates that antibiotic selection should be dictated by patient tolerance, drug interactions, as well as site of infection [7]. Source control is a key component of VRE treatment and includes removal of suspected infected central lines, urinary catheters, or drainage of abscesses. A subset of VRE infections are from ampicillin-susceptible isolates, and in these cases, ampicillin is the preferred agent. Other antimicrobials commonly used to treat VRE include daptomycin and linezolid. Linezolid acts by binding the 23S prokaryotic ribosomal subunit preventing protein synthesis [46]. It has high oral bioavailability and tissue penetration and is bacteriostatic against VRE. Side effects of linezolid include reversible myelosuppression as well as neuropathies from mitochondrial toxicities. Linezolid interacts with serotonergic or adrenergic agent to cause serotonin syndrome. It is recommended that serotonergic or adrenergic agents be discontinued prior to receipt of linezolid [47]. In contrast to linezolid, daptomycin has concentration-dependent bactericidal activity against VRE. Daptomycin is renally cleared and must be dosed for renal function. Side effects include myalgias and rhabdomyolysis; therefore weekly creatine kinase monitoring is recommended while on this agent. Although the FDA-approved dosing recommendation of daptomycin is 6 mg/kg, subsequent retrospective cohort studies indicate that higher-dose treatment results in faster microbiologic clearance and lower 30-day mortality rates without adverse event [48]. Thus, high-dose daptomycin 8–10 mg/kg is likely superior for complicated VRE infections like bloodstream infection. Several studies have compared the efficacy of linezolid to daptomycin [5, 49–53]. While most of these studies concluded that linezolid was superior to daptomycin, these studies also acknowledged

significant study limitations, including, importantly, suboptimal daptomycin dosing. A subsequent multicenter study of veterans with VRE bacteremia concluded that daptomycin even dosed at 6 mg/kg is superior therapy to linezolid [54]. Thus, in the absence of a randomized control trial of linezolid versus optimally dosed daptomycin, it remains unclear which of these agents is optimal for the treatment of VRE infection.

Quinupristin/dalfopristin is a streptogramin antibiotic that has in vitro activity against VRE, but its side effect profile and lack of proven efficacy against VRE argue against its use as a first-line agent to treat VRE infection [53]. Tigecycline is structurally similar to tetracyclines but has expanded activity to include activity against VRE. It has higher tissue penetration than blood penetration and is not recommended for VRE bacteremia [55]. Currently, tigecycline carries an FDA black box warning for increased mortality particularly in its use to treat ventilator-associated pneumonia [56]. Thus, this agent should be used as a salvage agent only for VRE infection. Oral agents that have activity against VRE infections of the bladder include fosfomycin and nitrofurantoin. Fosfomycin has a low barrier for the development of resistance [57, 58]. Limited retrospective studies suggest that nitrofurantoin may have reduced efficacy in elderly individuals with compromised renal function and may result in pulmonary toxicities in these populations. Oritavancin and dalbavancin are analogs of vancomycin. While oritavancin has clinical activity against VRE, especially isolates with vanA gene resistance, dalbavancin has in vitro activity only against VRE with vanB gene-mediated resistance [56].

Resistance to daptomycin and linezolid has emerged [59]. Daptomycin-non-susceptible VRE may have thicker cell walls with reduced penetration of daptomycin. Although initially classified as having an MIC of >4 ug/mL by the CLSI, daptomycin treatment of isolates with an MIC 3–4 also appears to be ineffective [60]. Linezolid-resistant enterococci may form from a point mutation in a ribosomal subunit or from the mobile *cfr* gene element that can transfer between bacterial species [61]. Due to the development of these resistance patterns, combination therapies have been pursued to treat these isolates. For example, daptomycin and beta-lactams have been shown to have synergistic activity in vitro putatively because beta-lactam agents alter enterococcal cell membrane potential to allow enhanced bactericidal activity of daptomycin. Case reports have documented successful microbiologic clearance of highly resistant enterococcus using combination daptomycin and beta-lactam therapies [54, 60], but more rigorous studies need to be performed before this synergistic combination is accepted practice.

Methicillin-Resistant *Staphylococcus aureus* (MRSA)

Staphylococcus aureus (*S. aureus*) is a gram-positive cocci and a frequent cause of skin/soft tissue infections, bacteremia, infective endocarditis, pneumonia, and osteomyelitis [62]. Methicillin was first used in 1959 to treat infection by penicillin-resistant *S. aureus*. As early as 1961, the first reports of methicillin-resistant *Staphylococcus aureus* or MRSA were reported in the United Kingdom [63]. Currently, MRSA is a global infection in both the hospital and community setting.

Table 1 Mechanism of action of resistance genes in MRSA and VRE and antibiotics identified with in vitro activity

Organism	Resistance gene	Resistance mechanism	Antibiotic affected	Antibiotic considerations (in vitro activity)
MRSA	*MecA*	Encodes for penicillin-binding protein 2a (PBP2a), which has lower affinity for β-lactams	Methicillin	Vancomycin Daptomycin Linezolid Ceftaroline Delafloxacin Doxycycline Tigecycline Omadacycline Eravacycline Sulfamethoxazole-trimethoprim Clindamycin Oritavancin Dalbavancin
VRE	*VanA*, *VanB*, *VanC*, *VanD*, *VanE*, *VanG*	Alteration of cell wall precursors from D-alanyl-D-alanine to D-alanyl-D-lactate	Vancomycin	Daptomycin Linezolid Dalfopristin-quinupristin Oritavancin Tigecycline

Resistance is typically mediated by methicillin-resistant penicillin-binding protein encoded by the *mecA* gene. This variant penicillin-binding protein 2 lowers the avidity of penicillin binding to the staphylococcal cell wall. The mecA gene is found on a mobile genetic element called the staphylococcal cassette chromosome *mec* (*SCCmec*). There are several types of *SCCmec* that correspond to different strains of MRSA and may distinguish community- from hospital-based strains [64]. More recently, MRSA has been isolated with a novel gene, *mecC*, mediating resistance. These cases of *mecC* MRSA appear restricted to animals with sporadic cases in humans documented in Europe [65]. In the context of solid organ transplantation, MRSA has been associated with perioperative surgical site infection and increased mortality, underscoring the importance of identification and eradication of MRSA in the pre-transplant setting (Table 1).

Disease Epidemiology

Solid Organ Transplantation

A meta-analysis of nine studies of MRSA colonization in the adult SOT population identified a 0.1–27.1% pooled prevalence of MRSA colonization in the pre-transplant setting. Immediately prior to transplantation, the prevalence of

MRSA colonization is 8.5% (95% CI 3.2–15.8%) [12]. These data are largely drawn from studies of liver transplant candidate ($N = 7$) studies and the remaining two studies reporting data on kidney, pancreas, and lung transplant candidates. A single-center retrospective study of pediatric SOT patients found the prevalence of MRSA colonization to be 13%, with lung, cardiac, and abdominal visceral organ transplant recipients most likely be colonized [66].

Studies of MRSA colonization with end organ disease who are potential candidates for organ transplantation have been performed. For example, a meta-analysis of MRSA colonization in dialysis patients documented an estimated prevalence of MRSA colonization in this patient to be 6.2% (95% CI 4.2–8.5%) [67]. Patients with MRSA colonization were more often on hemodialysis than on peritoneal dialysis [67]. Left ventricular assist devices (LVADs) are often bridges to heart transplantation. Rates of infection of these devices are as high 60–70% with MRSA infections accounting for 30–44% of infection [68]. These infections may manifest as driveline exit site infections, pocket infection, or pump infections [68]. Although these data indicate that MRSA is prevalent in the pre-transplant subject, additional studies with larger pre-transplant patient populations are needed to truly understand the epidemiology of MRSA in the pre-transplant setting.

Stem Cell Transplantation

Data regarding the epidemiology of MRSA colonization in stem cell transplant candidates is sparse [69]. A recent single-center retrospective study was performed in a tertiary care cancer center that mandates MRSA screening 2 weeks prior to transplantation. This study evaluated the prevalence of MRSA colonization among $N = 1895$ stem transplant candidates from 2008 to 2012. This study found that only 1.1% of this patient population was colonized with MRSA. Given the gaps in the literature regarding MRSA colonization in the patient listed for stem cell transplant, it is difficult to draw firm conclusions about the epidemiology of this pathogen in this patient population.

Clinical Implications

Solid Organ Transplantation

Only three out of nine studies followed adult patients from the time of identification of MRSA colonization pre-transplant into the post-transplant setting. These three studies reported data from liver transplant recipients alone. Data from these three studies indicate that pre-transplant carriage of MRSA results in a 5.5 times increased risk of post-transplant MRSA infection [12]. In a single-center retrospective study of pediatric organ transplant recipients, pre-transplant MRSA colonization resulted in infection in 3.9% of recipients [66]. Among patients with end-stage renal disease

on dialysis who represent a candidate pool of renal transplant recipients, those who were MRSA colonized were more likely to develop MRSA bacteremia with a relative risk of 11.5% (95% CI 4.7 to 28.0) [67]. These studies suggest that MRSA colonization places transplant candidates at risk for subsequent invasive MRSA infection.

Stem Cell Transplantation

Available data does not indicate the pre-transplant MRSA colonization portends post-transplant MRSA infection. However, these data are from single-center retrospective studies and were not performed during MRSA outbreaks, which have been reported to cause high rates of mortality in the stem cell transplant setting [69].

Disease Diagnostics

MRSA colonization may be identified as a colonizing agent via swab of mucosal surfaces, typically the nares, although there is evidence that swabbing multiple services for MRSA may result in increased sensitivity of testing [70]. MRSA infection is typically identified after culturing the relevant infectious source. The CLSI recommends both broth microdilution testing and cefoxitin disk diffusion testing to identify MRSA isolates. Cefoxitin disks are preferred over oxacillin disks because cefoxitin is a more potent inducer of the *mecA* gene. Any given staphylococcal culture may comprise methicillin-resistant and methicillin-sensitive strains, and this is termed hetero. Heteroresistance may be missed by cefoxitin disk diffusion testing unless cells are cultured at 33–35 °C and read at 16–18 h after plating. Newer chromogenic agar-based testing permits detection of MRSA isolates by pigment change. In addition to the aforementioned cell culture-based testing, there is also FDA-approved molecular PCR-based testing for *mecA* gene expression. There are also latex agglutination assays to assess for the expression of the protein product of the *mecA*, the penicillin-binding protein 2. (Please see ▶ Chap. 62, "Emerging Diagnostics for Transplant Infectious Diseases.")

Management

Prevention

-Although prior infection with MRSA does not induce durable immunity to prevent future infection, there is evidence that individuals colonized with MRSA have less severe MRSA infection [71]. These data suggest that prior immunity to MRSA may be partially immune-protective. MRSA prevention via active immunization from vaccines or passive immunization from monoclonal antibodies has been studied. One vaccine, StaphVAX, that included antigens against *S. aureus* polysaccharide

capsule failed to show efficacy in phase III clinical trials in the hemodialysis patient population. Another vaccine candidate, V710, which includes the antigenic MRSA scavenger protein IsdB, was studied in a phase III study of cardiac surgery patients. This study was halted due to increase in mortality from *S. aureus* infection. Current vaccine strategies under study include regimens that target several *S. aureus* antigens [71].

Infection Control

MRSA may be spread in the hospital and community setting. Within the healthcare environment, routine hand hygiene, environmental cleaning, and antimicrobial stewardship are the backbone of infection control measures to prevent the spread of MRSA. The value of patient isolation and contact precautions for MRSA colonization has recently been questioned, and several centers no longer require these measures to prevent the spread of MRSA [72].

Decolonization

In areas with high prevalence of MRSA, pre-transplant nasal swab to identify nasal colonization is recommended [73]. The efficacy and timing of nasal decolonization in the context of the transplant host as a means to prevent invasive infection are unclear [74]. However, MRSA decolonization procedures have been shown to be effective in individuals with end-stage renal disease on hemodialysis [75].

Treatment

Pre-transplant MRSA infection should ideally be treated to cure prior to transplantation [73]. MRSA treatment regimens by clinical manifestation have been reviewed extensively elsewhere [45, 62]. Source control is key to eradication of infection, and this may include device or line removal as MRSA has been known to create biofilms on prosthetic joints, catheters, and heart valves. Glycopeptide antibiotics like vancomycin are commonly used to treat MRSA infections, including uncomplicated and complicated bacteremia. Vancomycin inhibits bacterial cell wall synthesis and the permeability of the bacterial cell membrane [76]. MRSA isolates with decreased susceptibility to vancomycin were reported in Japan as early as 1997. CLSI minimum inhibitory concentration (MIC) for vancomycin intermediate sensitivity (VISA) is 4–8 ug/mL and for vancomycin resistance >16 ug/mL (VRSA). Resistance to vancomycin may be mediated by molecular changes to the staphylococcal cell wall.

Daptomycin, a cyclic lipopeptide antibiotic, is bactericidal against MRSA and disrupts cell membrane function and protein and nucleic acid synthesis [77]. Daptomycin-resistant MRSA may occur in the context of prolonged

infection without appropriate source control or inadequate vancomycin dosing. Typically, daptomycin resistance occurs in the context of prior vancomycin and/or daptomycin receipt; however cases of spontaneous resistance have been documented. Available data suggests that daptomycin may be non-inferior to vancomycin in the treatment of MRSA bacteremia and may actually be superior to vancomycin in isolates with a vancomycin MIC of 1 [78]. In addition, daptomycin may have a better side effect profile than vancomycin, resulting in fewer cases of renal insufficiency.

For uncomplicated skin and soft tissue infections, oral antibiotic therapy may be reasonable; oral options include trimethoprim-sulfamethoxazole, clindamycin, and doxycycline. Another oral antibiotic, bacteriostatic oxazolidinone, linezolid, inhibits the staphylococcal ribosome function and achieves excellent levels in the skin/soft tissues as well as the lung. There is evidence that linezolid may be superior to vancomycin for the treatment of MRSA pneumonia. Currently, the Infectious Diseases Society of America recommends linezolid and vancomycin as agents for the treatment of MRSA pneumonia [79].

The FDA has recently approved new antimicrobials for the treatment of MRSA. For example, the fifth-generation cephalosporin, ceftaroline, is approved to treat skin and soft tissue as well as MRSA pneumonia [80]. Oritavancin and dalbavancin are antibiotics that are chemically similar to vancomycin because they all prevent cell wall formation by binding to the peptidoglycan cell wall residues [80]. However oritavancin and dalbavancin have a unique lipid side change which confers a long half-life, permitting single-dose therapy. Of note, optimal dosing for renal insufficiency still needs to be established for dalbavancin.

For highly resistant MRSA isolates, synergistic therapies have been attempted and reported as case series and case reports [62]. There is a currently a rich pipeline of investigational agents with antimicrobials for MRSA that may provide improved outcomes for the treatment of MRSA infections. For example, a new class of anti-infectives, synthetic retinoids, have in vitro and in vivo activity against dormant MRSA subpopulations that persist after initial infection to cause relapsed disease [81].

Carbapenem-Resistant *Enterobacteriaceae* (CRE), *Acinetobacter* Species, and *Pseudomonas aeruginosa*

Disease Epidemiology

Multidrug-resistant gram-negative bacteria are on the rise, with high associated mortality, particularly in transplantation. The 2011 Annual Report of the European Antimicrobial Resistance Surveillance Network (EARS-Net) identified that nearly 52% of all *K. pneumoniae* were resistant to ceftriaxone and produced ESBL and nearly 10% of all *E. coli* were resistant to ceftriaxone with over 75% producing ESBL [82]. In addition to ESBL-producing bacteria, carbapenem-resistant gram-

negative bacteria, in particular *Acinetobacter* species, *Pseudomonas aeruginosa*, and *Enterobacteriaceae*, are escalating global public health threats.

Over the past two decades, *Enterobacteriaceae*, a family of gram-negative bacteria part of the commensal gut flora, have increasingly become more resistant to antibiotics. In the United States, carbapenem-resistant *Enterobacteriaceae* (CRE) has increased from 1.2% in 2001 to 4.2% in 2011 and is now present in all states [83]. Infection with CRE has been associated with mortality rates as high as 70% [83]. The major mechanism of resistance is the presence of β-lactamases, encoded by the gene *bla* [84]. In addition to this, many of the bacteria in this family can also carry plasmid-borne genes active against a variety of antibiotics, thus forcing providers to rely upon antibiotics considered the last line of defense [84]. Phenotypic resistance to carbapenems is typically caused by either β-lactamase activity combined with structural mutations or production of carbapenemases [84]. Carbapenemases are classified by their structure and belong to three classes of β-lactamases: classes A, B, and D; classes A and D require serine at their active site, whereas class B requires zinc for β-lactam hydrolysis [84]. One of the most common carbapenemase genes includes the *Klebsiella pneumoniae* carbapenemases (KPCs), which are capable of hydrolyzing all β-lactams and often have acquired resistance to fluoroquinolones, aminoglycosides, and trimethoprim-sulfamethoxazole [84]. Clonal expansion of KPC-producing *Enterobacteriaceae* initially caused global spread of carbapenem resistance. The class D OXA β-lactamases or oxacillinases are typically found in *Acinetobacter* species and increasingly in *Enterobacteriaceae* [84]. The class B metallo-β-lactamases (MBLs) are a complex group of enzymes that hydrolyze all β-lactams except monobactams. Interestingly, the spread of New Delhi metallo-β-lactamase (NDM)-producing *Enterobacteriaceae* is not associated with clonal strains, but rather due to inter-regional spread of multiple clones associated with outbreaks [85].

Among the increasingly reported multidrug-resistant pathogens are the lactose non-fermenting gram-negative bacteria, including carbapenem-resistant *Pseudomonas aeruginosa* (CRPA) and carbapenem-resistant *Acinetobacter baumannii* (CRAB). These are typically associated with hospital-acquired infections and can lead to large outbreaks with high associated mortality rates, ranging from 16% to 49% [86]. CRAB has a limited number of virulence factors, which is why infections due to this organism classically occur in those who are critically ill [87]. Risk factors for CRAB include immune suppression, burn injuries, mechanical ventilation, and prior colonization [87]. CRAB is able to survive for a prolonged period of time and spread throughout the healthcare institutions. Carbapenem resistance in *A. baumannii* is mediated classically by class D beta-lactamases (OXA-23) or oxacillinases, some of which are located chromosomally and some which are plasmid-mediated. Reports of CRPA strains are increasing, with rates as high as 50% in some institutions. Carbapenem resistance in *P. aeruginosa* has been mediated by outer membrane protein inactivation as well as through carbapenemases, such as metallo-β-lactamases (MBLs) and Verona integrin-mediated (VIM) B-lactamases [88].

Solid Organ Transplant

The prevalence of infections due to multidrug-resistant gram-negative bacteria following SOT is increasing, with an estimated 10–20% of recipients becoming infected with these organisms [89]. Transplantation has been identified as an independent risk factor for carbapenem-resistant *K. pneumoniae* [90]. Colonization with KPC-producing CRE in liver transplant recipients has led to high infection rates with high associated mortality, particularly when acquired in the hospital setting [91]. In a CRE outbreak at a tertiary care center, KPC *K. pneumoniae* disproportionately affected SOT recipients with a 30-day mortality rate as high 42% [92].

The incidence of SOT carbapenem-resistant infections varies considerably by type of organ. Many studies have reported early infection post-transplantation, with a median time of typically <50 days [83]. These infections are associated with a tenfold risk of death, although it is important to note that many of the epidemiologic studies in SOT occurred prior to development of anti-CRE antibiotics [83]. Kidney transplant recipients tend to have lower rates of CRE infection than liver transplant recipients, who have higher rates of surgical site infections and intra-abdominal infections. In addition to infections, there have been 7 cases of donor-derived infections reported with CRE and 1 large outbreak of 14 recipients exposed to carbapenem-resistant *Acinetobacter* [93–95]. No resistant infections occurred in patients who received immediate treatment post-transplant in response to culture results, whereas 50% developed infection without postexposure antibiotics.

P. aeruginosa is common in lung transplantation and typically colonizes up to 80% of patients with cystic fibrosis and bronchiectatic lung disease. Patients with colonization prior to transplant have a 4.7 times higher risk of infection compared to noncolonized patients [96]. CRPA is increasing in patients with CF, particularly with patients exposed to carbapenems [96].

Bone Marrow Transplant

Patients with hematologic malignancies are at increased risk for CRE infections due to multiple reasons, including chemotherapy-induced neutropenia with subsequent gastrointestinal mucositis, prolonged hospitalization, and exposure to broad-spectrum antibiotics [83]. ESBL bacteremia prevalence rates in patients with hematologic malignancy have ranged from 17% to 37% [32]. In areas with higher rates of CRE, such as Italy and Israel, patients with hematologic malignancies represent up to 24% of all patients with CRE bacteremia [83]. CRE are also becoming increasingly common in HSCT recipients; Italian transplant centers have reported an increase in post-allogeneic transplantation CRE infection rates from 0.4% in 2010 to 2.9% in 2013 [97]. CRE bacteremia has been reported at a rate of 2% in HSCT recipients within 12 months of transplantation [32]. Given the delay in diagnosis and that typical recommendations for neutropenic fever do not cover CRE pathogens, patients with hematologic malignancies who develop CRE bacteremia have high

associated 30-day mortality rates ranging from 52% to 63% [32, 97]. A likely explanation for high mortality rates is due to the fact that the recommended empiric therapy for neutropenic fever does not treat CRE, and thus appropriate CRE-active therapy is delayed.

Patients undergoing HSCT are especially at risk for acquiring *P. aeruginosa*. Outbreaks of both CRAB and CRPA have been associated with hematological-oncological wards with high associated mortality rates [98]. Environmental reservoirs, including sanitary and water supply systems, have been implicated in outbreaks, mainly due to biofilm formation [98].

CRE Screening

The incidence of colonization and infection with extended-spectrum β-lactamase (ESBL)-producing *Enterobacteriaceae* is increasing and is high in patients with cancer, HSCT, and SOT recipients [82]. A number of studies have reported screening high-risk patients for ESBL-E, with higher rates of subsequent infections in patients who were positive for colonization, yet there is no consensus on the implementation of screening consistently for patients [82]. Colonization by CRE has been described as a significant risk factor for infection by the same bacteria, with Gianella et al. reporting that liver transplant recipients colonized with CRE were 13.9 times more likely to develop a CRE infection than those not colonized [99]. A multicenter study evaluating 57 SOT recipients with CRE colonization found 1-year post-transplant survival approaching 80% [100]. Further studies are needed in regard to identifying if pre-transplant CRE screening is necessary, especially since there are discrepant results determining risk of subsequent infection patients colonized with CRE prior to liver transplantation [89, 99].

The sensitivity of surveillance cultures varies widely among MDR-GNB species, and the natural history of colonization has not been clearly described. A prospective cohort study from Brazil that collected weekly samples immediately before liver transplantation and weekly thereafter identified CRAB as the most common GNB in 46% of patients, followed by CRE in 40% of patients [101]. The CDC have recommended screening for CRE in patients receiving healthcare in areas with endemic CRE; while earlier detection may be helpful to prevent cross-transmission through appropriate contact precautions, further data is needed to identify risk of development of infection.

Disease Diagnostics

In the United States, the CRE epidemic is mediated by rapid expansion of CP-*K. pneumoniae* sequence type 258, which expresses class A KPC carbapenemase [102]. One of the key challenges in controlling the spread of CRE is that not all carbapenem resistance equates to the production of carbapenemases. Current testing requires clinical laboratories to perform susceptibility testing

on isolates recovered in cultures, which can delay diagnosis by 2–5 days. There are several commercial tests for rapid identification of carbapenem resistance and can be divided into two categories: molecular tests that detect the presence of a carbapenemase and phenotypic tests that detect the in vitro activity of carbapenemase enzymes [102]. Nucleic acid amplification tests have been developed to identify carbapenemases and have some advantages, including rapid turnaround time, identification of specific carbapenemase genes which may help in antimicrobial choice, and, in some cases, the ability to detect directly from clinical specimens [102]. The latter advantage may complicate some specimens as occasionally isolates may harbor a carbapenemase gene but are susceptible in vitro to carbapenems; the significance of these findings is unclear. There are currently two tests available that can detect carbapenemase genes present from bacteria in the blood; the culture step is critical because it allows for biological amplification of the organisms and subsequent high sensitivity for resistance genes [102].

In addition to nucleic acid amplification, there are non-nucleic acid-based tests for the detection of CRE that are performed on bacteria grown in pure culture. The RAPIDEC® CARBA NP (bioMérieux) is a rapid phenotypic carbapenemase detection test performed on bacterial colonies. The test is based on a pH change indicated when imipenem is hydrolyzed by bacteria [102]. In addition to this, some laboratories have adapted the matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI TOF MS) to detect carbapenemase activity by incubating the organism with a carbapenem and using mass-based detection of the carbapenem and its degradation production [102].

Treatment of CRE

In the recent years, there have been a variety of new antibiotics that have come to market or are in phase II–III trials of development. Prior to these newer agents, antimicrobial therapy relied heavily upon older agents including polymyxins, aminoglycosides, fosfomycin, and tigecycline [83]. Polymyxins such as colistin and polymyxin B work by disrupting the gram-negative cell membrane through electrostatic interaction with lipopolysaccharide, causing leakage of the intracellular components and subsequent cell death [87]. Polymyxins have been shown to have efficacy against KPC-producing CRE and CRAB, but associated nephrotoxicity has been documented in renal SOT, which may limit its use in renal transplantation [103]. Additionally, polymyxins, when administered parenterally, poorly penetrate lung tissue [83].

In terms of aminoglycosides, gentamicin is the most active aminoglycoside against CRE, with reported susceptibility rates ranging from 13% to 90% [83]. Gentamicin works by interfering with bacterial protein synthesis by binding to the 30S ribosomal subunit. Susceptibility rates have been lower with amikacin, and similar to polymyxins, aminoglycosides have high rates of nephrotoxicity. Fosfomycin, a parenteral agent only available in Europe at this time, has been shown to be beneficial in patients with CRE UTIs, given most CRE have been found to be susceptible to it. Unfortunately, clinical data to support the oral formulation in the setting of CRE UTI has not been well evaluated, with 1 retrospective

study showing only 6 out of 13 patients achieving microbiologic cure [104, 105]. Recently, a new semisynthetic aminoglycoside was improved for use in MDR gram-negative urinary tract infections, plazomicin, and was found to be non-inferior in comparison to meropenem [106].

Tigecycline is a glycylcycline antibiotic that inhibits bacterial protein synthesis by binding to the 30s ribosomal subunit [87]. It exhibits a broad range of activity against gram-positive agents and gram-negative bacteria. It has been approved for intra-abdominal and skin and soft tissue infections; however it is suboptimal in the treatment of bacteremia [87]. Two new tetracyclines have recently been approved by the FDA: eravacycline for complicated intra-abdominal infections and omadacycline for both acute bacterial skin and skin structure infections and community acquired pneumonia [107].

In 2015, the FDA approved ceftazidime/avibactam for the treatment of complicated intra-abdominal and urinary tract infections. In vitro evidence has shown >97% of isolates tested were susceptible, with the exception of NDM-producing isolates [108]. Of importance, this agent has only been approved for complicated intra-abdominal infections and complicated urinary tract infections.

In 2014, a novel antipseudomonal cephalosporin combined with B-lactamase inhibitor was introduced on the market (ceftolozane/tazobactam). It is stable against AmpC- and ESBL-producing bacteria as well as CRPA, but is inhibited by carbapenemases and is inactive against CRAB. Similar to ceftolozane/tazobactam, meropenem/vaborbactam is an existing carbapenem combined with a novel B-lactamase inhibitor that has been approved for UTI. However, its spectrum of activity covers both ESBL- and KPC-producing isolates, but not CRPA, MBL, or CRAB.

In terms of antibiotics in the pipeline, there are four agents aimed at treating MDROs: aztreonam/avibactam, cefiderocol, imipenem/relabactam, and tebipenem. Aztreonam/avibactam has been shown to have in vitro activity against Ambler class A, C, and D carbapenemases. Cefiderocol is a novel siderophore cephalosporin, structurally similar to ceftazidime and cefepime, which utilizes iron transport mechanisms to increase periplasmic concentrations in the bacteria. It has been found to have in vitro activity against KPC, NDM, OXA, and VIM carbapenemases [109]. Imipenem/relabactam is an existing antipseudomonal carbapenem attached to a novel B-lactamase inhibitor in phase II trials for UTI and IAI and may have activity against MBLs. Finally, tebipenem is an oral carbapenem stable against ESBL and AMPc, but is inactivated by KPC, OXA, and MBL carbapenemases (Table 2).

Prevention of CRE Infection

Although there are new antimicrobial agents in the pipeline, the high associated morbidity and mortality in SOT and HSCT necessitate development of prevention strategies. The 2015 CDC Facility Guidance for Control of CRE recognizes optimizing compliance with hand hygiene and contact precautions, increased

Table 2 Antibiotics affected by Ambler class beta-lactamases and antibiotics with in vitro activity

Ambler class	Beta-lactamase type	Activity	Enzyme examples	Common bacteria	Antibiotic considerations
A	Penicillinases	Hydrolyzes penicillins and cephalosporins	CTX-M, KPC, SHV, TEM	*E. coli*, *Klebsiella*, *Enterobacteriaceae*, *Pseudomonas*	Ceftazidime/avibactam Meropenem/vaborbactam Aztreonam/avibactam Cefiderocol Ceftolozane/tazobactam
B	Metallo-beta-lactamases	Uses zinc for hydrolysis of the B-lactam ring	IMP, NDM, VIM	*Pseudomonas*, *Acinetobacter*	Aztreonam/avibactam Cefiderocol
C	Cephalosporinases	Hydrolyzes broad- and extended-spectrum cephalosporins	Amp C	*Serratia*, *Pseudomonas*, *Acinetobacter*, *Citrobacter*, *Enterobacter*, *Morganella* (SPACE-M)	Carbapenems Cefepime Ceftazidime/avibactam Meropenem/vaborbactam Aztreonam/avibactam Plazomicin Ceftolozane/tazobactam
D	Oxacillinases	B-lactamase production and reduced permeability or increased efflux	OXA	*Acinetobacter*, *E. coli*, *Pseudomonas*	Ceftazidime/avibactam Ceftolozane/tazobactam

environmental cleaning, increasing personnel education in regard to CRE, minimizing the use of indwelling devices, and most importantly active antimicrobial stewardship program [83]. Active surveillance has been recommended in areas of high endemic CRE rates, as well as during times of controlling outbreaks. Furthermore, infection prevention programs should follow guidelines for endoscope reprocessing given outbreaks associated with contaminated duodenoscopy, including one associated with the death of a kidney-pancreas transplant recipient [110].

In a prospective study of liver transplantation (LT) recipients who developed CRE infection, the need for renal replacement therapy after LT, mechanical ventilation >48 h, hepatitis C recurrence, and CRE colonization were independent risk factors for invasive infections; the authors subsequently developed a risk score with a high negative predictive value [99]. Use of a score system may help clinicians identify the majority of colonized patients after LT with a low

probability for developing CRE infection; further research is necessary to identify if the scoring system can be validated in other facilities. In terms of lung transplantation, many centers will treat recipients with a history of *P. aeruginosa* with antipseudomonal therapy for 2–3 weeks postoperatively to reduce the risk of pneumonia and allograft colonization; additionally, surgical debridement of the sinuses after transplant has been associated with reduced incidence of bacterial pneumonia, although further studies are needed for CRPA [96].

A key factor in the prevention of carbapenem-producing organisms is antimicrobial stewardship. Selective antimicrobial pressure can select for an antibiotic-resistant strain of *Acinetobacter*, which can subsequently spread within an institution [87]. Carbapenem use has been linked to the development of CRE infections as well as the receipt of other antimicrobials, including fluoroquinolones, and B-lactams have been independently associated with CRE infection [83].

Environmental disinfection is important in the control and spread of CRAB. Environmental cleaning with phenol, sodium dichloroisocyanurate, and vaporized hydrogen peroxide has all been studied and is efficacious [87]. *P. aeruginosa* is common in environmental reservoirs, and different strategies have been effective in identifying and eliminating sources of this pathogen, including hand hygiene, contact precautions, screening patients, and point-of-use filters [98]. Hospital construction measures aimed at controlling environmental contamination by and spread of CRPA have been effective at minimizing the risk of infection in immunocompromised hosts [98].

Currently there are no formal recommendations regarding perioperative antibiotic prophylaxis outside of the 2013 clinical practice guidelines for antimicrobial prophylaxis in surgery, which gives general guidelines for prophylaxis but is not specific to MDROs [111]. Given colonization with MDRO has been found to be an independent risk factor for development of infection in SOT and HSCT, it may be imperative to consider a regimen that targets those pathogens [2]. Furthermore, a recent retrospective cohort study identified MDROs in 15% of donor cultures, including those with extended-spectrum cephalosporin-resistant *Enterobacteriaceae* and CRE [1]. Colonization with CRE may limit antimicrobial choice, and thus pre-transplant consultation with transplant infectious disease specialists is recommended.

Conclusion

Pre-transplant colonization with multidrug-resistant organisms is increasingly prevalent and is often associated with post-transplant infection. These data underscore the importance of pre-transplant screening and decolonization procedures. There is a need for further research to understand the epidemiology of pre-transplant MDRO colonization, appropriate screening modalities and timing of screening, as well as effective decolonization procedures.

Introduction

The incidence of multidrug-resistant Gram-negative bacterial infections, in particular those due to extended-spectrum β-lactamase (ESBL)-producing Enterobacterales (ESBL-EB) and carbapenem-resistant Enterobacterales (CRE), has been increasing worldwide [1–5]. This is of particular concern to immunocompromised patients, including solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients [6–8], although risk factors vary based on geographical location and organ transplanted. ESBL-EB and CRE infections can cause significant

challenges in a patient's posttransplant course. Here we will review the clinical implications of these infections including recommendations for diagnosis and treatment.

Disease Epidemiology

ESBL-Producing Enterobacterales

ESBL enzymes are a family of diverse and evolving β-lactamases, often encoded by plasmids, which can hydrolyze third-generation cephalosporins and confer resistance to penicillins, first through third-generation cephalosporins and aztreonam. They are inhibited by clavulanic acid and remain susceptible in vitro to cephamycins and carbapenems, although the former antibiotics are not recommended for treatment as ESBL-producing organisms usually develop resistance to cephamycins through other mechanisms. The most common type of ESBL is a CTX-M enzyme (named for its ability to hydrolyze cefotaxime), but SHV(sulfhydryl variable) and TEM (named for the first patient to have this enzyme identified) enzymes are also frequently encountered [3, 9].

In SOT recipients, the proportion of Enterobacterales that harbor ESBL enzymes in clinical blood samples fluctuates by region and local resistance patterns, ranging from 3% in the USA (although this estimate is from 2007) to 60% in China [5, 10–13]. Similarly, the risk of developing an ESBL-EB infection posttransplant varies by geography but ranges between 3.4 and 16.9% in abdominal organ transplant recipients (Table 1) [14–21]. The highest risk has been reported in Brazil, where 16.9% of kidney transplant patients at one hospital developed an ESBL-EB urinary tract infection (UTI) [15]. The risk of ESBL bacteremia is estimated to be closer to 4% [14, 18]. Bacteremia is most commonly secondary to a UTI, especially in kidney transplant patients, but can also be caused by catheter-associated infections and surgical site infections [14]. In one study analyzing Gram-negative bacteremia after SOT, the highest incidence of bacteremia was in the first month [13], although other studies have found that the mean or median time from transplant to ESBL-EB infection can vary significantly from 15 days to 52 months [14, 18, 20–22].

Klebsiella pneumoniae and *Escherichia coli* are the most common ESBL-EB identified in SOT recipients [5, 14–17, 21]. Regional differences, however, do exist. A study in France reported *Enterobacter cloacae* as the most common ESBL-EB isolated in urine within 3 months of kidney transplant [18], and a study in China documented *Klebsiella aerogenes* as the most frequent cause of ESBL-EB bacteremia [11]. In China, the most common ESBLs identified in SOT recipients were in the TEM family, but CTX-M-9 and SHV β-lactamases were also frequently detected [16]. In France, CTX-M-1 was the most common β-lactamase identified in liver transplant patients [21].

The risk factors for developing an ESBL-EB infection following SOT include older age, increased immunosuppression, diabetes, posttransplant infection, reoperation or

hemodialysis, graft rejection, hospitalization or antibiotic use in the last 6 months, pretransplant ESBL colonization, and a model for end-stage liver disease (MELD) score ≥ 25 in liver transplant patients [11, 15, 20, 23]. Organ transplant itself has also been identified as a risk factor for ESBL *E. coli* bacteremia [24].

Lastly, patients undergoing HSCT are at particularly high risk for bloodstream infections due to prolonged neutropenia and breakdown of the gastrointestinal mucosal border from high-dose conditioning regimens. Recipients of allogeneic HSCT have a higher incidence of bacteremia than patients undergoing autologous HSCT [25]. In patients with hematologic malignancies who develop Enterobacterales bacteremia, approximately 17–37% will harbor an ESBL [8]. For HSCT recipients, the ESBL prevalence is similar and ranges from 9 to 44% of all Enterobacterales infections [25–30]. The risk of developing an ESBL-EB infection after a HSCT ranges from 0.4 to 3.5%, although most of the literature has been limited to bloodstream infections [25, 31, 32]. The majority of ESBL-EB infections are due to *E. coli* or *K. pneumoniae* [26, 31–33] that produce a CTX-M β-lactamase, although production of SHV and TEM β-lactamases has also been identified in this patient population [27, 29, 31, 32]. In one retrospective cohort, the median time from HSCT to ESBL-EB infection was 141 days [32]. Risk factors for developing an ESBL-EB infection in HSCT patients have not been well defined, but likely include prior antibiotic use, prior hospitalizations, and pretransplant colonization with ESBL-EB [31, 32].

Carbapenem-Resistant Enterobacterales

Enterobacterales develop carbapenem resistance through a heterogenous array of mechanisms, including acquisition of carbapenemases. The plasmid-mediated *K. pneumoniae* carbapenemase (KPC) is the most common means of carbapenem resistance in the USA, South America, Europe, China, and Israel and is easily transferred between bacterial species. Other carbapenemases include oxacillinase (OXA)-48-like β-lactamases and metallo-β-lactamases (MBLs) including Verona integron-encoded MBL (VIM), imipenemase (IMP), and New Delhi MBL (NDM). NDMs are the most common carbapenemases in India, Pakistan, and the UK [7].

The risk of CRE infection following SOT depends on geography, occurrence of local outbreaks, patterns of resistance, and the organ transplanted. The risk is documented to range from 0.4 to 26.3%, but the majority of data is limited to single-center studies analyzing abdominal organ transplant recipients (Table 2) [22, 34–45]. In the USA, the incidence of CRE infection posttransplant is less than 10% [35–37, 42, 43], but in Brazil the risk can be as high as 26% in renal transplant patients [34]. These estimates probably more accurately reflect institutional trends rather than true national risks. However, a national surveillance program in Italy reported that 26.5% of all Gram-negative isolates from SOT recipients were carbapenem resistant [46]. Most CRE infections occur within the first 3 months

after transplant, but the median or mean time from transplant to infection ranges from 11 to 218 days [22, 34–45, 47].

In liver transplant patients with CRE infections, bacteremia and intra-abdominal infections, including surgical site infections, are the most common sites of infection and frequently occur in tandem [34–39, 47]. Risk factors include hepatitis C virus, hepatocellular carcinoma, higher MELD score, Roux-en-Y choledochojejunostomy, bile leak, renal replacement therapy and mechanical ventilation for greater than 48 h after transplant, pretransplant colonization with CRE, combined organ transplant, and need for reoperation after transplant (Table 3) [37–39, 47]. In renal transplant patients, UTIs are the most common source of CRE infection, with secondary bacteremia frequently observed [34, 40–45]. Central venous catheters have also been implicated in CRE infections, and in one study including heart, liver, and kidney transplant recipients, 75% of the primary bloodstream infections were catheter-related [34]. Risk factors for CRE infections in renal transplant patients include multi-organ transplantation, ureteral stents, deceased donor allografts, transplant admission length of stay, pretransplant CRE colonization, and prior broad-spectrum antibiotics [40, 42, 43].

Most studies have focused on carbapenem-resistant *K. pneumoniae*, the most common type of CRE infection in SOT recipients [39, 44]. However, one study evaluating CRE infections in renal transplant patients identified *Enterobacter cloacae* in 4 patients (11.8%) and *Escherichia coli* in 3 (8.8%) [44]. The most common carbapenemase described in SOT recipients is KPC [35, 39], but there have been reports of infections due to NDM- and OXA-48-producing Enterobacterales [7].

Patients with hematologic malignancies are at high risk for Gram-negative bacteremia although few studies have specifically analyzed the epidemiology of

CRE in HSCT recipients. Geography can contribute significantly, and in 13 centers in Italy, where CRE is an endemic nosocomial pathogen, 58% of the *K. pneumoniae* isolated from patients with hematologic malignancies were carbapenem resistant [48]. This was associated with a worrisome increase in resistance from 2010 to 2013, and the 21-day mortality in this group was 52%. In contrast, in two New York City oncology centers, 6.5% of Enterobacterales blood isolates among neutropenic patients with hematologic malignancies were carbapenem resistant [49]. Specific to HSCT recipients, one large study of 65 HSCT centers in Europe, Australia, and Asia found that 8.4% of Enterobacterales isolates were carbapenem resistant in patients with Gram-negative bacteremia [50]. Additionally, the incidence of CRE has been increasing in HSCT patients [7, 51]. In one Italian study, the incidence of CRE in allogenic HSCT patients increased from 0.4% in 2010 to 2.9% in 2013. The authors hypothesize that this was due to select transplant centers having large outbreaks of KPC-producing CRE in a country where CRE was already endemic during that time [51, 52]. For neutropenic patients with hematologic malignancies, risk factors for CRE bacteremia include prior β-lactam/β-lactamase inhibitor (BLBLI) or carbapenem use, current trimethoprim-sulfamethoxazole or glucocorticoid use, and prior CRE [49]. In HSCT recipients who develop Gram-negative bacteremia after transplant, carbapenem resistance was associated with breakthrough bacteremia on a carbapenem, longer hospitalization, being in the intensive care unit, and prior antibiotic use (Table 3) [50].

Clinical Impact in Transplant

ESBL-Producing Enterobacterales

Infections due to ESBL-EB have been associated with increased morbidity and mortality among SOT recipients. The 30-day mortality rate for abdominal SOT recipients with ESBL-EB infections can be up to 26%, with the highest mortality reported in bacteremic patients (Table 1) [14, 16, 20, 21]. In the context of lung transplantation, one small study in Israel identified five patients with definitive ESBL-producing *K. pneumoniae* infections, and all five died within 14 months of follow-up; the proportion of deaths attributable to the ESBL infection is unknown [22]. In general, patients with ESBL-EB infections posttransplant have a higher mortality than patients who do not develop ESBL-EB infections [20, 21]. However, this may be confounded by underlying comorbidities and individual risk factors contributing to the acquisition of an ESBL-EB infection. When comparing patients with resistant versus susceptible Enterobacterales infections, outcome results are conflicting [11, 20, 53].

ESBL-EB UTIs in renal transplant patients are associated with high rates of recurrence. One study demonstrated an increase in the incidence of ESBL-EB UTIs from 13% for patients with their first UTI to 45% for patients with their third UTI [15, 17]. In addition, acute organ rejection has been associated with ESBL-EB

infections [11, 16, 20], but any impact on long-term graft function has not been definitely demonstrated [19, 20].

Donor-derived infections are a unique and emerging concern for transplant recipients, especially as the prevalence of multidrug-resistant organisms increases. There have been at least five probable cases of ESBL-EB infections transmitted from donors to organ transplant recipients. In the first and second cases, the donor had an ESBL-EB UTI, and one kidney recipient developed a complicated UTI and pseudoaneurysm at the arterial anastomosis, and the other kidney transplant recipient developed ESBL-EB pyelonephritis and perinephric abscess. Both recipients survived but required allograft nephrectomies. In the remaining three probable cases of transmission, the source of donors' infection was unknown. Two liver transplant recipients developed intra-abdominal infections, and one liver transplant patient developed ESBL-EB bacteremia. One of the patients with the intra-abdominal infection died within 3 months of transplant. In all five cases, the donor's culture results were either not available or not adequately communicated to the recipient's healthcare team prior to the development of the recipient's infection [54]. It is also possible that donor-derived infections have occurred where the link between donor infection and recipient disease went unrecognized or unreported. Clinical presentation may also be different than for recipient-derived infections. Timely inter-facility communication is imperative in both preventing and treating patients with donor-derived infections.

Among HSCT patients, the mortality associated with ESBL-EB infections is similarly high, with one study estimating a 1-year mortality of 52% for patients with multidrug-resistant infections, of which 87% of the multidrug-resistant isolates were ESBL-EB [33]. In neutropenic cancer patients, including those with HSCTs, the 30-day mortality rate associated with ESBL-EB bacteremia was reported to be 38% [27]. Cancer patients with ESBL-EB bacteremia are suspected to have an increased mortality compared to patients without resistant organisms [27, 29], although conflicting reports exist [30, 33].

Carbapenem-Resistant Enterobacterales

CRE infections portend an increased risk of morbidity and mortality among SOT recipients [22, 36, 37, 42, 45, 47]. The 30-day mortality rate among SOT recipients with CRE infections ranges from 0 to 50% and can approach 75% at 1-year (Table 2) [22, 34–45, 47]. Mortality rates are typically higher in bacteremic patients compared to those with urinary infections, and in one study, the 30-day mortality rate increased from 25% in patients with a UTI to 44% in patients with bacteremia [34]. SOT recipients with CRE infections are more likely to have microbiologic failure [55] and develop recurrent infections [42, 45] than those with infections due to susceptible bacteria. Further, the relatively limited antimicrobial armamentarium, frequent need for nephrotoxic agents, and often delayed time to initiation of adequate antibiotic therapy [55] also impact morbidity and mortality.

In one of the largest studies addressing donor-derived infections due to multidrug-resistant Gram-negative organisms, 30 patients received an organ from a deceased

donor found to harbor carbapenem-resistant Gram-negative bacteria. Four (29%) of 14 patients who received an organ from a high-risk donor who was bacteremic or harbored an infection of the transplanted organ had proven transmission of the carbapenem-resistant bacteria, all due to carbapenem-resistant *K. pneumoniae*. However, none of the organ recipients who received appropriate antibiotic therapy, defined as targeted therapy initiated within 7 days of transplantation and continued for at least 7 days, developed an infection with the resistant organism [56]. In the literature, there have been at least nine cases of reported CRE transmission from donor to organ recipient [54, 57]. Rapid diagnosis and communication with the recipient's healthcare team can significantly impact empiric antibiotic regimens and mortality [54].

Among patients with a hematologic malignancy and CRE infection, the mortality rate can be greater than 50% at 30 days, with one study demonstrating a median time from infection to death of only 4 days [48, 49]. This is likely similar in patients who have undergone HSCT, and in Italy the 90-day mortality of this group was 58% [51]. Allogenic HSCT recipients with CRE infections have a higher mortality than autologous HSCT recipients [51]. As with SOT, delay in administration of appropriate antibiotic therapy is associated with high bacteremia-associated mortality rates in patients with hematologic malignancies [49].

Disease Diagnostics and Clinical Evaluation

ESBL-Producing Enterobacterales

Historically, the Clinical and Laboratory Standards Institute (CLSI) recommended confirming ESBL production by phenotypic testing, typically with the addition of clavulanic acid [58]. However, in 2009 and 2010, respectively, the European Committee on Antimicrobial Susceptibility Testing (EUCAST) and CSLSI lowered the breakpoints for cephalosporins and aztreonam and no longer recommend phenotypic ESBL confirmation for Enterobacterales [56, 58–61]. This was based on data demonstrating that in vitro and in vivo efficacy correlated better with the minimum inhibitory concentration (MIC) and pharmacokinetic data rather than with the presence of a β-lactamase [59]. Nevertheless, these organizations acknowledge that ESBL phenotypic testing may still be useful for epidemiologic and infection control purposes [59, 61]. With this update, most labs are no longer screening for ESBLs, and the presence of an ESBL-producing isolate is often assumed when resistance to ceftriaxone, cefotaxime, or ceftazidime is documented [58, 62]. Because of this, differences in the EUCAST and CLSI breakpoints for ceftazidime and cefpodoxime may affect the reported prevalence of ESBL-EB [63]. In the recently published MERINO trial, 86% of *E. coli* and *K. pneumoniae* bloodstream isolates which were non-susceptible to ceftriaxone or cefotaxime tested positive on an ESBL phenotypic screen, and the presence of an ESBL gene was confirmed in 85% through whole-genome sequencing [62].

Molecular testing for ESBL production has the potential to rapidly diagnose both the organ donor and recipient, allowing for quicker initiation of appropriate

antibiotics. The Verigene Gram-negative blood culture test (Luminex, US) is one of the commercially available molecular testing methods for ESBLs. It uses microarray hybridization and signal amplification to test for CTX-M β-lactamases as well as many carbapenemases within 2 h [64]. This microarray system has been shown to reduce the time to bacterial identification compared to conventional phenotypic analysis as well as the time to initiate optimal antimicrobial therapy [65, 66]. The sensitivity ranges from 77 to 100% for all tested antibiotic resistance genes and the specificity from 99 to 100%. False-negative results can occur, especially in polymicrobial infections, and this cannot replace traditional susceptibility testing [64]. Additional non-Food and Drug Administration (FDA)-approved molecular diagnostic kits using real-time PCR are available and include the Antibiotic Resistance Genes Microbial DNA qPCR Array (Qiagen, Netherlands) and Antibiotic Resistance TaqMan Assays (ThermoFisher Scientific, USA) [67]. Additional methods are also being studied to rapidly identify ESBL genes including loop-mediated isothermal amplification (LAMP) [68], liquid chromatography and tandem mass spectrometry proteomic analysis [69], and whole-genome sequencing [67]. A notable limitation of molecular testing is that it can only detect known antibiotic resistance genes or mutations and novel resistance mechanisms will be missed [67]. Molecular testing may fail to detect less common ESBLs, and most of the current molecular tests only focus on identifying the CTX-M family of β-lactamases.

Carbapenem-Resistant Enterobacterales

Similar to ESBL testing, CLSI lowered the carbapenem breakpoints for Enterobacterales in 2010 and no longer recommends routine testing for carbapenemase production. However, phenotypic screening for carbapenemases is recommended by CLSI when the imipenem or meropenem MIC is 2–4 μg/mL or when the ertapenem MIC is >2 μg/mL [60]. EUCAST has higher MIC breakpoints for meropenem and imipenem than CLSI (≤2 μg/mL vs. ≤1 μg/mL) but a lower threshold to perform carbapenemase screening (MIC >0.125 μg/mL) [61]. This may lead to differences in detection of carbapenemases. In one study, application of the CLSI screening breakpoint did not detect 14% of carbapenemase-producing Enterobacterales isolates; in contrast, implementation of the EUCAST breakpoints failed to detect <2% of isolates. CLSI guidelines based on phenotypic resistance patterns and traditional antimicrobial susceptibility testing are easier for laboratories to implement and maintain. However, they will likely continue to fail to identify a small proportion of patients with carbapenemase-producing organism. Epidemiologically, this may make CRE outbreaks more difficult to trace as not all carbapenemase-producing isolates will be identified; however, at the individual patient level, it is not known whether identification of carbapenemases should effect treatment decisions if the MIC value remains within the susceptible range [70].

In 2015, the Centers for Disease Control and Prevention (CDC) simplified the surveillance definition of CRE to Enterobacterales resistant to imipenem, meropenem, doripenem, or ertapenem or that demonstrates carbapenemase production. Previously,

the definition did not include ertapenem and required the isolate to be non-susceptible to imipenem, meropenem, or doripenem and resistant to a third-generation cephalosporin [71, 72]. By modifying this definition, most carbapenemase-producing CRE are now captured, including those producing OXA-48-like carbapenemases which could have previously gone undetected. However, this definition now captures more CRE isolates which are not carbapenemase producers but may carry other resistance determinants, including overproduction of AmpC or ESBL in combination with other mutations such as porin modifications or efflux pumps [71].

Testing for carbapenemases is often still necessary for infection prevention and epidemiologic purposes, especially in the setting of an outbreak. The most common phenotypic tests include the modified Hodge test (MHT), the Carba NP test, and carbapenem inactivation method (CIM) test. None of these tests is able to differentiate between specific carbapenemases. The MHT is easy to perform, and in the USA, it has a sensitivity between 93% and 98%. Unfortunately, its ability to detect NDMs is poor, and it has a relatively low specificity. This limits its ability to be used in low resource settings outside of the USA, despite its low cost, where KPCs are not the most common carbapenemases [71]. The Carba NP test detects hydrolysis of imipenem by a carbapenemase and is quicker to perform than the MHT. The sensitivity is between 73 and 100% for most carbapenemases except OXA-48-like carbapenemases [71, 73]. Different variations of this assay have been produced including Rapid CARB test (Rosco Diagnostics, Denmark) and Rapidec Carba NP (bioMérieux, France) [71]. The CIM and modified CIM (mCIM) tests asses for the hydrolysis of meropenem. The mCIM has a high sensitivity, ranging from 93 to 100% for all major types of carbapenemases [71, 74]. More specific assays such as using EDTA to test for the presence of an MBL and boronic acid to assess for a KPC have been used [71, 73]. A new rapid phenotypic carbapenemase test, BD Phoenix CPO detect (BD Diagnostic Systems, US), was recently approved by the FDA. This test is unique because it can classify types of carbapenemases and is completely automated [74]. Lastly, matrix-assisted laser desorption ionization-time-of-flight (MALDI-TOF) mass spectrometry (MS) is being developed to detect carbapenem breakdown products but has a low sensitivity for detecting OXA-48-like carbapenemases [71].

Molecular testing for carbapenemases can be helpful in rapidly determining which carbapenemases and resistance mechanisms are present. Several commercial PCR assays are available, including, but not limited to, Xpert Carba-R (Cephid, US), eazyplex SuperBug panels (Amplex, Germany), and Check-Direct CPE assay (Check-Points, Netherlands); however, not all assays detect all carbapenemases [71]. Xpert Carba-R is FDA approved in the USA for testing on rectal surveillance swabs and pure bacterial colonies and is validated in the European Union for use on rectal swabs. It takes less than 1 h to run and can detect KPC, NDM, IMP, VIM, and OXA-48-like carbapenemases [75]. The sensitivity has been reported to be 93.5–100% with a specificity of 98.6–100%, although there have been concerns regarding its ability to detect the VIM carbapenemase [67]. The FilmArray blood culture identification panel (bioMérieux, France) is a multiplex PCR test that is FDA approved for the diagnosis of bacteremia. It can detect KPCs (as well as other antimicrobial resistance genes) directly from a positive blood culture bottle within 1 h [67, 76]. Additionally,

many hospitals develop "in-house" DNA detection assays that can have high sensitivity and specificity [64].

The Verigene Gram-negative blood culture test (Luminex, US), a microarray test, can also detect KPC, NDM, VIM, IMP, and OXA carbapenemases in 2 h with a sensitivity close to 100% [66, 71]. However, a positive blood culture and Gram stain are needed before the appropriate panel can be selected [66]. As whole-genome sequencing becomes more affordable and widely adapted, it also has the potential to assist with rapid detection of carbapenemases [67]. As with all molecular-based assays, only known carbapenemases genes can be tested, making it imperative to perform conventional antimicrobial susceptibility testing alongside these new tests.

Management

ESBL-Producing Enterobacterales

Carbapenems demonstrate the most reliable activity for ESBL-EB infections and should be the first-line therapy for transplant recipients [9, 77, 78]. Carbapenems are typically not affected by ESBL hydrolysis or large bacterial inoculums [77].

First-generation β-lactam/β-lactamase inhibitor (BLBLIs), namely, piperacillin/tazobactam (PTZ), should not be the first choice of therapy for ESBL-EB infections in transplant recipients. ESBL-EB are usually susceptible in vitro to PTZ, but treatment failures have been described, possibly due to high inoculum effects [77]. One post hoc analysis of six prospective cohorts found no difference in the 30-day mortality between those treated with a BLBLI versus those treated with a carbapenem [79]. However, the MERINO trial, published in 2018, was the first randomized, non-inferiority clinical trial to compare PTZ to meropenem in patients with ceftriaxone-resistant *E. coli* or *K. pneumoniae* bacteremia. PTZ did not reach the non-inferiority endpoint, suggesting worse outcomes in the PTZ group and raising serious concerns about using BLBLIs in patients with ESBL-EB infections. 24% of the subjects in the trial were immunocompromised, but details regarding organ transplantation were not delineated [62].

Cefepime may also exhibit in vitro activity against ESBL-EB. However, treatment of ESBL-EB infections with cefepime has been associated with increased mortality in several studies. Cefepime is generally not recommended for patient with ESBL-EB infections, especially in those patients with MICs $\geq$4 μg/mL [77, 80].

Fosfomycin is only available in the oral formulation in the USA but has the potential to treat UTIs due to susceptible ESBL-EB [77]. One study of ESBL uropathogens found that while only 4% of *E. coli* isolates were resistant to fosfomycin, 46% of the *Klebsiella* species isolates were resistant [81]. Additionally, retrospective data show that microbiologic cure rates with fosfomycin for ESBL-EB UTIs may only reach 57% and solid organ transplant patients could be more likely to fail therapy [82]. Therefore, the use of fosfomycin in the management of UTIs in transplant recipients should be guided by antimicrobial susceptibility testing, and

additional studies addressing the use of this agent in the transplant population are warranted.

Second-generation BLBLI antibiotics such a ceftazidime/avibactam (CAZ/AVI), ceftolozane/tazobactam (TOL/TAZ), meropenem/vaborbactam (MER/VAB), and imipenem/relebactam (IMI/REL) all have activity against ESBL-EB. Each respective beta-lactamase inhibitor (avibactam, tazobactam, vaborbactam, and relebactam) can inhibit ESBLs including those in the CTX-M, TEM, and SHV family [83]. Up to 99.6% and 87.1% of ESBL-EB isolates are susceptible in vitro to CAZ/AVI and TOL/TAZ, respectively [84, 85]. CAZ/AVI was originally studied in patients with complicated intra-abdominal infections (RECLAIM Trial), complicated UTIs (RECAPTURE Trial), and nosocomial pneumonias (REPROVE Trial) and was non-inferior to carbapenem therapy in each study [86–88]. All three studies showed that patients with ceftazidime-resistant Enterobacterales had similar cure rates irrespective of whether they were treated with CAZ/AVI versus a carbapenem [86–88]. Additionally, the REPRISE study was a randomized, phase III trial limited to patients with complicated UTIs or intra-abdominal infections due to ceftazidime-resistant Enterobacterales or *Pseudomonas aeruginosa*. Rates of clinical cure were similar for those treated with CAZ/AVI compared to those treated with best available therapy, 97% of whom received a carbapenem [89]. TOL/TAZ was shown to be non-inferior to meropenem in patients with complicated intra-abdominal infections (ASPECT-cIAI trial), including a subset of patients with ESBL-EB infections. The clinical cure rate among these patients was 95.8% [90]. MER/VAB and IMI/REL have not been extensively studied for the management of infections due to ESBL-EB, but these agents should maintain adequate activity against ESBL-EB infections [83]. Due to their broad spectrum of activity, however, these second-generation BLBLIs are best suited for the management of CRE and other multidrug-resistant Gram-negative pathogens and should be used in a stewardship-concordant manner. For more information on the stewardship implications of drug resistance, please refer to ► Chaps. 7, "Antimicrobial Stewardship for Transplant Candidates and Recipients," and ► 8, "Antimicrobial Prophylaxis in the Age of Emerging Transplant Infections" strategies.

The ideal preventative strategies for ESBL-EB infections in transplant recipients remain unknown. Depending on local epidemiology, as many as 31% of pre-transplant liver and kidney patients have been reported to be colonized with ESBL-EB, a factor which has been associated with posttransplant infection [21, 54]. One single-center US study described a 10% rate of fecal ESBL-EB carriage among HSCT candidates, and this was also associated with a risk of ESBL-EB bacteremia following transplant [31]. Guidelines from the American Society of Transplantation (AST) do not recommend screening for ESBL-producing bacteria in asymptomatic patients and instead place emphasis on improving infection control practices, minimizing unnecessary device use, and reducing unnecessary antibiotic exposure before and after transplantation [78]. Intestinal decolonization in patients with ESBL-EB colonization is not recommended and has been associated with the development of colistin- and tobramycin-resistant *K. pneumoniae* isolates [78, 91]. As described above, ESBL-EB donor-derived infections can also occur, and clear

and timely communication between hospitals and providers is critical for success in these scenarios [54].

Carbapenem-Resistant Enterobacterales

CAZ/AVI and MER/VAB are emerging as the first-line therapy for patients with infections due to susceptible CRE isolates [92]. While both display in vitro activity against KPC-producing CRE, neither is active against MBL-producing Enterobacterales. In contrast to MER/VAB, CAZ/AVI is active against OXA-48-producing Enterobacterales (Table 4). In retrospective, observational studies, CAZ/AVI has been associated with improved clinical outcomes compared to colistin- or aminoglycoside-based regimens [92].

CAZ/AVI has not been systematically evaluated in SOT patients. However, in one observational study of 109 patients with carbapenem-resistant *K. pneumoniae* bacteremia, 37% of whom were SOT recipients, higher clinical success rates were reported among patients who received CAZ/AVI-based therapy compared to those who received other regimens (85% vs. 41%, $p = 0.006$). While organ transplant was not a risk factor for clinical failure, 55% of the SOT patients demonstrated clinical failure at 3 days [93]. In another study inclusive of SOT and HSCT recipients treated with CAZ/AVI for invasive CRE infections, the 30-day mortality rate was 24%; 40% of patients with microbiologic failure were SOT recipients [94]. Three patients in this study developed resistance while on CAZ/AVI, and concerns about the development of CAZ/AVI resistance due to porin mutations or alterations in the omega loop of the KPC enzyme are growing [92]. One study also reported bla_{KPC-3} mutations which developed on therapy, conferring resistance to CAZ/AVI but restoring susceptibility to meropenem [95]. Treatment failures may also be caused by CAZ/AVI heteroresistance [96].

MER/VAB was recently approved by the US FDA for the treatment of complicated UTIs. In the TANGO II Trial, which evaluated the safety and efficacy of MER/VAB versus best available therapy (defined as mono- or combination therapy with polymyxins, carbapenems, aminoglycosides, tigecycline, or CAZ/AVI alone) for CRE infections, MER/VAB was associated with a higher rate of clinical cure than best available therapy. While there was no significant difference in 28-day mortality, MER/VAB was associated with less nephrotoxicity than best available therapy (4% vs. 24%) [97]. In one case report of a liver transplant patient with a KPC-producing *K. pneumoniae* bacteremia and a subphrenic abscess, MER/VAB was successfully used as salvage therapy after the patient developed resistance to CAZ/AVI on therapy [98]. It is unknown whether MER/VAB will prove to be superior to CAZ/AVI due to a possible higher barrier to resistance among KPC producers, and empiric therapy should be guided by local epidemiology [92]. IMI/REL has a similar spectrum of activity as MER/VAB and may have a comparable role in treating patients with infections due to KPC-producing Enterobacterales [83]. However, while the phase III RESTORE-IMI 1 trial reported similar clinical response rates between patients receiving IMI/REL and colistin plus imipenem/cilastatin for

Table 4 Summary of novel antibiotics with activity against extended-spectrum β-lactamase-producing Enterobacterales and carbapenem-resistant Enterobacterales [8, 77, 92, 100, 108, 115]

Drug	Class	Active against ESBLs	Active against KPCs	Active against MBLs	Active against OXA-48-like β-lactamases	Dose for CrCl >50
Ceftolozane/tazobactam	BLBLI	Yes	No	No	No	1 g/0.5 g q 8 h
Ceftazidime/avibactam	BLBLI	Yes	Yes	No	Yes	2 g/0.5 g q 8 h[a]
Meropenem/vaborbactam	BLBLI	Yes	Yes	No	No	2 g/2 g q 8 h
Imipenem/relebactam	BLBLI	Yes	Yes	No	No	0.5 g/0.25 g q 6 h
Aztreonam/avibactam	BLBLI	Yes	Yes	Yes	Yes	In development
Plazomicin	Aminoglycoside	Yes	Yes	Some[b]	Likely	15 mg/kg q 24 h
Cefiderocol	Siderophore cephalosporin	Yes	Yes	Yes	Yes	2 g q 8 h
Eravacycline	Tetracycline	Yes	Yes	Yes	Yes	1 mg/kg q 12 h

ESBL extended-spectrum β-lactamase, *KPC K. pneumoniae* carbapenemase, *MBL* metallo-β-lactamase, *OXA* oxacillinase, *CrCl* creatinine clearance, *BLBLI* β-lactam/β-lactamase inhibitor, *g* grams

[a]Has also been studied with a dose of 2 g/0.125 g q 6 h

[b]Higher MICs reported in the presence of the New Delhi metallo-β-lactamase

imipenem-resistant Gram-negative infections, only a minority of clinical isolates were KPC-producing CRE [99].

None of the second-generation BLBLIs have activity against MBL-producing Enterobacterales, but aztreonam (ATM) may be effective in the management of Enterobacterales infections when used in conjunction with avibactam. While ATM is stable against MBLs, avibactam maintains activity against other β-lactamases, including ESBLs and KPCs, which are commonly co-produced by MBL-producing Enterobacterales [100]. A few case reports have described successful use of CAZ/AVI with ATM in patients with infections due to MBL-producing Enterobacterales, including one in a multivisceral transplant recipient and one in a child who was a HSCT recipient [100–102]. This combination is also effective against multidrug-resistant *Stenotrophomonas maltophilia* but unfortunately, due to different mechanisms of resistance, is not reliably active against *P. aeruginosa or Acinetobacter baumannii* [103–105]. Aztreonam/avibactam is currently being evaluated in a phase II clinical trial for complicated intra-abdominal infections [100].

Plazomicin was also recently approved by the FDA for the treatment of complicated UTIs. It is the most potent aminoglycoside against KPC-producing Enterobacterales but displays diminished activity against NDM-producing Enterobacterales [100]. The recently published phase III, open-label CARE trial evaluated 28-day mortality among patients with CRE bacteremia or nosocomial pneumonia receiving plazomicin or colistin, each combined with meropenem or tigecycline. Both clinically significant disease-related complications and 28-day mortality were lower in the plazomicin arm (24% vs. 50%), and rates of nephrotoxicity were lower among patients treated with plazomicin than colistin (16.7% vs. 50%) [106]. Additional studies addressing the role of plazomicin in solid organ and hematopoietic stem cell transplant recipients with invasive CRE infections are warranted.

Eravacycline, a tetracycline derivative with a chemical structure similar to tigecycline, has demonstrated potent in vitro activity against CRE, including KPC-, OXA-, and NDM-producing Enterobacterales. It has been approved by the FDA for use in complicated intra-abdominal infections but did not meet the non-inferiority outcome for complicated UTIs (https://clinicaltrials.gov/ct2/show/study/NCT01978938). Omadacycline, another tetracycline derivative with an oral formulation, may have activity against CRE although it has primarily been investigated for use in community-acquired pneumonia and skin and skin structure infections without a specific focus on drug resistance [107]. Additional studies evaluating the efficacy of eravacycline and omadacycline in patients with invasive CRE infections and its use in solid organ and hematopoietic stem cell transplant recipients are needed [100].

Cefiderocol is a new siderophore cephalosporin that has activity against CRE as well as carbapenem-resistant *P. aeruginosa* and *A. baumannii* in vitro, including activity against KPCs, oxacillin carbapenemases, and many MBLs [100, 108, 109]. In a phase II trial, cefiderocol was found to be non-inferior to imipenem/cilastatin for the treatment of complicated UTIs or uncomplicated pyelonephritis and has now been approved by the FDA for use in these conditions [108]. The

proportion of enrolled patients with uncomplicated pyelonephritis was limited to 30%, and individuals with CRE infections were excluded. While kidney transplant recipients were included in the study, a subgroup analysis of this population was not performed. A trial comparing cefiderocol to best available therapy for severe CRE infections, including bacteremia, nosocomial pneumonia, and complicated urinary tract infection, was recently completed (https://clinicaltrials.gov/ct2/show/NCT02714595). The final results are forthcoming, but documentation provided to the FDA suggested there was a higher infection-related mortality in patients treated with cefiderocol compared to the control group (15.8% vs. 8.2%). The use of cefiderocol for CRE infections in SOT and HSCT recipients warrants further evaluation.

Prevention of CRE infections, including rapid identification and control of outbreaks, is crucial to the well-being of transplant recipients given the associated morbidity and mortality due to these infections, as well as the limited therapeutic armamentarium. Implementation of the CDC CRE toolkit, which emphasizes the use of contact precautions, including proper hand hygiene, gowns, and gloves, as well as patient and staff cohorting wherever possible, is recommended by the American Society of Transplantation Infectious Diseases Community of Practice for the prevention of CRE transmission [78, 110].

Pretransplant colonization with CRE has been cited as a risk factor for post-SOT transplant CRE infections [38, 39, 42]. However, one prospective study described spontaneous CRE clearance in 83% of colonized patients and highlighted the complex and fluid nature of CRE colonization dynamics [111]. While screening for rectal colonization of CRE may assist in identifying SOT candidates and recipients at risk for subsequent CRE infection, the optimal approach to doing so remains unclear, and a history of CRE infection or colonization is not a contraindication to transplantation [78]. In one study of 232 patients undergoing HSCT, 6% were colonized with carbapenem-resistant *K. pneumoniae* at the time of transplant, and intestinal colonization with multidrug-resistant bacteria (vancomycin-resistant *Enterococci* and carbapenem-resistant Gram-negative bacteria) increased the risk of developing a multidrug-resistant bloodstream infection in the early posttransplant period. The authors of this study posit that gut decolonization could help reduce posttransplant multidrug-resistant bacteremia in HSCT recipients [112]. However, for SOT recipients, selective gut decontamination is not recommended and has been associated with the development of resistance to the antibiotic being used for decontamination [78, 113].

Donor-derived CRE infections have been reported, raising the issue of whether patients infected or colonized with CRE are acceptable organ donors. In one series inclusive of 14 patients who received organs from donors with CRE or carbapenem-resistant *A. baumannii* bacteremia or infection of the transplanted organ, transmission did not occur when recipients received at least 7 days of appropriate antibiotic therapy initiated within the first 6 days of transplant [56]. Current guidelines recommend at least 1 week of targeted antimicrobials for recipients whose donors are either bacteremic with CRE or if there is evidence of CRE colonization or infection of the transplanted organ [78].

Conclusion

SOT and HSCT recipients are at high risk for ESBL-EB and CRE infections given their frequent healthcare exposures and need for ongoing immunosuppression. A patient's risk depends on both individual factors, including which organ was transplanted, prior courses of antibiotics, previous colonization with ESBL-EB and CRE, and need for medical devices, as well as institutional risk factors, including recent outbreaks of multidrug-resistant infections. Donor-derived infections can also occur, and inter-facility communication is pivotal in ensuring appropriate management. Given the high morbidity and mortality associated with these infections, novel diagnostic techniques and treatment regimens continue to emerge. However, targeted research in SOT and HSCT recipients, particularly as it pertains to management strategies, is needed.

Key Points

- The risk of developing an ESBL-EB or CRE infection after transplant depends on individual health factors, local resistance patterns, and the organ transplanted. Donor-derived infections can also occur.
- ESBL and CRE infections are associated with significant morbidity and mortality in transplant recipients.
- CLSI and EUCAST cephalosporin breakpoints can be used to diagnose ESBL-EB and CRE, although molecular testing for resistance genes is emerging as a rapid diagnostic technique.
- Carbapenems should be used as a first-line therapy for transplant recipients with ESBL-EB infections.
- Treatment of CRE is challenging. Many novel therapeutic agents are either being used or are in development, but options for MBL-producing Enterobacterales infections remain limited.

Epidemiology of *Pseudomonas aeruginosa* Infection in the Transplant Population

Recognized as the sixth most common bacterial species contributing to healthcare-associated-infections (HAIs), PsA represents a major nosocomial pathogen in the general population. Further solidifying its rank among the most important nosocomial pathogens, PsA represents the second most common cause of ventilator-associated-pneumonia (VAP) in the United States [1]. When resistant to multiple conventional antibiotics, PsA infection is associated with a longer duration of hospitalization and substantially increased healthcare expenditure [2]. The high virulence and potential lethality of this pathogen in the nosocomial environment mandates that all infectious disease providers have a firm understanding of the epidemiology of PsA infection. This becomes particularly true in transplant patients, a population in which unchecked infection can rapidly lead to clinical deterioration.

Solid Organ Transplantation

Despite advances in surgical techniques, immunosuppression protocols, and the ongoing evolution of the field of transplant infectious disease, bacterial infections continue to represent a major source of morbidity and mortality in solid organ transplant (SOT) patients. A recent single-center study from Canada identified PsA as the fifth most common bacterial species and the third most common Gram-negative agent causing infection in graft recipients. Overall, PsA accounted for 5.5% of microbiologically proven bacterial infections in this cohort [3]. As in the general population, PsA most often contributes to bacteremia and respiratory tract infections in the SOT population as a whole [4, 5]. A 2018 study that reviewed 116 episodes of bacteremia in a cohort of renal transplant patients determined that PsA contributed to 8% of these infections [6]. In a broader cohort of patients that included liver, kidney, and heart transplant recipients in Spain, PsA accounted for 15% of 318 total bouts of bacteremia [7]. Like PsA infection in the general hospitalized population, PsA clearly remains one of the most common bacterial pathogens encountered in the SOT population.

There are, however, some critical differences between PsA infection in the general nosocomial population and SOT patients. Most importantly, multiple studies have suggested that antimicrobial resistance is more prevalent in PsA strains isolated from the SOT population. Whereas a recent study demonstrated that the overall rate of PsA bloodstream infection (BSI) in a cohort of SOT patients did not appear to differ significantly from that noted in non-SOT patients, the rate of meropenem resistance was significantly higher in transplant recipients [8]. The authors suggest that excessive antibiotic use, inconsistent infection control practices, and perhaps even climatic factors could account for this observation. Even more concerning is the prevalence of MDR and XDR PsA isolates in organ recipients. Consensus guidelines define MDR pathogens as those exhibiting nonsusceptibility to at least one agent in three or more antimicrobial categories. XDR pathogens are characterized by

nonsusceptibility to at least one agent in all but two or fewer antimicrobial categories [9]. In a single-center US study from 2009 that identified 207 PsA blood isolates obtained from 108 SOT and nine hematopoietic stem cell transplant (HSCT) patients, 43% of these were MDR. This figure was significantly higher than the 18% of PsA blood isolates that exhibited the MDR phenotype in a cohort of non-transplant patients. Previous transplant, prior ICU admission, and nosocomial acquisition all served as independent risk factors for infection related to MDR pathogens in this study [10]. This trend appears to extend to other site-specific PsA infections as well. The MDR phenotype was observed in 46% of patients who experienced PsA infection after abdominal organ transplantation [5]. Considering infection in lung transplant recipients, a recent study suggested that PsA may account for up to 27% of the bacteria isolated from recipients (only 1% with cystic fibrosis) in the immediate postop setting, and that 51% of these isolates may exhibit the MDR phenotype [11]. Duration of ICU stay, duration of ventilation, exposure to broad antimicrobials, bilateral transplant, and tracheostomy all appear to correlate with an increased risk of MDR infection in this population. Similarly, the XDR phenotype is also observed more frequently in SOT patients. A 2015 single-center Spanish study detected this resistance pattern in 63% of PsA strains isolated from the blood of transplant patients [7]. Furthermore, this highly resistant phenotype was associated with a mortality rate of 38%, a significant increase from the 16% mortality rate observed with other more susceptible isolates. While many transplant centers in the United States may not experience rates of MDR/XDR infection that are this high, these figures do not appear to represent isolated experiences. A meta-analysis of studies from North America, Europe, and Asia determined that of the PsA isolates contributing to bacteremia in liver transplant patients, 47% were MDR and 63% were XDR [12]. These alarming figures highlight the shifting climate of PsA infection in the SOT population, a trend that could forecast the need for significant changes in the future management of PsA infection.

Another key characteristic that defines the epidemiology of bacterial infection in the SOT population is a strong correlation between the organ transplanted and the frequency of infection at specific sites. This correlation holds true for PsA infection. The respiratory tract is the single most common site of PsA infection in recipients of lung or heart transplants [3]. Mechanical ventilation prior to transplant and significant transfusion requirements may serve as risk factors in the development of early pneumonia after thoracic transplantation [13]. Urinary tract infection (UTI) rates related to PsA are highest in renal and renal/pancreas transplant patients [3]. Of the 7% of renal transplant patients who experienced urinary tract infection (UTI) in the large RESITRA cohort based in Spain, PsA accounted for 10% of these infections [13]. Likewise, the hepatobiliary system is the most common site of infection in liver transplant patients [3]. Recipients of hepatic grafts procured from living donors may be at particularly high risk for PsA-related intraabdominal complications. In a group of patients experiencing PsA infection after living donor liver transplantation, intraabdominal infection was observed in 52% of patients [14].

The timing of PsA infections in SOT recipients appears to differ from that of hosts who have not undergone transplant. Traditional teaching suggests that infections

caused by healthcare-associated pathogens are highest within the first month of SOT [15]. Bacteremia in the SOT population illustrates this principle well, as more than half of the BSIs that occur within the first 2 years after SOT are documented in the first month after transplant [16]. In the case of PsA infection, however, it is important to note that while the risk of infection related to this pathogen may decrease over time in the SOT population, some patients may remain at risk for PsA-related infection for a period that extends at least several months after transplant. In a 2011 Spanish study of an SOT cohort that documented 276 episodes of bacterial, mycobacterial, viral, and protozoal infection occurring greater than 6 months after transplant, 5% of all infections were related to PsA [17].

Rarely, early post-transplant *Pseudomonas* infections may arise following receipt of a PsA-contaminated graft. PsA infection of a fresh arterial anastomosis may lead to pseudoaneurysm formation, sepsis, and eventual rupture. Complications include massive hemorrhage, graft loss, embolic phenomena, and death. Unfortunately, poor outcomes may occur despite early administration of directed antibiotic treatment, and drug resistant pathogens like MDR/XDR PsA appear to have higher attack rates than organs contaminated by nondrug resistant bacteria attributed to the failure of routine perioperative antibiotic prophylaxis [18, 19]. Optimal management for a potential donor-derived transmission event due to MDR/XDR PsA or other drug-resistant pathogens is not well-defined but includes at a minimum: (1) appropriately targeted antibiotic treatment, (2) close clinical follow-up with early surgical intervention as needed, and (3) rapid, effective communications between transplant centers and organ procurement organizations so that other recipients of potentially PsA-contaminated organs can promptly receive targeted preemptive antibiotic treatment [19, 20].

Host Factors in Solid Organ Transplant Recipients

Multiple host-specific factors contribute to PsA infection in the SOT population. Preexisting comorbidities contributing to the indication for organ transplant can have a major impact on the susceptibility to infection. For instance, cystic fibrosis (CF) prior to lung transplant represents a significant risk factor for PsA pulmonary infection after transplantation. Quantifying this risk, one study observed a 60% rate of PsA respiratory infection in lung transplant recipients with CF compared to 38% in non-CF patients [21]. Compounding this problem, early nosocomial infection including pneumonia in CF patients is a known risk factor for increased mortality in the posttransplant setting. Early risk factors may have implications that extend to the late posttransplant period, as PsA infection late after lung transplant has been associated with the development of the bronchiolitis obliterans syndrome [22]. PsA may evoke the production of certain chemokines that predispose to this process [23]. Persistent sinus carriage in CF patients may predispose to recurrent pulmonary colonization that may progress to infection [24]. Other pretransplant comorbidities contributing to immune dysfunction or structural abnormalities including bronchiectasis may similarly serve as risk factors for recurrent PsA infection after lung transplant. In the renal transplant population, autosomal

dominant polycystic kidney disease, ureteral reflux, diabetes-related bladder dysfunction, and other preexisting structural and functional problems may serve as risk factors for recurrent infections of the urinary tract. At least one study has identified autosomal dominant polycystic kidney disease in renal transplant patients as an independent risk factor for infection with MDR/XDR pathogens, including *Pseudomonas* species, on multivariate analysis [25]. Primary sclerosing cholangitis (PSC) and other antecedent hepatobiliary comorbidities resulting in biliary stasis or recurrent infection may predispose to infection at the time of liver transplant. PSC and autoimmune hepatitis serve as risk factors for nonanastomotic biliary strictures, which can predispose to recurrent infection after transplant [26]. Although diabetic patients may enjoy substantial improvement in glucose control and quality of life after pancreas and/or renal transplant, hyperglycemia in the years leading up to SOT may contribute to chronic vascular, neuropathic, and musculoskeletal changes that predispose to diabetic foot infections after transplant. PsA contributes to diabetic foot infections with a respectable frequency in the transplant population [27]. These common examples highlight a few of the many ways in which preexisting comorbidities in organ recipients can predispose to PsA infection after SOT.

Complications directly related to surgical procedures represent another major class of risk factors predisposing to PsA infection in the SOT population. In lung transplant patients, anastomotic complications including leaks and stenoses are significant concerns. Compared to non-transplant patients requiring sternotomy for other indications, the rate of sternal infection in transplant recipients is substantially higher. In a study of patients undergoing heart transplantation, 6% experienced sternal infection, and PsA contributed to 15% of these infections [28]. Factors including the need for delayed sternal closure, bleeding complications, and repeat sternotomy may all potentially increase the risk of sternal infection. In recipients of abdominal organs, anastomotic stenoses can contribute to processes including pyelonephritis, pancreatitis, and cholangitis. Fluid collections related to anastomotic leaks or the cut edges of hepatic grafts procured from living donors may also predispose to infection in the abdomen. When compared to duct-to-duct anastomosis, Roux-en-Y hepaticojejunostomy may increase the risk of bacterial infection as bacterial species may more easily ascend the biliary tree after this surgical approach [29]. Vascular anastomoses may rarely predispose to intravascular bacterial infection as PsA has been known to contribute to mycotic pseudoaneurysm formation after liver and other solid organ transplants [30, 31]. In all transplanted organs, ischemic injury related to the procurement process itself, shock at the time of procurement, or vascular complications in the operating room can predispose to infection either by inducing organ dysfunction or producing areas of frank necrosis in the graft which can harbor chronically infecting organisms. In contrast to hepatocytes, which receive dual blood flow from both the hepatic portal vein and the hepatic artery, bile ducts only receive blood flow from the hepatic artery. As a result, the biliary tree is more susceptible to ischemic insult, and this factor is thought to contribute to the pathogenesis of nonanastomotic biliary stricture after liver transplant [26]. Biliary tract ischemia can predispose to chronic stasis and recurrent infection. Finally, one must anticipate the expected anatomical consequences of transplant when considering the

risk of PsA infection after SOT. Injury to the vagus nerve during pulmonary transplantation, for example, may impair the cough reflex that normally assists the host in clearing pathogens from the airways [32].

Indwelling prosthetic devices are another host factor predisposing to infection in the SOT population. Devices placed to augment cardiopulmonary support such as cannulae for extracorporeal membrane oxygenation (ECMO), ventricular assist devices (VADs), and balloon pumps may predispose to bacteremia, septic thrombophlebitis, and exit site infections. In a recent retrospective review of 175 initial episode VAD infections at a US hospital, 8% of infections were attributed to PsA [33]. When complicated by extensive biofilm formation, PsA-related VAD infections have the capability to persist after robust courses of antibiotics, potentially lingering into the peri-transplant period. Similarly, tracheostomy, prolonged intubation, bronchial stents, vascular grafts or stents, embolization coils, urinary catheters, ureteral stents, pancreatic duct stents, biliary stents, and venous catheters can also predispose to infection in this population.

Clinicians should consider the quality of the transplanted graft and donor derived risk factors when evaluating a patient with PsA infection. Processes such as aspiration in lung donors, antecedent trauma in the donor, size mismatch, and prolonged hospitalization may predispose to infection. Suboptimal graft function at the time of SOT related to factors including shock around the time of the donor's death, the age of the graft, steatosis, vascular disease, and other processes can contribute to chronic graft dysfunction that may increase the risk of subsequent infection. When considering an organ recipient's risk factors for PsA infection, providers need to evaluate two sets of risks, those in the recipient as well as those of the donor.

Finally, the complex interplay between immunosuppression and opportunistic infection may predispose to PsA infection in the SOT population. Neutrophil function appears to be essential for PsA clearance, as is evident by the predisposition of patients with neutropenia or neutrophil dysfunction to severe disseminated PsA infection (Fig. 1) [34–36]. As a result, any immunocompromising condition or medication that either directly impairs innate immunity or diminishes the ability of the adaptive immune response to augment innate immunity may decrease the ability of the host to clear bacilli. Providers should consider host factors including chronic underlying immunosuppressing conditions, induction immunosuppression, maintenance immunosuppressing medications, and therapy for rejection when considering a patient's risk of infection related to typical bacteria. Opportunistic infections in SOT patients may also increase the risk of bacterial infection. As early as the 1970s, researchers established a link between cytomegalovirus (CMV) infection and progression of bacterial disease in a murine model of PsA infection [37]. By the 1990s, studies had established a link between CMV and severe bacterial infections in SOT recipients [38]. We now know that strategies employing antiviral prophylaxis targeting CMV confer a substantial reduction in the rate of bacterial and fungal infections after transplant, and recent guidelines incorporate CMV prophylaxis into standard practice [39, 40]. Recent data also suggest an association between XDR PsA infection and opportunistic infection related to CMV and fungi [7]. CMV dysregulates the immune response via several mechanisms, increases the risk of

Fig. 1 Ecthyma gangrenosum in a 65-year-old woman with advanced endometrial cancer, chemotherapy-induced neutropenia, *Pseudomonas aeruginosa* bacteremia, and septic shock

allograft rejection, and should always be considered when assessing a patient's risk of infection related to pathogens such as PsA.

Hematopoietic Stem Cell Transplantation

While data suggest that the overall incidence of PsA infection in HSCT patients may be relatively low (in the range of 2%) in the modern era, the severity of these infections is substantial as the diagnosis of PsA infection in this population is associated with a mortality rate of 35% [41]. Importantly, PsA infection in HSCT recipients not only appears to be associated with substantial mortality but also seems to have a proclivity for recurrence. A 2007 study documented recurrence in 16% of patients occurring a median time of 9 days after stopping antibiotics [41]. High-grade graft-versus-host disease (GVHD) appeared to increase the risk of recurrent infection [41]. As in the general nosocomial population and the SOT population, the bloodstream and the respiratory tract appear to be the most common sites of infection in HSCT patients [41]. Addressing bacteremia specifically, relatively recent studies suggest that PsA contributes to 3–26% of BSIs in patients who have undergone HSCT [42–44]. Collectively, these data suggest that while PsA may not be a very common pathogen in the HSCT patients, it contributes to a substantial portion of the severe infections in this compromised population.

As in the SOT population, rates of antimicrobial resistance in PsA appear to be rising in the HSCT population. A 2014 study of an Australian HSCT cohort identified a common trend experienced at other institutions over the past several years [44]. In this work, PsA accounted for 17% of Gram-negative infections at all sites. During the course of a nine-year surveillance period, providers introduced fluoroquinolone prophylaxis into their practice. While the rate of Gram-negative infection remained relatively stable over the course of nearly a decade of monitoring, the rate of antibiotic resistance in these pathogens increased substantially. Specifically, rates of

fluoroquinolone and extended-spectrum beta-lactam resistance rose significantly. Fluoroquinolone resistance rose from 13% to 36% over the study period, and fluoroquinolone-resistant isolates were significantly more likely to exhibit an extended-spectrum beta-lactamase (ESBL) phenotype or resistance to fourth-generation cephalosporins, carbapenems, or aminoglycosides. Similar to the SOT population, bacteremia related to MDR pathogens was associated with an independently increased risk of mortality in this HSCT cohort [44]. PsA represents a major contributor to the overall incidence of MDR Gram-negative infections in HSCT patients as evidenced by a recent European study that identified PsA as the most common (61%) MDR Gram-negative species isolated from any site in HSCT patients [45]. As antibiotic options have become more limited in recent years, carbapenemase production has emerged as another significant concern in HSCT patients. In a 2017 Brazilian study of patients in a bone marrow transplantation unit who experienced BSI related to PsA isolates that produced the SPM-1 carbapenemase, mortality attributed to this infection was extremely high at 79% [46]. While carbapenem resistance is on the rise in the United States, carbapenemase-mediated resistance remains relatively rare, occurring in only 2% of all isolates in a recent multistate laboratory-based surveillance study [47]. However, if resistance rates were to accelerate, it is possible that the HSCT population could eventually experience mortality rates attributed to severe PsA infection that have not been witnessed in the medical field since the 1950s [42].

Host Factors in Hematopoietic Stem Cell Transplant Recipients

In HSCT patients, many risk factors for complications related to PsA infection become established well before transplant takes place. Chemotherapy, total body irradiation, cytopenias, immune dysregulation related to underlying hematologic disease, suboptimal nutrition, mucositis, prolonged hospitalization, prior antibiotic exposure, and indwelling catheters all serve to disturb the human microbiome and promote bacterial infection in this population. Complications directly related to the status of the patient's marrow including graft failure and recurrent primary disease can further predispose to infection. The type of HSCT also affects the risk of infection. As one example, a recent study identified haploidentical transplant as being associated with a greater risk of bacteremia related to pathogens including MDR PsA after HSCT [48]. The authors posited that a greater incidence of significant mucositis in haploidentical patients compared to HLA-identical siblings may have contributed to this finding. The use of anti-thymocyte globulin and the duration of neutropenia were also hypothesized to have also contributed to some of the effect observed in this study.

Of special note is antibiotic prophylaxis in this population. Fluoroquinolones have the capability to promote carbapenem resistance in PsA by inducing the expression of efflux pumps such as MexAB-OprM and promoting the loss of porins including OprD (Fig. 2). In a recent cohort of patients with hematologic malignancy and/or a history of HSCT, 84.6% of PsA isolates that contributed to bacteremia despite levofloxacin prophylaxis were resistant to meropenem; in contrast, only 27.6% of PsA isolates cultured from the blood of patients who were not treated

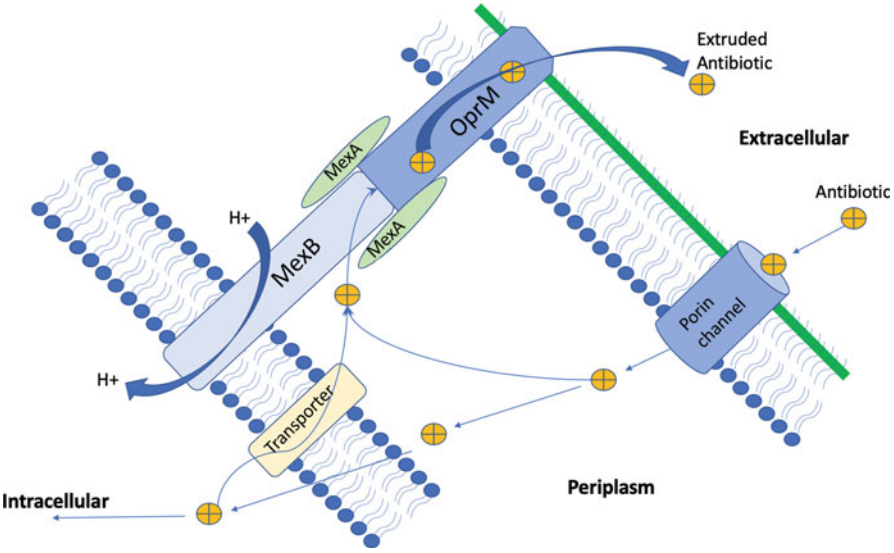

Fig. 2 Pseudomonas wall, with Eflux pump and Porin channel. https://www.semanticscholar.org/paper/Pseudomonas-aeruginosa%3A-arsenal-of-resistance-of-Zowalaty-Thani/cf8665b4be63a2822afed1933d2b77f00ee733f2/figure/0

with quinolone prophylaxis were resistant to meropenem in this work [49]. Changes in both efflux pump and porin expression were noted in isolates that were resistant to meropenem. These data emphasize the importance of prior antibiotic exposure including medications used for prophylaxis when crafting an empiric antibiotic regimen targeting PsA in the HSCT population.

GVHD is another significant risk factor for bacterial infection in the HSCT population. As an obligate aerobe, PsA is typically present at lower titers in stool [50]. As a result, this organism is less commonly associated with invasion of the gastrointestinal tract in normal hosts. In compromised hosts, however, especially those experiencing GVHD of the gut or mucositis and neutropenia related to chemotherapy and/or radiation, PsA has the capability to translocate across the gut. A recent study from the Dana-Farber Cancer Institute identified high grade GVHD of the gut, but not other sites, as a significant risk factor for BSI related to PsA and several common enteric pathogens [51]. Additionally, a recent study that included 3200 adult HSCT patients reported that both acute and chronic GVHD were associated with bacterial infections, including pseudomonal infections [52]. Gut permeability, immune dysregulation, and immunosuppressing therapy may all be involved in increasing the risk of PsA invasion in HSCT patients with GVHD.

Finally, as in the case of SOT patients, CMV infection similarly increases the risk of bacterial infection in HSCT recipients [53]. Immune dysregulation associated with CMV infection may contribute to some of this effect, but antiviral therapy treating CMV may also increase the risk of bacterial infection as it predisposes to leukopenia and renal dysfunction. There exists a clear link between GVHD,

immunosuppressive therapy addressing GVHD, and subsequent CMV reactivation. Corticosteroid dosage treating GVHD directly correlates with the risk of CMV reactivation in HSCT patients [53]. Conversely, in a complex interplay between pathogen and host immunity, primary CMV infection may also predispose to the subsequent development of GVHD. Primary immunologic mechanisms may contribute to this effect, but the reduction of immunosuppression in the setting of CMV infection also has the potential to increase the chance of new onset GVHD. Thus, clinicians can envision CMV and GVHD in HSCT patients as having a cyclical relationship, and PsA infection may become more likely in patients experiencing GVHD, CMV infection, or both of these processes.

Pathogenesis of Infection

The excess morbidity and mortality related to PsA infection observed in the transplant population represents the end result of a complex interaction between a virulent pathogen, host factors, and environmental factors. Recent trends in PsA infection in the immunocompromised population have spurred efforts to gain a deeper understanding of the pathogenesis of this infection.

Microbiology

As an obligate aerobic, flagellated, Gram-negative rod, PsA is most often seen in culture as a single bacterium but can occasionally form short chains (Fig. 3). The

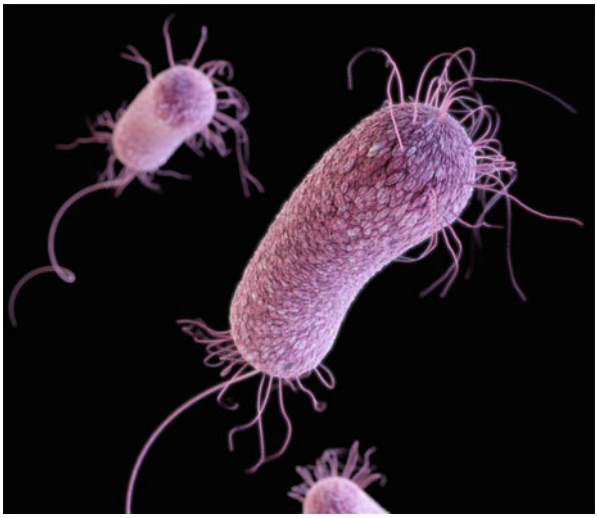

Fig. 3 *Pseudomonas* with flagella and pili. (Picture credit: https://phil.cdc.gov/Details.aspx?pid=16876)

species *aeruginosa*, Latin for verdigris (copper green), refers to the organism's predilection for forming blue/green colonies on solid media [50]. The production of the pigments pyoverdine and pyocyanin confer this characteristic coloration. PsA colonies often have a characteristic odor suggesting corn tortillas or grapes. With a proclivity for growth in aquatic environments, this organism may be identified in nosocomial water sources. Virulence factors in this pathogen are legion. Pili and flagella facilitate mobility, adhesion, and biofilm formation. Biofilm formation becomes particularly important in pulmonary infections and infections related to prosthetic devices. At least one in vitro study assessing biofilm formation along drivelines demonstrated that biofilm formation in PsA was more robust than coagulase-negative staphylococci or *Staphylococcus aureus* [54]. Various exotoxins including phospholipases, adenylate cyclase, elastases, and proteases assist in tissue invasion, induce apoptosis in leukocytes, and promote dysregulation of the host response [34].

Production of these virulence factors is carefully regulated through small, diffusible pheromone-like molecules released in a population-dependent manner. This type of chemical-based cellular communication, known as quorum-sensing, enables bacteria to coordinate expression of behaviors at times of high cell density [50]. While quorum-sensing systems have been shown to be important virulence regulators for a number of both Gram-negative and Gram-positive pathogens, PsA is remarkable for having at least four distinct quorum-sensing systems [55]. It has been suggested that this sophisticated collection of virulence regulators enables PsA to adapt and fine-tune virulence and behavioral traits to a wide range of environmental conditions [55, 56].

Environmental Factors in Transplant Recipients

In addition to virulence factors in the pathogen and risk factors in susceptible hosts, environmental factors can also promote the development of PsA infection in transplant recipients. Given its proclivity for growth in aquatic environments, PsA, including MDR/XDR PsA, may be isolated from water sources and aqueous solutions in the nosocomial setting. Faucets, aerators, showers, baths, therapy pools, drains, and other sources may contribute to colonization or infection [57, 58]. Inhalation of aerosols and ingestion may serve as common modes of transmission. Furthermore, compromised hosts may be at higher risk for the acquisition of PsA from the nosocomial environment [59, 60]. Interventions ranging from patient isolation to enhanced decontamination of patient rooms to expensive changes in facilities construction have attempted to address the broad problem of nosocomial spread. Emphasizing the importance of water sources as reservoirs for drug-resistant PsA and other MDR organisms, recent interventions targeting wastewater management have had some success in limiting transmission [61, 62]. More extensive measures including alterations in the construction of bathroom fixtures have been demonstrated to decrease rates of MDR PsA isolation from the environment, patient colonization, and infection in transplant patients [63]. These recent advances

underscore the importance of robust hospital epidemiology programs in monitoring and limiting the spread of PsA in the nosocomial setting.

Recent Diagnostic Advances

The morbidity and mortality associated with severe PsA infection coupled with rising rates of antimicrobial resistance have fueled recent efforts to advance diagnostic capabilities. Given the significantly increased mortality that can occur with any delay in therapy targeting BSIs, rapid identification of blood isolates remains a priority. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been used with some success in compromised hosts to accurately and rapidly identify bacterial species including PsA [64]. MALDI-TOF MS has also been adapted to detect gene products that confer resistance to antimicrobials, including extended-spectrum beta-lactamases [65]. Other rapid molecular diagnostic modalities include the Verigene Gram-negative blood culture (BC-GN) assay (Nanosphere Inc., Northbrook, IL), an FDA-approved multiplex DNA assay that has the capability to identify bacteria isolated from blood culture including PsA and detect molecular markers that predict drug resistance within 2 h of isolation [66]. Several other rapid molecular assays using DNA-based identification or peptide nucleic acid fluorescence in situ hybridization (PNA-FISH) have come to market. Looking to the future, innovative techniques, such as culture-independent whole genome sequencing or breath analysis tools that detect volatile organic compounds associated with PsA pulmonary infection may eventually become available in broader clinical practice [67, 68]. With the development of novel techniques and the optimization of rapid molecular diagnostics, clinicians in the future could enjoy more rapid and accurate diagnostic capabilities. While these technologies should accelerate the time to optimized antibiotics for PsA and other bacterial infections, their impact on patient care outcomes and their financial consequences (both expenses and cost savings) largely remain to be determined.

Resistance to Antimicrobials

Given the strong association between significant antimicrobial resistance and adverse outcomes including excess mortality in the transplant population, research efforts have sought to elucidate the multifarious mechanisms of resistance that PsA employs. Porin loss or modification prevents the transit of antimicrobials to their site of action. Carbapenem resistance, for example, is most often related to porin loss in PsA. Efflux pumps expel antimicrobials from the cell. Enzymes encoded on mobile genetic elements (i.e., transposons, integrons, plasmids) modify or degrade antibiotics (e.g., aminoglycosides and carbapenems, respectively) rendering them ineffective. Mutations in specific antibiotic targets may confer resistance; for example, DNA gyrase and topoisomerase mutations confer resistance to fluoroquinolones [50, 69]. Determining which resistance mechanism or combination of mechanisms is at

play can be a particularly difficult task for clinicians. Regimen selection for treatment of presumed MDR/XDR PsA isolates should be based on prior cultures, recent antibiotic exposure, and response to empiric therapy pending definitive susceptibility data. In such scenarios it is important, if possible, to work closely with clinical microbiology personnel to rapidly identify potential phenotypic and genotypic expressions of resistance.

Beta-lactamases are one of the most important enzyme classes conferring resistance in PsA isolates. One commonly used method of categorizing beta-lactamases, Ambler classification, is based on the structural homology of the enzymes (Table 1). Ambler class A ESBLs are present on mobile genetic elements and hydrolyze penicillins, cephalosporins, and the monobactam aztreonam. Enzymes of this class that have been documented in PsA strains include GES, PER, VEB, SHV, TEM, CTX-M, PME, BEL, and KPC [50]. KPC, though uncommon in PsA, has the additional capability to hydrolyze carbapenem antibiotics, as do certain GES variants [70]. Beta-lactamase inhibitors such as tazobactam and avibactam inhibit Ambler class A enzymes to varying degrees (Table 2). In recent years, plasmid encoded Ambler class B enzymes, also known as metallo-beta-lactamases, have become a greater concern and are the most frequently identified carbapenemases found in PsA (Table 2). These enzymes efficiently hydrolyze all beta-lactams with the exception of aztreonam. IMP, VIM, SIM, FIM, GIM, SPM, and NDM are members of this class that have been described in PsA [50, 71, 72]. AmpC is an important chromosomally encoded class C beta-lactamase that has activity against ticarcillin, piperacillin, and extended-spectrum cephalosporins (Table 2).

Table 1 Ambler classification of beta-lactamases found in *Pseudomonas aeruginosa*

Ambler Class	Activity	Example Enzymes
A	Hydrolyzes penicillins and cephalosporins	CTX-M, SHV, KPC, TEM
B	Hydrolyzes beta-lactam ring using zinc	IMP, VIM, NDM
C	Hydrolyzes broad and extended-spectrum cephalosporins	AmpC
D	Variable hydrolytic activity with ESBL and carbapenemase activity sometimes observed	OXA

Table 2 Beta-lactamase inhibitor activity versus beta-lactamases found in *Pseudomonas aeruginosa*

Ambler Class	Inhibited by avibactam?	Inhibited by tazobactam?	Inhibited by vaborbactam?	Inhibited by relebactam?
A	Yes	Partial	Yes	Yes
B	No	No	No	No
C	Yes	Partial	Yes	Yes
D	Yes	No	No	No

Hyperinduction of AmpC in PsA is caused by mutations in *amp* genes often following exposure to low-level beta-lactam concentrations [73–75]. OXA variants, members of the Ambler class D beta-lactamase family (Table 2), are the final known family of beta-lactamases in PsA isolates. Enzymes in this heterogeneous group can confer resistance patterns ranging from amoxicillin nonsusceptibility to effective late generation cephalosporin and carbapenem resistance [76].

As resistance rates in the transplant population have risen in recent years, it has become increasingly important that clinicians improve their understanding of the mechanisms that confer resistance to antibiotics typically reserved for MDR/XDR isolates. For example, compared to many other beta-lactams, ceftolozane-tazobactam appears to be more resilient to the development of resistance related to new mutations [77, 78]. The development of new resistance in the setting of antibiotic exposure appears to occur primarily via changes that ultimately effect AmpC modification, the upregulation of AmpC production, and porin loss. Paradoxically, while the accumulation of AmpC-related mutations may confer high-level resistance to ceftolozane-tazobactam, certain mutations involved in this process may also increase susceptibility to other beta-lactams including imipenem, cefepime, and piperacillin-tazobactam. The horizontal acquisition of ESBLs, OXA as one example, may also contribute to the development of broad resistance to agents including ceftolozane-tazobactam [78]. Resistance may emerge in patients on therapy, a phenomenon that was reported at rates of 10.6% and 14% in two recent studies [78, 79].

Like ceftolozane-tazobactam, ceftazidime-avibactam is susceptible to cleavage by certain ESBLs. When resistance to ceftazidime-avibactam is related to de novo mutations, AmpC overexpression and efflux pumps appear to contribute. Changes in porin expression seem to be less important factors in this process [80, 81]. Interestingly, ceftazidime-avibactam related selection pressure in vitro was associated with the uniform development of large chromosomal deletions in one study. In some cases, up to 7% of the PsA genome was deleted after prolonged exposure to ceftazidime-avibactam or ceftazidime. Deletion of genetic elements encoding efflux pumps was noted in multiple isolates. As in the case of ceftolozane-tazobactam resistance, the molecular changes that confer ceftazidime-avibactam resistance may be associated with an increased susceptibility to other antimicrobials including aminoglycosides [82]. In patients failing therapy with ceftolozane-tazobactam or ceftazidime-avibactam, including aminoglycoside sensitivities in repeat susceptibility testing may be useful in guiding therapeutic choices.

While ceftolozane-tazobactam and ceftazidime-avibactam are resistant to hydrolysis by most ESBLs, particularly concerning are recent reports describing the new development of resistance related to mobile genetic elements in the Enterobacteriaceae. KPC-3 documented in a *Klebsiella* isolate was recently found to confer resistance to ceftazidime-avibactam, a combination previously thought to be impervious to cleavage by all Ambler class A ESBLs [83]. Reports like this raise concern for the possibility of increasing rates of resistance in common Gram-negative species potentially contributing to worsening trends in PsA resistance related to the interspecies transfer of mobile genetic elements like plasmids.

Upregulation of efflux pumps, located on chromosomes or plasmids, leads to expulsion of antibiotics from inside the cell and is a common method of intrinsic or acquired resistance in PsA. Two major contributors in clinical PsA isolates are MexAB-OprM and MexXY(-OprA). In wild-type strains of PsA, such as PA01, MexAB-OprM is expressed at moderate levels while the MexXY(-OprA) is inducible by ribosome-targeting antibiotics under standard laboratory conditions [84]. The MexAB-OprM is known to expel numerous antibiotics including beta-lactams, carbapenems (except imipenem), fluoroquinolones, macrolides, sulfonamides, and trimethoprim. In addition, the MexXY(-OprA) demonstrates resistance to aminoglycosides, fluoroquinolones, and specific beta-lactams such as cefepime but not ceftazidime. Studies have found that overexpression of such efflux pumps does not necessarily lead to high-level antibiotic resistance but can contribute to the development of MDR PsA. One particular study found a strong association between fluoroquinolone prophylaxis and breakthrough bacteremia with meropenem-nonsusceptible PsA in HSCT recipients [49]. The investigators note the selection of meropenem- nonsusceptible PsA may not only be due to induction of cross-resistance but may be influenced by epidemiology of PsA bloodstream infections at their center.

Resistance to colistin and polymyxin B, antibiotics often reserved for the most resistant MDR/XDR isolates, also occurs in PsA. While resistance to these antimicrobials in wild-type strains is not common, resistance reliably occurs in the setting of gradually escalating antibiotic concentrations. Mutations in *pmrB*, the sensing kinase component of the *pmrCAB* operon, most commonly confer resistance to these antimicrobials [85]. Mutations in *pmrB* ultimately result in a net decrease in the negative charge on lipopolysaccharide in the PsA cell, a process that renders the cationic antibiotics colistin and polymyxin B ineffective [86]. In 2015, researchers in China identified *mcr-1*, a gene that encodes a phosphoethanolamine transferase, which confers resistance to polymyxin B and colistin in an *Escherichia coli* [87, 88]. Although not yet described in clinical PsA isolates, plasmids carrying *mcr-1* are known to be functional in PsA, and mobile genetic elements such as this may facilitate increasing rates of colistin and polymyxin B resistance via horizontal transfer in the future.

Elevated minimum inhibitory concentrations (MICs) to plazomicin, a next-generation aminoglycoside, have been observed in PsA isolates. In the CANWARD study, 64 (10.8%) of 593 PsA isolates were MDR, and the observed plazomicin MICs in these organisms ranging from $\leq$0.12 μg/mL to >64 μg/mL [89]. In Enterobacteriaceae, plazomicin overcomes the effects of multiple antibiotic modifying enzymes, a major source of resistance in these Gram-negative species. However, certain enzymes with ribosome methyltransferase activity do appear to render it ineffective [90]. A similar mechanism may exist in PsA. While the precise mechanisms of plazomicin resistance in PsA have not been completely elucidated, authors have posited that reduced permeability and efflux pumps may be contributing factors [89].

Fosfomycin resistance in PsA is related to the FosA enzyme that confers an antibiotic-modifying effect. Inactivation of the GlpT transport protein may also

contribute to resistance [91]. Even when confronted with pressures exerted by emerging therapeutics, PsA possesses a potent and diverse array of resistance mechanisms that prevent its clearance and promote its pathogenicity.

Emerging Therapeutic Strategies

Delays in appropriate therapy targeting severe PsA infections are clearly associated with adverse clinical outcomes including mortality [92]. Ensuring that initial empiric antibiotic therapy is appropriate becomes especially important in transplant patients, compromised hosts who often have decreased physiologic reserve. Additionally, optimizing the delivery of appropriate therapeutics to the site of infection requires extra care in SOT and HSCT patients. Disseminated infections related to resistant pathogens occasionally require providers to carefully consider the penetration of less commonly employed antibiotics into more challenging sites of infection, such as the central nervous system or the prostate. Complex medication interactions, dysfunction in major organ systems, and malabsorption related to factors including GVHD further complicate therapeutic decisions in this population. In patients with diminished ability to clear bacterial pathogens, source control considerations become extremely important. Retained prosthetic devices, infected fluid collections, and necrotic tissue associated with infection may all predispose to recrudescence if not appropriately managed. With appropriate concern regarding rising rates of resistance in the nosocomial population, multiple recent, high-profile studies have challenged long-held assumptions surrounding the duration of therapy for common clinical syndromes related to infection. Though innovative and insightful, one frequently cited work that addressed the optimal duration of therapy for intraabdominal infections did not incorporate significant numbers of patients treated with immunosuppression or those with substantial cytopenias [93]. Similarly, HSCT providers may find it challenging to extrapolate from studies addressing the duration of therapy for Gram-negative bacteremia that do not include recent recipients of allogeneic stem cell transplants [94]. In general, it is reasonable to consider more conservative courses of therapy in transplant patients with significant infections related to PsA. When devising the duration of therapy for PsA infection in a transplant patient, it is important to contemplate the net state of immunosuppression of the host, the completeness of source control, the effectiveness of the therapy delivered, the risk of incurring resistance, the risk of antibiotic side effects, anatomic factors such as the patency of surgical anastomoses, and the host's physiologic reserve. Robust courses of appropriate therapy become more important in the treatment of MDR and XDR PsA isolates, pathogens that frequently require the use of emerging therapeutics to effect durable clearance.

There are many important patient-, site-, and agent-specific characteristics to consider when treating MDR PsA in immunocompromised patients, as dosing and treatment for this organism is typically more aggressive while concomitant co-morbidities may create difficult-to-manage dosing situations. Knowledge of

specific pharmacokinetic and pharmacodynamic characteristics of antimicrobials and susceptibility data are necessary for therapeutic optimization. Factors affecting efficacy and safety are the site of infection, weight of the patient (e.g., obese, malnourished, edematous), utilization of ECMO, and line access, as extended infusion beta-lactams can complicate therapy. Appropriate evaluation of renal function is paramount. Characteristics that influence renal function to consider include (but are not limited to) serum creatinine in relation to overall muscle mass, patients with a single kidney, falsely appropriate urine output in the setting of diuretics, potential for augmented renal clearance, acute post-operative changes, and in the case of acute or chronic renal failure, the modality of renal replacement therapy. Volume of distribution may also be impacted in critically ill patients due to acute changes in volume status.

Utilization of prolonged- or continuous-infusion dosing of select beta-lactam antibiotics for Gram-negative infections, including pseudomonal infections, is supported by in vitro, in vivo, and human studies demonstrating that increased time of free active drug above an organism's minimum inhibitory concentration (MIC) is associated with improved outcomes [95, 96]. This is reflected in the dosing regimens of newer beta-lactam antibiotics. For example, the duration of infusion for ceftolozane-tazobactam and ceftazidime-avibactam are 1 and 2 h, respectively. For pulmonary infections, some investigators have proposed using inhaled antibiotics as options that reduce risk of adverse effects from agents with important systemic toxicities, such as aminoglycosides and polymyxins. In addition, inhaled antibiotics could increase concentrations at the site of infection (i.e., pulmonary tissues) compared to intravenous administration. However, the role of inhaled agents for the treatment of invasive disease is unclear at best [97, 98].

The twofold crises of rapidly growing antibiotic resistance and a meager antibiotic pipeline have led to renewed interest in combination antibiotic therapy for the treatment of extensively resistant Gram-negative infections, including those due to MDR/XDR PsA. Treatment with more than one anti-pseudomonal agent may be considered for severe PsA infections while awaiting in vitro susceptibility testing. Whether combination therapy (e.g., synergistic) therapy has a role for the treatment of severe, difficult-to-treat PsA infections is unclear and should be considered with careful attention to issues such as severity of infection (rapid progression, relapsed infection, salvage treatment) and the risk of possible adverse effects [99]. Recently, several new anti-pseudomonal drugs have fortunately come to market in the United States and worldwide; however, resistance in PsA to some of these agents has already been reported in case reports and banked collections of isolates. One final important consideration is the limited amount of clinical data with new antibiotics for the treatment of MDR/XDR PsA in immunocompromised populations. For purposes of this chapter, larger studies will be discussed focusing on safety and efficacy of *new agents* targeted against MDR/XDR PsA in general populations. When possible, use of new agents in immunocompromised patients will be highlighted. Some of these agents are already available in North America and/or Europe; they may not all be accessible in all countries.

Ceftolozane-Tazobactam

Ceftolozane-tazobactam is a semisynthetic cephalosporin approved by the FDA in December 2014. Current indications approved for use by the FDA are complicated urinary tract infections (cUTIs), including pyelonephritis, and complicated intraabdominal infections (cIAIs) in combination with metronidazole. Ceftolozane is a novel, broad-spectrum cephalosporin with potent anti-pseudomonal activity including against MDR isolates. Ceftolozane's bactericidal activity results from inhibition of cell wall biosynthesis via binding to penicillin-binding proteins (PBPs), including PBP1b, PBP1c, and PBP3. Tazobactam is an irreversible inhibitor of several beta-lactamases, binding covalently to some chromosomal- and plasmid-mediated bacterial beta-lactamases. Drug adverse events associated with ceftolozane-tazobactam are similar to that of most other cephalosporins (e.g., rash, diarrhea, nausea, headache, pyrexia). Primary monitoring parameters include daily serum creatinine in patients with changing renal function for evaluation of necessary renal dose adjustments, per the FDA-approved package insert.

With the addition of tazobactam, an eightfold increase has been observed in the activity of ceftolozane over ceftazidime against PsA [100]. In previously characterized PsA strains, ceftolozane/tazobactam was superior to piperacillin-tazobactam and imipenem and comparable to doripenem in isolates susceptible to ceftazidime and imipenem-cilastatin. In MDR PsA isolates resistant to ceftazidime and imipenem-cilastatin, ceftolozane-tazobactam demonstrated the most activity followed by doripenem. In fact, ceftolozane-tazobactam retained its overall activity against ceftazidime-resistant isolates [100]. Similarly, a recent study by Farrell et al. tested susceptibilities of 1971 isolates of PsA to ceftazidime, meropenem, piperacillin-tazobactam, levofloxacin, gentamicin, colistin, and ceftazidime-avibactam. In MDR PsA, ceftolozane-tazobactam was found to be second only to colistin in terms of activity [101]. In XDR strains, ceftolozane-tazobactam had maintained "appreciable activity"; however, in metallo-beta-lactamase producing strains no drugs were active [101, 102].

Ceftazidime-Avibactam

Ceftazidime is a third-generation cephalosporin that was approved by the FDA in 1985. In February 2015, ceftazidime combined with the non-beta-lactam beta-lactamase inhibitor, avibactam, received FDA approval for the treatment of cIAI (used in combination with metronidazole) and cUTI, including pyelonephritis. Given ceftazidime's extensive history of clinical use, the approval process for ceftazidime-avibactam relied on ceftazidime historical data plus ceftazidime/avibactam phase I and II data only [103]. The addition of avibactam allows ceftazidime to maintain in vitro activity against class A, some class C, and class D beta-lactamases. A unique feature of avibactam compared to earlier beta-lactamase inhibitors is that avibactam binds *reversibly* to beta-lactamases, creating an

opportunity for the molecule to be recycled with additional beta-lactamases, potentially extending and augmenting its inhibitory effectiveness [103, 104]. Adverse drug reactions associated with ceftazidime-avibactam are similar to that of most other cephalosporins (e.g., rash, diarrhea, nausea, headache, pyrexia). Primary monitoring parameters include at least daily serum creatinine in patients with changing renal function for evaluation of necessary renal dose adjustments, per the FDA-approved package insert. A recent US study evaluating activity of ceftazidime-avibactam against 7868 PsA isolates found that ceftazidime-avibactam inhibited 97.1% of isolates at the susceptible breakpoint of $\leq$8 μg/ml, including 86.5% of MDR, 75.9% of XDR, and 71.8% of isolates resistant to ceftazidime, meropenem, and piperacillin-tazobactam [104]. Among non-beta-lactam compounds tested, only amikacin and colistin showed reasonable in vitro activity against more resistant isolates of PsA.

A multinational, phase III, double-blind, non-inferiority trial demonstrated ceftazidime-avibactam was non-inferior to meropenem in the treatment of nosocomial pneumonia [105]. Thirty percent (107/355) of isolates collected were PsA and 25% of those were nonsusceptible to ceftazidime. Nine PsA isolates were resistant to ceftazidime-avibactam compared to 31 nonsusceptible to meropenem. A recent pooled data analysis of results from phase III trials of ceftazidime-avibactam demonstrated similar clinical and microbiological efficacy versus predominantly carbapenem comparators for management of cIAI and cUTIs caused by PsA, including MDR isolates [106].

Cefiderocol

Cefiderocol is a novel siderophore cephalosporin with affinity mainly for PBP3 and a spectrum of activity that includes MDR organisms such as PsA, *Stenotrophomonas*, and *Acinetobacter baumannii*. A unique characteristic of cefiderocol compared to other cephalosporins is that it does not inhibit cell wall biogenesis but rather chelates iron, essential for bacterial survival, within Gram-negative organisms including PsA [107]. A recent phase II study cefiderocol was found to be non-inferior to imipenem/cilastatin for treatment of cUTI caused by Gram-negative pathogens, including MDR PsA [108]. At test of cure, the proportion of patients who met the composite outcome of clinical and microbiological success for treatment of PsA was similar between the cefiderocol and imipenem-cilastatin groups but lower than the overall response rate (73% for the cefiderocol group and 55% for the imipenem-cilastatin group) [108]. All post-randomization factors that might have been expected to influence outcomes (i.e., proportion of patients with acute uncomplicated pyelonephritis, reduced renal function, concomitant bacteremia, or PsA infection) favored the imipenem/cilastatin group. Cefiderocol was well tolerated with a safety profile similar to that of other cephalosporin antibiotics [108]. Cefiderocol was FDA approved in late 2019 is anticipated to be available to physicians across Europe and other countries soon.

Meropenem-Vaborbactam

In November 2017, the combination of meropenem and a novel non-beta-lactam cyclic boronic acid-based beta-lactamase inhibitor, vaborbactam, received FDA approval for the treatment of adults with cUTI and pyelonephritis due to drug-resistant Enterobacteriaceae expressing class A and class C beta-lactamases [109]. However, it is important to note that the addition of vaborbactam to meropenem does not increase the activity of meropenem against PsA [110, 111]. Therefore, meropenem-vaborbactam is not recommended as therapy against meropenem-resistant PsA and has no additive effects for treatment of meropenem-susceptible isolates.

Imipenem-Relebactam

Imipenem-relebactam was approved by the FDA in July of 2019. Relebactam is a novel non-beta-lactam beta-lactamase inhibitor structurally similar to avibactam with activity against class A and class C beta-lactamases. The addition of relebactam to imipenem has demonstrated significant improvement in activity of imipenem against PsA by reducing the MIC up to ~eightfold [112]. This combination is unique in that both imipenem and relebactam are not subject to removal via efflux pumps in PsA. One of the most significant impacts of the addition of relebactam to imipenem is restoring activity of imipenem to PsA previously identified as imipenem non-susceptible isolates [113]. For PsA, 94% (796/845) and 70.3% (594/845) of isolates were susceptible to imipenem-relebactam and imipenem, respectively; 80.5% (202/251) of imipenem-nonsusceptible isolates were deemed susceptible with addition of relebactam [113]. This combination provides a potential alternative to polymyxins, aminoglycosides, and combination therapy for management of MDR PsA infections.

Plazomicin

Plazomicin, a next-generation aminoglycoside newly FDA approved in 2018, has demonstrated in vitro activity similar to that of amikacin for MDR PsA [89, 114]. Phase III clinical data exists for treatment of cUTIs due to MDR Enterobacteriaceae [115]; however, no clinical data is currently available for treatment of PsA infections. Due to activity similar to amikacin, its utility in MDR *P. aeruginosa* infections is not well established at this time.

Investigational Agents: Aztreonam-Avibactam, Intravenous Fosfomycin

Another agent with broad Gram-negative activity currently in the therapeutic pipeline is aztreonam-avibactam. In addition, intravenous fosfomycin is an agent

available in other countries for MDR Gram-negative bacterial infections but is not yet available in the United States at the time of this chapter writing. Avibactam is a non-beta-lactam beta-lactamase inhibitor structurally similar to relebactam and has been discussed previously as a component of ceftazidime-avibactam [103, 116]. This agent is active in vitro against class A and C beta-lactamases, which is significant because aztreonam can be hydrolyzed by enzymes in both of these classes [116]. A recent study of over 11,842 clinical isolates of PsA collected worldwide found that the in vitro activity of aztreonam-avibactam was less potent in PsA than Enterobacteriaceae [116]. This finding has been replicated in another study [117], suggesting the resistance to aztreonam in PsA may include other mechanisms, such as other beta-lactamases and efflux pumps.

Fosfomycin is a well-known antimicrobial agent historically utilized as an oral sachet for treatment of UTIs; however, intravenous formulations are available in countries outside of the United States for management of non-urinary sources of infection. Fosfomycin acts by inhibiting formation of a peptidoglycan precursor thereby disrupting synthesis of the bacterial cell wall. While intravenous fosfomycin is a potentially promising option for management of MDR PsA infections, it is a bacteriostatic antibiotic and significant resistance has been reported in PsA. Given these issues and the lack of robust clinical data, use of intravenous fosfomycin as monotherapy for MDR PsA in the absence of documented susceptibility is not recommended at this time [118].

Conclusion

P. aeruginosa is one of the most versatile and formidable opportunistic pathogens encountered by solid organ and hematopoietic stem cell transplant patients. Ubiquitous in nature, the organism is a common inhabitant of the hospital-built environment and a frequent nosocomial pathogen. *P. aeruginosa* produces a diverse array of virulence factors and is capable of infecting nearly any tissue in the transplant recipient. In addition to its remarkable versatility and virulence, the bacterium can carry multiple antibiotic drug resistance determinants, which complicates treatment and has led to the emergence of MDR and XDR strains. The combination of virulence, versatility, and increasing drug resistance in *P. aeruginosa* highlight the need for optimized treatment approaches, emerging therapeutics, and infection prevention.

Key Points

- Hematopoietic stem cell and solid organ transplant recipients are at particularly high risk for *P. aeruginosa* infection as a consequence of significant exposure to the healthcare environment and broad spectrum antimicrobial agents.
- Host risk factors for *P. aeruginosa* infection include preexisting comorbidities, anatomic issues related to surgical procedures, the use of indwelling prosthetic

devices, immunosuppression, and post-transplant complications such as rejection, graft-versus-host disease, and opportunistic infection (e.g., CMV infection).
- Despite advances in antimicrobial stewardship, rates of MDR and XDR *P. aeruginosa* continue to rise, particularly in the transplant population. Interdisciplinary collaboration is important when evaluating empirical and directed antimicrobial therapy.
- *P. aeruginosa* has potential to express variety of antibiotic resistance *mechanisms*, including porin loss, beta-lactamases, and efflux pumps. While there is no one-size-fits-all approach for treatment of MDR and XDR *P. aeruginosa*, recently approved antibiotics offer new treatment options for these infections.

Introduction

Acinetobacter species are an important cause of infection in transplant recipients. *Acinetobacter* infections most often occur in the setting of hospitalization, particularly critical illness and prolonged mechanical ventilatory support. They are notoriously challenging to treat due to intrinsic and acquired resistance to multiple classes of antibiotics. However, with appropriate therapy guided by knowledge of local antimicrobial susceptibilities, successful treatment is possible even in immunocompromised patients.

Disease Epidemiology

Acinetobacter species are aerobic, non-lactose fermenting, catalase-positive, and oxidase-negative gram-negative coccobacilli that have emerged as an important cause of healthcare-associated infections. The genus encompasses more than 50 distinct species that are ubiquitous in the environment, though only a minority of species cause disease in humans [1]. *Acinetobacter baumannii (A. baumannii)* is the major pathogen causing human disease. It is found in soil, vegetables, fish, and meat, but unlike some other species, it is not ubiquitous in the environment, and asymptomatic carriage in the community is uncommon. Rather, it is predominantly associated with infection and epidemic spread in hospitals [2]. *A. pittii*, *A. nosocomialis*, *A. lwoffi*, *A. radioresistans*, *A. ursingii*, and other species can also cause disease in humans, including immunocompromised hosts [3]. *A. baumannii*, *A. calcoaceticus*, *A. pittii*, and *A. nosocomialis* are grouped together into the *A. calcoaceticus-A. baumannii* complex because they are difficult to distinguish by most laboratory methods due to their high degree of phenotypic and genotypic similarity. Unlike the other members of this group, *A. calcoaceticus* is predominantly an environmental organism and rarely causes human disease. *A. seifertii*, the newest addition to this complex, is an emerging pathogen in hospitals [4]. Selected species and their sources are outlined in Table 1.

A. baumannii primarily causes nosocomial infections, particularly hospital-acquired pneumonia and bloodstream infections. It also causes urinary tract infections, skin and soft tissue infections, and neurosurgical infections. Community-acquired infections with *A. baumannii* can occur as well, most commonly in tropical regions with high humidity, and it has caused skin and soft tissue infections in the setting of trauma during warfare and natural disasters. *A. baumannii* accounts for

Table 1 Selected *Acinetobacter* species found in human specimens

Species	Habitat or source
A. baumannii	Humans
A. bereziniae	Human skin, sewage, vegetables, meat, animals
A. calcoaceticus	Soil, water, vegetables, animals, human skin
A. guillouiae	Water, vegetables, human skin
A. haemolyticus	Human skin, water
A. johnsonii	Human skin, water, sewage, animals
A. junii	Human skin, water, sewage, animals, soil
A. lwoffii	Human skin, water, sewage, sea food, animals, vegetables
A. nosocomialis	Human skin, sewage, vegetables
A. pittii	Human skin, sewage, soil, water, vegetables, animals, cheese, meat
A. radioresistens	Human skin, soil, water, animals
A. seifertii	Human skin
A. schindleri	Animals, humans
A. ursingii	Humans

Adapted from [5]

approximately 3–7% of healthcare-associated pneumonia [6, 7], though there is widespread geographic variation and the reported incidence is as low as 2% [8] or as high as 36% of hospital-acquired pneumonia [9]. It is a member of the group of "ESKAPE" pathogens that commonly cause nosocomial and multidrug-resistant infections, along with *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Enterobacter* species [10]. Carbapenem-resistant *Acinetobacter baumannii* (CRAB) has been on the rise in recent years. In data from the US National Healthcare Safety Network (NHSN) from 2011 to 2014, 56–64% of *Acinetobacter* isolates from ventilator-associated pneumonias and 47–57% of isolates from central line-associated bloodstream infections were carbapenem-resistant [11]. The prevalence of CRAB is highest in Southern Europe, the Middle East, Asia, and South America [12].

Infection typically occurs in patients with prolonged hospitalization and critical illness, frequently occurring in the intensive care unit. Risk factors for infection with *A. baumannii* include underlying illness severity, mechanical ventilation, prior residence in long-term care facilities, central venous catheterization, recent invasive procedures, and treatment with broad-spectrum antimicrobials [13]. *A. baumannii* is linked to overall high rates of mortality, particularly in patients with bacteremic pneumonia and especially with those isolates found to be multidrug resistant. But given that these infections typically occur in patients with severe underlying illness, the degree of attributable mortality is less clear [2].

The hospital environment is an important reservoir of infection, as *A. baumannii* can survive for several weeks on equipment and surfaces, including tables, sinks, humidifiers, pillows, curtains, bed rails, supply carts, ventilators, and infusion pumps [14]. It can also form biofilm on endotracheal tubing, causing both colonization and infection in the lungs of intubated patients [15]. Patients colonized or infected with MDR *Acinetobacter* can easily contaminate their environment. However, the most common method of transmission is by the hands of healthcare workers [2]. Disinfection of patient care areas and hand hygiene are essential to prevent spread between patients. Due to its ability to persist in the hospital environment, *A. baumannii* frequently causes outbreaks in healthcare facilities [16].

A. baumannii displays intrinsic resistance to penicillins and first- and second-generation cephalosporins and can rapidly acquire resistance to fourth-generation cephalosporins, extended-spectrum penicillins, carbapenems, aminoglycosides, tetracyclines, and fluoroquinolones. Multiple resistance mechanisms can be involved, including β-lactamases, cephalosporinases, carbapenemases, efflux pumps, and porin mutations. Mechanisms of carbapenem resistance are most commonly due to class D oxacilinases (OXA) and class B metallo-β-lactamases, which can spread via plasmid-mediated transfer and have become widely disseminated in many countries [12]. Common mechanisms of resistance are described in Table 2.

The prevalence of multidrug-resistant (MDR) *Acinetobacter* species has been rising since the late 1980s, particularly among critically ill patients. MDR infections with *Acinetobacter* are defined as being resistant to one agent in three different

Table 2 Common resistance mechanisms of *A. baumannii* [17, 18]

Resistance to beta-lactams	• Hydrolysis by beta-lactamases, including class A, class B, class C, and class D • Changes in penicillin-binding proteins • Alterations in the structure and number of porin proteins, resulting in decreased permeability to antibiotics • Activity/overexpression of efflux pumps
Resistance to aminoglycosides	• Aminoglycoside-modifying enzymes
Resistance to quinolones	• Modification in structure of DNA gyrase, resulting in lower affinity of quinolone binding • Activity of efflux pump
Resistance to tetracyclines	• Transposon-mediated efflux pumps (tet A and tet B) • Ribosomal protection protein (shields ribosome from action of tetracycline)
Resistance to polymyxins	• Modification in the lipopolysaccharide that prevents binding of antibiotic to cell membrane

classes of antimicrobials [19]. Accordingly, the CDC has labeled MDR *Acinetobacter* as a serious threat, and the World Health Organization (WHO) has designated *Acinetobacter* as a critical priority organism for research and development of new antibiotics for resistant bacteria [20, 21].

Clinical Impact in Transplant

Acinetobacter infections in solid organ transplant recipients are frequently multidrug- resistant and associated with a high rate of mortality. Infection typically occurs greater than 48 hours after hospitalization, particularly in patients with ICU admission and prolonged mechanical ventilation. Timing of onset posttransplant can vary but is most often early (less than 6 months) after transplantation [22]. Overall 30-day mortality in solid organ transplant recipients with *Acinetobacter* infection ranges from 24% to 65% [22–26], with mortality of up to 91% reported for extremely drug-resistant (XDR) *A. baumannii* infections [27]. XDR *Acinetobacter* is defined as non-susceptibility to at least one agent in all but one or two antimicrobial categories. Delay in appropriate antibiotic therapy is a major contributor to mortality [22, 25, 28], and MDR or XDR infections are associated with higher mortality in some studies [22]. Polymicrobial infections are common, including infection with other multidrug-resistant organisms [24].

Similar to non-transplant recipients, risk factors for *Acinetobacter* infection in transplant recipients include prolonged hospital and ICU admission, mechanical ventilation, central venous catheterization, exposure to broad-spectrum antibiotics, higher illness severity, and invasive procedures [29]. In one single-center study, cardiothoracic transplant recipients were at higher risk than abdominal transplant recipients for *Acinetobacter* infection, particularly for extensively drug-resistant infection [24]. Receiving high-dose corticosteroids may also be a

risk factor [23]. The respiratory tract is the most common site of infection. Other typical sites of infection include bloodstream infection, including central venous catheter-associated infections, urinary tract infection, skin and soft tissue infection, and intra-abdominal infection in abdominal organ recipients [30]. There have also been reports of less common sites of infection including mediastinitis [24, 31], renal abscess [32], endocarditis [33], and necrotizing fasciitis [34]. Risk factors for multi or extensively drug-resistant infection include prolonged use of broad-spectrum antibiotics, particularly carbapenems, and prolonged endotracheal intubation [22, 35]. Higher mortality from *Acinetobacter*-related sepsis has been associated with use of expanded criteria donors and anti-thymocyte globulin [36].

Lung transplant recipients are especially impacted by *Acinetobacter* when it colonizes the respiratory tree. Low rates of microbiologic cure and increased mortality after lung transplant in patients with MDR *A. baumannii* infection have been reported. In one series of six lung transplant recipients with *A. baumannii* pneumonia, four of the six patients failed to clear the infection and ultimately died, despite extended courses of antibiotics and reduction of immunosuppression [37]. In another retrospective study of lung transplant recipients, those infected with *Acinetobacter baumannii* had a lower probability of survival compared to patients with other types of bacterial infection, including *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *and Stenotrophomonas maltophilia* [38]. Donor-derived *A. baumannii* infections have been associated with prolonged ICU stay and mechanical ventilation [39].

Abdominal organ transplant recipients are also susceptible to *Acinetobacter* and have high rates of MDR infection. One series of 33 abdominal organ transplant recipients with *A. baumannii* infection found that 79% of patients had healthcare-associated infection and 82% had received antibiotics within the preceding 2 weeks. The most common sites of infection were the respiratory tract, blood, urine, and peritoneum. MDR or XDR isolates were predominant, occurring in 85% of cases in a single-center study from North America [22]. In another series of living-related liver transplant recipients, CRAB bacteremia was associated with 50% mortality, which was significantly higher than non-bacteremic CRAB infections and bacteremia due to other organisms [30]. Donor infection with MDR *Acinetobacter* may be considered a relative contraindication to transplant, but this is controversial. Furthermore, donor culture data are frequently not available at the time of transplantation. There have been reports of successful transplantation from organ donors infected with *Acinetobacter* infection, including CRAB infections, when recipients receive appropriate antibiotics within 7 days of transplant [40, 41]. Consequently, we recommend a case-by-case approach, weighing the recognized detrimental impact of *A. baumannii* donor colonization, against the urgency to move to transplant in the intended recipient.

In hematopoietic cell transplant recipients, *A. baumannii* is an uncommon cause of infection. *Acinetobacter* species represent only 1–3% of bloodstream infections in this population [42, 43]; however, once again, multidrug resistance is common, and associated mortality is high. In one South Korean study of 19

hematopoietic stem cell transplant (HSCT) recipients with CRAB bacteremic pneumonia, infection occurred post-engraftment and was associated with longer hospital stay prior to HSCT and ICU level care. Death occurred in 18/19 (95%) of cases [44].

Diagnosis

Ventilator-associated pneumonia and bloodstream infections are the most common clinical presentations of *Acinetobacter* infection. *A. baumannii* can colonize the respiratory tract, gastrointestinal tract, and wound sites, and its presence must be interpreted together with clinical signs to determine whether growth in culture represents colonization or infection. Infection often occurs in patients previously colonized with *A. baumannii*, making it essential to interpret culture results in clinical context. As with other causes of VAP, typical signs include fever, tachypnea, purulent secretions, hypoxia, increased mechanical ventilatory support, and new or worsening infiltrate on chest imaging. Other *Acinetobacter* species are most commonly found in catheter-associated bloodstream infections and have a more benign clinical course compared to *A. baumannii* [13]. For example, in one series of *Acinetobacter* bloodstream infections, *A. baumannii* carried significantly higher mortality than *A. nosocomialis* or *A. pittii* (37% vs 16% and 14%, respectively) [45].

Acinetobacter can be isolated in culture specimens from sputum, blood, cerebrospinal fluid, and other sites and grows readily on standard culture media. It should be suspected when non-fermenting catalase-positive, oxidase-negative gram-negative coccobacilli are seen in the right clinical setting. *Acinetobacter* species are difficult to decolorize and may incorrectly be identified as gram positive. Phenotypic tests can distinguish many species of *Acinetobacter*, but they cannot identify more recently described genomic species and cannot distinguish between closely related members of the *A. calcoaceticus-A. baumannii* complex. Because of their high degree of similarity, *A. pittii* and *A. nosocomialis* are frequently misidentified as *A. baumannii* in clinical laboratories [1]. Matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectrometry (MS) can identify most clinically relevant *Acinetobacter* species accurately since the database was recently expanded [46]. However, MALDI-TOF MS is inadequate to distinguish between different clones of *A. baumannii*, which can be done using pulsed-field gel electrophoresis, amplified fragment length polymorphism analysis, multilocus sequence typing, and other PCR-based methods [47]. In addition, *A. baumannii* has an intrinsic class D OXA-51-like carbapenemase that can be used as a marker for species identification [48]. Real-time PCR of OXA-51 can be used to monitor treatment response, but this requires further study and is likely cost prohibitive for many regions of the world [49, 50]. Antibiotic susceptibility testing should include third- or fourth-generation cephalosporins, beta-lactamase inhibitors, and carbapenems and may also include tetracyclines, glycylcyclines, polymyxins, aminoglycosides, and fluoroquinolones.

Susceptibility testing must be done for each carbapenem individually, as susceptibility to one does not necessarily confer susceptibility to other members of the class. Multiplex PCR for carbapenemase genes has shown promise for rapid detection of carbapenem resistance and tracking spread of carbapenem-resistant strains in an outbreak setting [49]. However, this approach does not encompass all known carbapenem resistance mechanisms and consequently would not capture all CRAB strains.

Treatment

Multiple classes of antimicrobial agents are considered effective against *Acinetobacter* when susceptible. They include beta-lactam/beta-lactamase inhibitor combinations including sulbactam and piperacillin-tazobactam, broad-spectrum cephalosporins, carbapenems, aminoglycosides, quinolones, polymyxins, and tetracyclines and glycylcyclines [18]. However, most *Acinetobacter* strains have the ability to evade treatment with antimicrobials because of intrinsic resistance and/or acquired resistance, resulting in MDR infections and giving *Acinetobacter* its reputation as a difficult-to-treat infection [18].

The most commonly used antimicrobials used to treat multidrug-resistant *Acinetobacter* are discussed below (Table 3). Evidence regarding these agents is limited to mostly retrospective cohort or non-randomized small prospective studies [19]. Additional potential options include fluoroquinolones and aminoglycosides, but neither should be considered as preferred empiric options given high rates of resistance to these classes, in N. America and beyond. In addition, aminoglycosides should not be given as monotherapy and are mostly used as combination therapy due to the rapid acquisition of resistance.

Carbapenems

Carbapenems are generally considered the treatment of choice for infections caused by *Acinetobacter* when susceptible, due to intrinsic and often upregulated expression of chromosomally encoded AmpC cephalosporinases and a favorable safety profile [51, 52]. Discordance between various carbapenems has been reported; however, imipenem, meropenem, and doripenem all have activity. Ertapenem on the other hand is not reliably active, and there is limited data available for oral carbapenems outside the United States. Susceptibility to one carbapenem does not necessarily predict susceptibility to another [53].

Carbapenem resistance in *Acinetobacter* is increasing and is mediated by both plasmid and chromosomally encoded carbapenemases [54]. These include naturally producing oxacillinases (OXA) such as OXA-23, OXA-24 or 40, OXA 51, OXA-58, and OXA 143, which are class D beta-lactamases that are responsible for the majority of carbapenem resistance around the world [1]. Carbapenem-resistance in

Table 3 Currently approved treatment options for MDR *Acinetobacter*

Treatment	Recommended adult dosing (nl CrCl)	Adverse effects	Comments
Carbapenems	Meropenem 1gm IV q8 Imipenem 500 mg IV q6	Rash GI disturbance CNS toxicity/ seizure	• Drug of choice • Can see discordance between various carbapenems
Polymyxins	Colistin 5 mg/kg/day IV or polymyxin B 2.5 mg/kg/day IV	Nephrotoxicity Neurotoxicity	• Requires complex PK/PD dosing with a loading dose • Colistin requires prodrug conversion and is preferred agent for inhalation and for UTI
Sulbactams	6 to 9 grams a day	Rash/ hypersensitivity reaction	Usually given as ampicillin-sulbactam or cefoperazone/ Sulbactam
Tetracyclines	Minocycline 200 mg x 1 followed by 100 mg q12	Neurologic (dizziness) GI disturbance Tooth discoloration	Available in both IV and PO formulations
	Eravacycline 1 mg/kg IV q12	Infusion site reactions Nausea/ vomiting/ diarrhea Tooth discoloration	FDA approved for intra-abdominal infections
Glycylcyclines	Tigecycline 100 mg x 1 followed by 50 mg q12	Nausea/ vomiting	Limited by ability to achieve high serum levels and not recommended for bacteremia

Acinetobacter may also be due to the presence of class B beta-lactamases or metallo-beta-lactamases; these isolates may have had a role in transmission of the *bla* $_{NDM}$ gene to other *Enterobacteriaceae* [1].

Most carbapenem-resistant *Acinetobacter baumannii* (CRAB) isolates are usually not resistant to just carbapenems but other commonly used antibiotic classes as well, retaining susceptibility to only tigecycline, polymyxins, and sometimes aminoglycosides. Other mechanisms of resistance that are commonly expressed include efflux pump mechanisms, penicillin-binding protein alterations, and modification of outer membrane proteins or porins [18]. More than one of these resistance mechanisms is typically present, leaving a paucity of active drug options [54]. Infections with CRAB have been increasing, and nearly half of all clinical cultures with Acinetobacter in selected metropolitan regions in the United States were reported as carbapenem non-susceptible, with a crude annual incidence of 1.2 cases/100,000 persons [55]. Worldwide, the proportion of XDR *Acinetobacter* strains has increased from less than 4% in 2000 to greater than 60%. In general these strains are associated with longer hospitalizations,

increased cost, and greater mortality than those caused by carbapenem-susceptible strains [1].

Polymyxins

Polymyxins are cationic polypeptides that interact with the lipid A of the outer membrane of gram-negative bacteria and have been brought back into use because of their activity against multidrug-resistant gram-negative infections, including CRAB [51, 56, 57]. Polymyxins are available in two forms, polymyxin B and colistin (polymyxin E); both are bactericidal and differ only by one amino acid in structure. Colistin, however, is typically administered as its inactive prodrug colistin methanesulfonate (CMS) and undergoes conversion to active drug in plasma, requiring a large loading dose in order to achieve therapeutic concentrations. Polymyxin B is administered as an active drug and is associated with less nephrotoxicity than colistin [58]. Neurotoxicity is also less common with more recent formulations. Both colistin and polymyxin B achieve relatively poor concentrations in the lung, bone, and CSF. Colistin is preferred for urinary tract infections. While resistance against polymyxins remains relatively rare, a surveillance study of US hospitals found that about 5% of all *Acinetobacter* strains were resistant to colistin [59, 60].

A small prospective study evaluated the efficacy and toxicity of intravenous colistin in ventilator-associated pneumonia (VAP) and found no difference in inhospital mortality when comparing patients treated with colistin and patients treated with imipenem [61]. Similar findings were reported in a case-control study comparing patients with VAP secondary to MDR *Acinetobacter* or *Pseudomonas* treated with imipenem versus colistin [95].

Because of concerns over nephrotoxicity and poor penetration into lung tissue, directly administered CMS to the lungs has also been utilized for treatment of pneumonia. Inhaled CMS for the treatment of MDR *Acinetobacter* VAP has been reported in small prospective studies as a safe and effective option [62, 63]. Nebulized CMS can be used either alone or in conjunction with intravenous colistin for the treatment of VAP. In a randomized controlled study of a hundred patients with MDR *Pseudomonas* or *Acinetobacter* VAP, patients who received inhaled CMS in addition to intravenous antibiotics as compared to those who received inhaled normal saline with IV antibiotics had increased rates of microbiological clearance and similar rates of favorable clinical outcome. However, there were more bronchospasm events reported in the group who received inhaled CMS, although not statistically significant [64]. In another case-control study of 80 patients with *Acinetobacter* PNA who received systemic colistin versus 43 patients who received intravenous and inhaled colistin, there were no differences in clinical and microbiological outcomes [65].

Colistin has a low penetration into the CSF, and therefore intravenous colistin is not effective for Acinetobacter meningitis or CNS infections. In limited case series, intrathecal or intraventricular colistin has been used for the management of MDR

Acinetobacter meningitis or ventriculitis, often in conjunction with IV colistin when limited systemic drug therapeutic options exist [66, 67]. Rarely, meningeal irritation has been reported in these cases.

Sulbactam

Of the beta-lactamase inhibitors, sulbactam has the greatest intrinsic bactericidal activity against *Acinetobacter*. Commercially available as ampicillin-sulbactam in the United States, it has been suggested that anywhere from 6 grams to 9 grams of high-dose sulbactam may be effective against *Acinetobacter* infections, although the optimal dose is unknown [56]. In a small prospective study of 28 critically ill patients with MDR *Acinetobacter* VAP, there were no differences in clinical or microbiological outcome in patients treated with sulbactam versus colistin [68]. In a small retrospective cohort study, critically ill trauma patients with *Acinetobacter* VAP were treated with imipenem or ampicillin-sulbactam; there were no differences in regard to associated mortality, duration of mechanical ventilation, or length of stay in the ICU or hospital [69]. In certain locations worldwide, sulbactam is also available as combination cefoperazone/sulbactam; in a recent study in China, patients treated with cefoperazone/sulbactam had lower 28-day mortality rates than those receiving tigecycline for MDR infections [70].

Recent data suggests that higher doses of sulbactam should be considered when treating *Acinetobacter* infections. In an observational study of 58 patients with CRAB VAP, high-dose sulbactam at 8 grams a day was used and shown to be effective with a 30-day mortality of 29% [71]. In a meta-analysis of 12 observational trials involving 1500 patients, those treated with higher doses of sulbactam of greater than 9gm/day had significantly improved clinical response [72]. Sulbactam remains a safe and effective therapeutic option against *Acinetobacter* when susceptible [52].

Tetracyclines and Glycylcyclines

Minocycline and doxycycline have been shown to have activity against *Acinetobacter*. In isolates resistant to tetracycline or doxycycline, minocycline activity may be preserved given that the tet(A) resistance determinant that codes for a tetracycline-specific efflux pump does not confer resistance to minocycline. Minocycline may also retain activity against tigecycline-resistant strains and had activity against 79% and 84% of MDR *Acinetobacter* isolates in two large antimicrobial surveillance studies [73]. Due to its effective penetration into lung tissue, IV minocycline remains an option for treatment of pneumonia with MDR *Acinetobacter* and is FDA approved for this indication [74]. The breakpoint is not well validated based on clinical outcome data, and in the setting of an MIC of 4 μg/mL or greater, caution may be warranted in using minocycline as monotherapy or with bacteremia

[1]. In a small observational study, a total of 53 patients were treated with minocycline, and although the majority received combination therapy, 73% of patients had a successful clinical outcome [75].

Glycylcyclines are related to tetracyclines and include tigecycline, a semisynthetic derivative of minocycline which inhibits protein synthesis. Tigecycline is able to evade common mechanisms of resistance to tetracyclines in *Acinetobacter*, including efflux pumps coded by tet (A-E) and tet (K) resistance determinants and tet (O) and tet (M) determinants that provide ribosomal protection [18, 56]. There is no CLSI breakpoint for *Acinetobacter*, but usually an MIC less than 2 μg/mL is considered susceptible.

However, tigecycline is limited by its ability to achieve high serum levels and therefore should not be routinely used in patients with bacteremia. In a meta-analysis that included 7 controlled and 17 single-arm studies, patients treated with tigecycline had higher inhospital mortality rates, a lower microbial eradication rate, and a trend toward longer hospital stays [76]. Given these finding and limited ability to achieve serum levels, tigecycline should be used with caution, especially in the treatment of bacteremia or VAP [1, 53]. Other pooled analyses indicate that cure rates may be better in intra-abdominal infections and skin and soft-tissue infections [52, 77]. Given this data, a high-dose regimen (200 mg/day) or combination therapy can be considered when using tigecycline to treat MDR *Acinetobacter* infections [78].

Eravacycline, a new antimicrobial in the tetracycline class, was recently approved by the FDA in 2018 for the treatment of intra-abdominal infections and is generally better tolerated than tigecycline, making it an attractive option. Eravacycline has a broad spectrum of activity, including MDROs such as MRSA, VRE, carbapenem-resistant *Enterobacteriaceae*, and *Acinetobacter*. It has demonstrated activity against a large number of *Acinetobacter* isolates, including those with varying patterns of carbapanem resistance, fluoroquinolone, and aminoglycoside resistance and even those with reduced susceptibility to tigecycline [79]. Eravacycline MICs have been found to be two- to eightfold lower than tigecycline MICs against CRAB, but at this time, clinical outcomes are lacking and will likely emerge over the next few years [80].

Combination Therapy

Given *Acinetobacter's* ability to acquire multidrug resistance through various mechanisms, combination therapy is theoretically an attractive treatment option for these infections and is frequently used to treat MDR *Acinetobacter* infections. However, at this time no clear evidence exists to support its approach over monotherapy [81, 78]. Two open-label randomized controlled trials in patients with CRAB infection compared the use of colistin alone to colistin plus rifampin and found no difference in mortality or clinical response, although microbiologic clearance improved with combination therapy [82, 83]. The use of colistin with fosfomycin when compared to

colistin alone for the treatment of patients with CRAB infections had no effect on clinical outcome or mortality [84].

A retrospective single-center study of combination intravenous colistin plus carbapenem treatment of 69 solid organ transplant recipients with XDR *Acinetobacter* infection suggested improved outcomes. In this study, XDR *Acinetobacter* infections were more common among heart and lung transplant recipients with a median time to infection of 172 days after transplant, and the most common site of infection was respiratory. Treatment with a colistin-carbapenem combination was independently associated with survival at 28 days [24].

However, a recent randomized controlled trial in Europe that enrolled 406 patients and compared colistin alone to colistin and meropenem for MDR gram-negative rod infections, including CRAB, showed no difference in clinical outcomes. Immunocompromised patients were included in each arm, including patients on immunosuppression and with malignancy; more than three-fourths of enrolled patients had an infection with *Acinetobacter*. Treatment with colistin monotherapy compared to treatment with colistin and meropenem resulted in no change in clinical outcomes, which was a composite outcome of survival, microbiological cure, hemodynamic stability, improved oxygenation, and severity of illness [85].

Further clinical trials with larger patient populations are needed to evaluate the use of combination therapy in the setting of MDR *Acinetobacter* infections, including close monitoring of polymyxin doses and therapeutic drug monitoring.

Cefiderocol

Cefiderocol is a newly developed cephalosporin, conjugated with a siderophore on its side chain with stability against multiple beta-lactamases providing activity for MDR gram-negative isolates, including CRAB [86]. In vitro studies have demonstrated activity against OXA-23, OXA-40, and OXA-58 isolates as well as NDM- and IMP-producing *Acinetobacter baumannii* isolates. In clinical studies, cefiderocol was found to be superior to imipenem for the treatment of complicated UTIs in a phase III RCT, but no CRAB isolates were included. Ongoing clinical trials are currently recruiting patients for the treatment of other severe infections including bloodstream infections and VAP/HAP and will likely include MDR *Acinetobacter* infections [80]. At least in the United States, FDA approval was obtained in 2019 for the treatment of complicated UTIs.

Infection Prevention

Acinetobacter is a ubiquitous pathogen with an ability to survive for prolonged periods in the environment, contributing to its ability to cause horizontal transmission resulting in infections and outbreaks. Consequently, it is imperative to consider the hospital environment and infection control options. A previous study replicating hospital conditions has shown that *Acinetobacter* could survive for an average of 20 days at a relative humidity of 31% and be isolated from a hospital bed rail 9 days

after discharge of an infected patient [87, 88]. The hospital environment and equipment can therefore serve as a secondary reservoir for *Acinetobacter*, contributing to transmission.

The majority of these outbreaks occur in intensive care units, frequently in patients who require mechanical ventilation. On some occasions, contaminated hospital equipment or shared equipment is identified and may often include a component of the ventilator circuit [87, 89]. Various infection prevention measures, often combined together as a bundle, have been effective in controlling these outbreaks. These include hand hygiene, the implementation of contact precautions, patient cohorting, environmental disinfection, and the use of chlorhexidine bathing [90, 91]. In addition, in some outbreak settings, the use of active surveillance has been utilized to rapidly identify colonized patients; whole genome sequencing can be utilized for strain typing and to assist in outbreak investigations [92]. Lastly, in a Taiwanese cohort, the use of antimicrobial stewardship and judicious antimicrobial use have been associated with decreasing MDR *Acinetobacter* rates [93, 94].

Conclusion

Acinetobacter has emerged as a key transplant pathogen, both in solid organ and bone marrow transplant recipients. *Acinetobacter baumannii* is the major pathogen in humans, concentrates itself in hospital environments, especially intensive care settings, and is prone to epidemic spread within healthcare settings. Because the organism has uniquely significant antimicrobial resistance, with multidrug and extremely drug-resistant isolates being increasingly discovered, treatment is complex, and morbidity and mortality are high. Early identification of infected individuals and instigation of appropriate antibiotics remains the mainstay of therapy.

Key Points

- *Acinetobacter* infection is associated with significant morbidity and mortality, especially *A. baumannii*.
- *A. baumannii* is typically very drug resistant, often exhibiting multi-class resistance or XDR characteristics. Consequently, early identification of the organism and associated sensitivity profile is key to minimize unnecessary antibiotic toxicity and for ultimately successful treatment.
- Acinetobacter infections have a predilection for hospitalized patients, especially bacteremia and hospital-acquired or ventilator-acquired pneumonias.
- Multiple strategies for treatment exist, including antibiotics, perhaps in combination, and strict adherence to infection control protocols to prevent ongoing environmental and nosocomial spread.
- *A. baumannii* remains a significant threat in hospitals and to transplanted patients, even despite the recent development of a number of promising and active antibiotics.

Introduction

The genus of *Burkholderia* continues to attract significant interest from many researchers in a range of fields. *Burkholderia* are found in soil and water and have the ability to cause serious human disease, promote plant growth through fungicidal activity, fix nitrogen, and degrade man-made pollutants [1, 2]. The genus represents some 70 species, including many that are pathogenic to humans. Particular species of interest in the setting of the immunocompromised transplant recipient include the *B. pseudomallei* complex (Bpc) which causes melioidosis, as well as *B. gladioli* and the *B. cepacia* complex (Bcc), both of which can cause pneumonia and septicemia (Table 1). A feature of these organisms is their ability to persist and establish chronic infection within a susceptible host [1, 2]. Infections are difficult to manage as a result of significant resistance to disinfectants and antibiotics. The combination of the intrinsic properties of the bacteria and host factors contributes to significant morbidity and mortality in the transplant setting. This chapter will explore the clinical features of these infections, including consideration of modes and risk factors of acquisition, clinical management strategies, and discussion of emerging novel therapeutic approaches.

The Importance of *Burkholderia* Speciation

Careful characterization and classification of *Burkholderia* species and strains are very important from the point of view of predicting disease extent, prognosis, and the specifics of therapeutic measures that will be required to treat the affected individual. Additionally, understanding the modes of transmission and true pathogenic potential via molecular strain analyses has proven to have relevance to both public health preventative/product safety strategies and the specific transplant risk-benefit for an individual patient [3]. Notwithstanding, there are difficulties identifying these organisms and there are many questions still to be answered.

B. pseudomallei Complex

Bpc are facultative intracellular Gram-negative rods including *B. pseudomallei*, *B. mallei*, and *B. thailandensis* that are saprophytes and that are found in the soil in tropical and subtropical areas, including Thailand, India, and Northern Australia [4] (Fig. 1).

B. pseudomallei causes the most frequent serious infection in humans in the form of the clinical entity called melioidosis. Skin inoculation, inhalation, and ingestion are the most common routes of acquisition, [5] and a variety of disease presentations are possible including acute, subacute, or latent infection. Clinical illness can span a spectrum of presentations including localized or disseminated abscesses, necrotizing pneumonia, osteomyelitis, and overwhelming septicemia, with case fatalities

Table 1 Important *Burkholderia* species [1]

(A) *B. pseudomallei* complex (Bpc)

B. dolosa (genomovar VI)
B. contaminans
B. ambifaria
B. pyrrocinia

reaching up to 50%. Relapse after apparently treated infection is well described, typically due to reactivation of the original infecting strain [6].

Equines are the only known reservoir of *B. mallei*, and humans can become infected when they have close contact with infected animals via aerosols or ingest contaminated meat or water. This organism is endemic in Africa, Asia, the Middle East, and Central and South America and causes the animal disease entity known as glanders. Similar to melioidosis, glanders can present with a spectrum of illness ranging from localized to disseminated, but is fatal in up to 90% of cases [7]. *B. thailandensis* is generally considered nonpathogenic in humans, but cases of septicemia and pneumonia have been described in the USA from travelers to endemic areas [8].

Clinical risk factors for developing melioidosis include diabetes mellitus, excessive alcohol use, chronic renal or lung disease [including cystic fibrosis (CF) [9]], thalassemia, occupational or environmental exposure, and immunosuppression or immunodeficiency [10]. Animal models suggest survival relates to the host's ability to mount a pro-inflammatory protective interferon-gamma-mediated macrophage response [1, 11].

Although the isolation of *B. pseudomallei* from clinical specimens has been enhanced by the utilization of selective media, even with positive cultures, identification of *B. pseudomallei* can be difficult in clinical microbiology laboratories in non-endemic areas where clinical suspicion is low. Ashdown's medium is commonly used to selective isolate *B. pseudomallei* (Fig. 2). It contains crystal violet and gentamicin and produces characteristic purple, dry, and wrinkled colonies [12]. Commercial identification systems may fail to distinguish between *B. pseudomallei* and closely related species such as *B. thailandensis*. Genotypic identification of suspected isolates by sequencing of gene targets such as *groEL* and *s*pecific PCR-based identification using *B. pseudomallei*-specific gene targets are available [13]. Matrix-assisted laser desorption/ionization time-of-flight

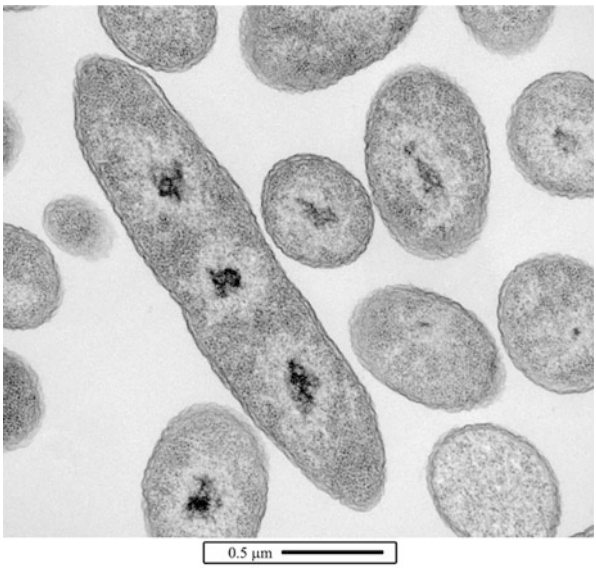

Fig. 1 An example of Bpc – a transmission electron microscope picture of *B. thailandensis* magnified 62,000× [68]. Note the three chromosomes

(MALDI-TOF) mass spectrometry can also be useful for the rapid identification of *Bpc* but has been limited by the availability of a database containing validated reference spectra [3]. Although various serological tests have been developed, they generally have low sensitivities and specificities and are not widely employed [12].

Transplantation and Bpc

From the transplant perspective, Bpc infection is an uncommon pathogen. Donors who have spent time in an endemic area are at risk of transmitting chronic or latently infected Bpc to recipients, so a careful epidemiological history is pertinent, particularly in regard to lung and liver donation. Transplant recipients from an endemic area are at risk of infection due to recrudescence from a latent or chronic focus or primary infection if they visit an endemic area after transplant [1, 10, 14]. While no randomized data exist to support the assertion, it seems probable that in any patient with a latent or chronic nidus, infection will be prevented with routine post-transplant trimethoprim-sulfamethoxazole prophylaxis. Infection due to *B. pseudomallei* needs to be included in the differential diagnosis in transplant recipients presenting with fever of unknown origin who have a history of prior treatment for melioidosis or who travel to endemic regions. Three cases of lung transplantation in the setting of chronic *B. pseudomallei* infection have been reported [15].

Management of Bpc

Bpc is intrinsically resistant to many antibiotics, including penicillin, ampicillin, first- and second-generation cephalosporins, streptomycin, and polymyxin.

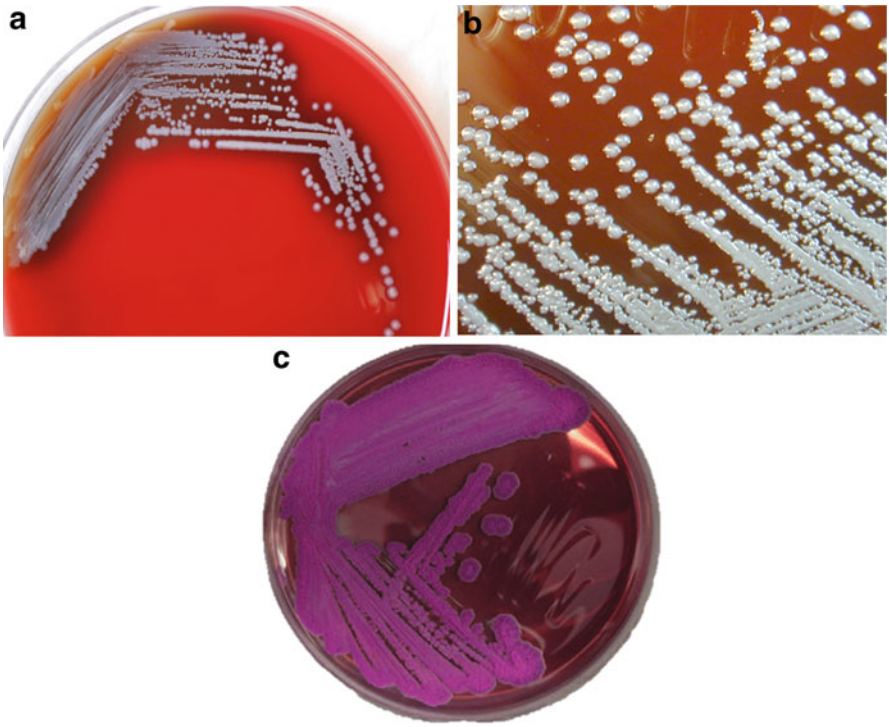

Fig. 2 *B. pseudomallei* (**a**) an enlarged view (**b**) a closeup view on a medium of sheep blood agar, at 48 h, (**c**) on Ashdown's media at 48 h [12]

However, therapy consisting of 10–14 days of an intravenous third-generation cephalosporin or carbapenem as part of an intensive phase, followed by a 3–6-month maintenance phase with oral trimethoprim-sulfamethoxazole (or amoxicillin-clavulanate), is usually effective [1, 2, 10]. Treatment failure occurs in approximately 10–15% of cases and typically represents acquired resistance via a class A β-lactamase in combination with an efflux pump and an outer membrane permeability barrier. In these instances, carbapenems are usually effective [2].

B. gladioli

Although this soil-dwelling organism is an uncommon pathogen, it is an important agent for nosocomially acquired infections in immune-competent and immune-deficient patients [16]. It can infect the respiratory tracts, both transiently and chronically, of patients with CF and chronic granulomatous disease (CGD) pre-transplant. The situation is quite different in the post-lung transplant setting where CF lung transplant recipients in particular have presented with *B. gladioli* abscesses, tracheobronchitis, sinusitis, pneumonia, and bacteremia [16–19]. In a

detailed examination of the effect of the presence of specific *Burkholderia* species on lung transplant outcomes, *B. gladioli* was associated with a statistically significant mortality hazard ratio of 2.2 [18].

It is suggested that oxidation-fermentation-polymyxin B-bacitracin-lactose (OFPBL) medium is the most useful for the recovery of *B. gladioli*, but there is a significant risk of misidentification when phenotypic methods are used alone, with Bcc commonly mistakenly identified as *B. gladioli* [20]. Molecular identification of *B. gladioli* is mainly based on rRNA gene-specific signatures and can be performed by means of species-specific PCR, amplified rRNA gene restriction analysis (ARDRA), or sequencing of the 16S rRNA gene [20].

Transplantation and *B. gladioli*

From the transplant perspective, donors with known B. *gladioli* colonization or infection cultured from any site should be regarded with great caution. Infection control measures, including segregation and avoidance of direct person-to-person contact between *B. gladioli* colonized/infected and pre- or post-transplant patients, are prudent [18]. In any post-transplant recipient, a new *B. gladioli* isolate should be aggressively treated.

Management of *B. gladioli*

There is no direct evidence of patient-to-patient spread, although increased colonization rates have been noted in siblings [18]. The antibiotic susceptibility pattern of *B. gladioli* is quite different from that of both *B. pseudomallei* and *B. cepacia* complex organisms; and the general susceptibility to aminoglycosides, meropenem, and ticarcillin-clavulanic acid is a useful characteristic for use in the differentiation of *B. gladioli* and Bcc in particular. Nevertheless, aminoglycoside-resistant isolates may appear in the course of chronic infections [20], and antibiotic therapy for this species may require consideration of a wider range of agents (see below).

B. cepacia Complex

Bcc organisms are the most infamous *Burkholderia* species and are ubiquitously found in soil and contaminated water (Fig. 3). The group currently consists of approximately 21 species. Notably, species names have replaced the genomovar designations of the early 2000s [1], and that has made comparisons between the literature over this time period confusing. Bcc is a human pathogen almost exclusively in people with CF and CGD where it can cause pneumonitis, bronchitis, septicemia, cutaneous nodules, osteomyelitis, and death. The most common species of Bcc to cause chronic infection in humans are *B. cenocepacia*, *B. multivorans*, and,

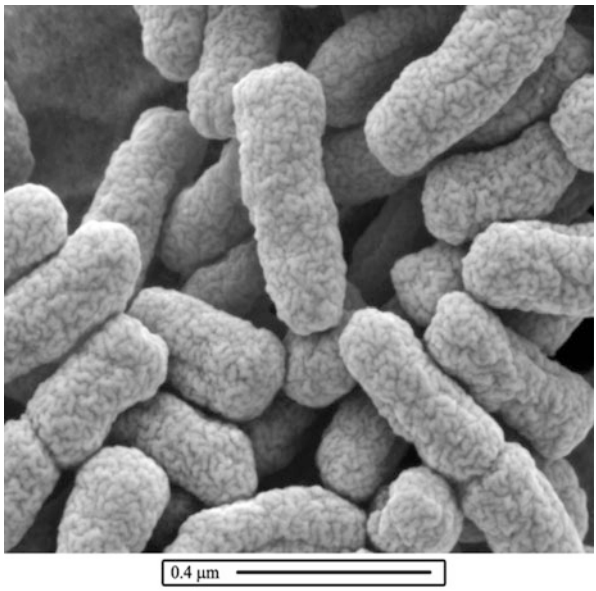

Fig. 3 An example of Bcc – a scanning electron microscope picture of *B. cenocepacia* magnified 137,500× [68]

to a lesser extent, *B. dolosa*, *B. cepacia*, and *B. vietnamensis* although all species of Bcc have been seen in humans.

In routine clinical laboratories, the identification of putative Bcc isolates is generally performed using a combination of selective media, conventional biochemical analysis, and/or commercial systems. Several different media have been developed for the selective isolation of Bcc isolates, in particular *B. cepacia*-selective agar (BCSA) (Fig. 4) or OFPBL agar. Organisms not belonging to the Bcc that are capable of growth on BCSA include *B. gladioli* and *Ralstonia* [21, 22]. Identification of the species requires genotyping with repetitive element PCR (rep-PCR) or multi-locus sequence typing (MLST), and *B. cenocepacia* strain typing requires multi-locus sequence typing [23].

Bcc Virulence Features

While there are some differences in structure and pathogenic potential among the different species of Bcc, there are also common features and mechanisms of virulence (Fig. 5). Bcc demonstrates the ability to invade and can survive within macrophages. Flagella and pili are seen in some species of Bcc and assist in adhesion and motility, the production of biofilms, and the infected host's inflammatory response [24]. Virulence factors that enhance epithelial cell's pathogenicity include metalloproteases, lipases, serine proteases, and lipopolysaccharides. Metalloproteases contribute significantly to Bcc's destruction of lung matrix type IV collagen and fibronectin. Serine protease, just as lipase, has been shown to be a key factor in the intracellular invasion of lung tissue and additionally enhance the ability of Bcc to use

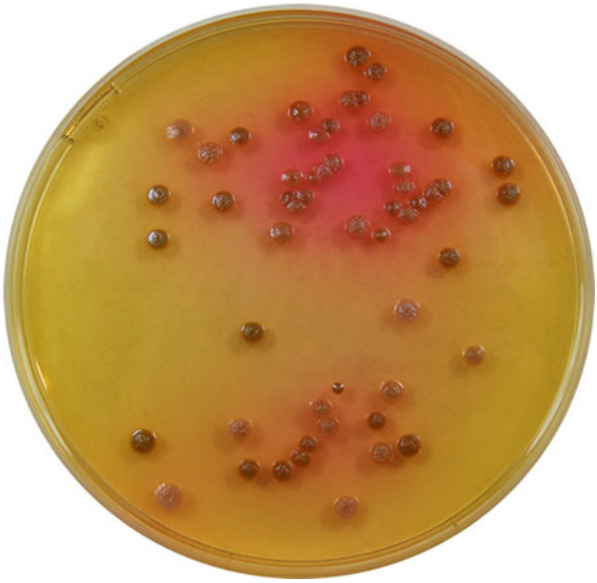

Fig. 4 *B. cepacia* on selective media [13]

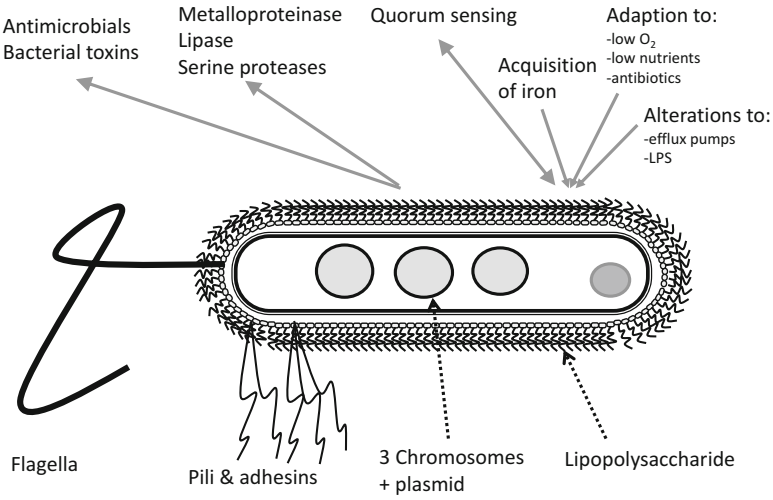

Fig. 5 Virulence features of the Bcc species. Bcc have both physical (lower half of the drawing) and biochemical and pathophysiological tools to survive (upper half of the drawing)

ferritin as an iron source, providing a unique early advantage over other bacteria [25]. Lipopolysaccharides induce an inflammatory response in the lungs of infected patients, allowing the infection to become increasingly necrotizing [25, 26]. The severity of Bcc infection is due in part to its formation of antibiotic-resistant biofilms. The development of the biofilm is orchestrated through the pili and flagella's tissue attachment and lateral movement to enlarge the colony [27]. *B. cepacia* and

B. cenocepacia use quorum sensing to control the expression of their virulence factors such that their pathogenicity is only expressed when a high enough population density exists to take over the host before it can mount a response [1, 25].

Bcc Antibiotic Resistance Mechanisms

Antibiotic resistance in Bcc is mediated via four main mechanisms [2, 28]:

- Antibiotic modification is commonly used by Bcc. The presence of class A β-lactamases provides resistance to β-lactam antibiotics such as penicillins, cephalosporins, clavams, carbapenems, and monobactams.
- Reduced permeability of the cell envelope via a unique lipopolysaccharide structure inhibits the binding of polymyxin to the bacteria's outer membrane.
- Overexpression of efflux pumps due to upregulation of transporters in the presence of antibiotics contributes to resistance to chlorhexidine, ciprofloxacin, tobramycin, minocycline, and chloramphenicol.
- Alterations in antibiotic cellular targets account for a portion of resistance to levofloxacin and trimethoprim.

Bcc Associated with CF

Individuals with CF can become infected with Bcc as a result of transmission from person to person, an infected hospital environment/medical device, or even community environmental contact. The incidence of the Bcc in CF varies from country to country/center to center and is between 3% and 20%. Additionally, the exact proportion of the individual Bcc species varies within that percentage, with *B. multivorans* and *B. cenocepacia* being the commonest species seen in Canada, the USA, and the UK. Following recognition of person-to-person and hospitalization-based transmission, infection control and segregation strategies have been published, and their implementation has been shown to reduce transmissions and alter the epidemiology [29]. Notwithstanding, subsequent outbreaks despite these strategies suggest other routes of transmission might be possible [26]. The prevalence of *B. cenocepacia* (more commonly acquired by person-to-person transmission) has decreased, and *B. multivorans* (more commonly acquired from the environment) has increased [26]. Patients tend to retain the same species and strain over time, but if the strain does change, then *B. cenocepacia* is the most common replacement strain [1]. Using multi-locus sequence typing or whole genome sequencing, it is possible to further define particular B. *cenocepacia* strains including the ET12 strain (ST28) (most commonly seen in Canada and the UK), the PHDC strain (seen in the Mid-Atlantic USA), the Midwest clone (seen in the Western USA), and the Czech strain (ST32) (seen in Europe) [28]. These molecular techniques are particularly useful in investigating Bcc outbreaks [30]. *B. contaminans* is the most frequently seen species in people with CF in Argentina, Portugal, and Spain [1, 31]. The association

of *B. contaminans* with contaminated food sources, medicines, and devices (see below) has raised questions about the source of these organisms [31].

Outcomes of Bcc Infection

In general, all Bcc species are associated with an accelerated chronic loss of lung function and increased mortality when compared to non-Bcc-infected individuals [31, 32]. In addition, there is evidence of lower survival in patients infected with *B. cenocepacia* than in those with *B. multivorans* [33]. Notably the ET12 strain of *B. cenocepacia* is thought to be particularly pathogenic [18, 34]. The notorious "c*epacia* syndrome" of rapidly progressing cavitary pneumonitis, with subsequent septicemia and universal mortality, is linked with *B. cenocepacia*, *B. multivorans*, and *B. dolosa* [1, 18].

Bcc Associated with Contaminated Medicines, Medical Fluids, and Devices

Outbreaks of Bcc have included pneumonia following inoculation of contaminated mouthwash, nasal spray, an intensive care unit sublingual probe, or hospital disinfectants [35–39]. Shampoo, albuterol inhalers, and other products have been found to be contaminated without overt disease transmission [35, 36]. Almost all these contaminations occur in the factory production process. Indeed, Bcc (*B. cepacia* and *B. contaminans*) are among the most frequently isolated microbial species in product recalls as logged by the US Food and Drug Agency; Bcc were present in 22% of non-sterile product recalls and 2.5% of sterile product contaminations [35, 36]. The key features which allow Bcc to survive in such harsh and diverse circumstances include an innate resistance to antimicrobials, efflux-mediated preservative resistance, and an ability to grow in many different substrates over a broad range of temperature.

Infection with Bcc from contaminated medical products may occur in immune-competent and immune-deficient, non-CF individuals with the resultant clinical syndrome being a product of the route of infection (i.e., direct septicemia via infusions or pneumonia following inhalation), the inoculation size, and the immune competency of the host. The use of catheters (hemodialysis, endotracheal tubes, urinary catheters) is a risk factor for acquisition of Bcc which has resulted in reported outbreaks of infection in oncology and dialysis wards and intensive care units.

Transplantation and Bcc

From the general transplantation perspective, donors with known Bcc cultured from any site should be regarded with great caution. From the specific viewpoint of lung transplantation, the isolation of Bcc at any time is a serious "red flag."

Although one US study [18] suggested there was no difference in pre-transplant survival based on the presence of Bcc, a more extensive Canadian review shows an increased waiting list mortality with Bcc [33]. In a recent systematic review and meta-analysis, the pre-transplant presence of Bcc had the most significant association with post-lung transplant mortality, with an adjusted odds ratio of 2.49 [34]. In one large transplant study, outcomes were similar between uninfected recipients and those infected with *B. multivorans*, whereas recipients infected with B. *gladioli* and *B. cenocepacia* had significantly greater post-transplant mortality than uninfected patients [17]. Other studies confirm the importance of *B. cenocepacia* specifically as explaining the excess mortality noted with Bcc [40, 41]. The actual *B. cenocepacia* strain, particularly the presence of the ET12, warrants further study in this regard [18, 34]. A recent small case series places *B. dolosa* in an intermediate position, with an effect between that seen with *B. cenocepacia* and non-Bcc-infected individuals [42]. Further individual case reports describe a fatal outcome in a patient infected with *B. pyrrocinia* [43], a near-fatal but ultimately successful outcome associated with *B. contaminans* [44], and a favorable outcome in a *cepacia* syndrome patient infected with *B. ambifaria* [45].

In all analyses, most of the increased risk of mortality occurs within the first 6 months after transplant, relating to overwhelming chest sepsis in the form of pneumonitis, mediastinitis, empyema, and septicemia. When censored conditionally on 1-year survival, long-term outcomes are similar to patients transplanted without Bcc. It appears that the vast majority of Bcc infectious problems post-lung transplant are rooted in the organisms' present pre-transplant and seeded at the time of surgery, rather than being de novo acquisition at a later stage.

Specific culture for Bcc should be undertaken pre-transplant in all patients and the species present confirmed. In areas of the world with known, highly pathogenic strains (e.g., ET12 in Canada and the UK), strain typing should also be undertaken. The combination of center experience with CF and Bcc, as well as the potential recipient's medical acuity, trajectory, other comorbidities, and specifics of the Bcc species and strain present, must be integrated into the decision regarding whether to transplant or not.

Current Strategies to Manage Bcc

Preventive Strategies

Infection control measures including segregation and avoidance of direct person-to-person or equipment contact between Bcc-infected and non-infected CF patients (pre- or post-transplant) are prudent. Strict staff hand hygiene with gown and glove requirements, as well as patients wearing a mask outside of their consultation or hospital ward room and physically separated from one another, is part of standard preventative practices in North American CF clinics and inpatient areas [46]. Vaccination strategies are under investigation, and although research on a variety of small molecules to modulate host cell-mediated

responses to infection appears promising, no agents are ready yet for clinical practice [1, 28, 47].

Prophylaxis Strategies

There are no proven therapies to reduce CF-associated Bcc exacerbations [48] pre-lung transplant, but a carefully considered antimicrobial regimen of inhaled and intravenous antibiotics (see below) is strongly recommended to reduce the bacterial bio-burden of Bcc peri-transplant [40, 48–50].

Supportive Therapy

Poor glycemic control increases airway bacterial growth and hampers therapy of Bcc infection, so aggressive treatment of CF-related diabetes is recommended [51]. Nutritional support needs to be optimized. Facial sinus drainage procedures should also be considered as the upper airway remains a source of Bcc post-transplant although this strategy has not been demonstrated to reduce postoperative infection.

Interoperative Therapies

Two lung transplant centers suggest taurolidine either as a wash of airways and pleural spaces intraoperatively or as a regular perioperative nebulizer (2 ml 2%) [41, 52], while another suggests a dilute povidone-iodine wash intraoperatively [50]. Careful avoidance of airway spillage intraoperatively and repeated glove changes are highly advisable. Postoperative drainage of any infected/colonized spaces is necessary [50]; however, the potential for inadvertent contamination or seeding via unnecessary tube drainage or bronchoscopic biopsy should also be considered.

Immunosuppressive Therapies Post-Transplant

The transplant team should regard these patients as high risk of sepsis and should strategize the immunosuppression accordingly. This means using the least generally immunosuppressing regimen possible and would typically involve an IL2 blocker (e.g., basiliximab), rather than anti-thymocyte globulin [41], and potentially lower doses of corticosteroids and anti-proliferative agents (e.g., azathioprine or mycophenolate) [53]. Intravenous gamma-globulin or even photopheresis therapy can be used additionally or as alternative safe acute rejection prophylaxis agents [53].

Antibiotic Therapy

Consultation with experts in the management of Bcc infection is recommended with development of a careful plan for antibiotic therapy peri-transplant. There are no evidence-based guidelines for the management of acute or chronic infection with Bcc. Unfortunately, the clinical role of multiple combination bactericidal testing remains unclear, so there is no single best approach or clinical trials to guide therapy [54–57]. General principles for antibiotic therapy of Bcc include using susceptibility testing to guide drug selection, a combination of different classes of antibiotics, and observation of inflammatory markers (e.g., CRP)

to guide therapy duration. Due to the increased drug metabolism seen in people with CF, high doses of antibiotics and extended or continuous infusions of beta-lactams may maximize the antimicrobial action. Antibiotic options for Bcc currently include trimethoprim-sulfamethoxazole, beta-lactams (with ceftazidime and meropenem being the preferred choices), and the bacteriostatic drugs minocycline and chloramphenicol [1, 28, 54, 55]. In vitro susceptibility of Bcc to the combination of a cephalosporin and inhibitor of beta-lactamases, ceftazidime-avibactam, and ceftolozane-tazobactam has been demonstrated [58], and this treatment may restore susceptibility to cetazidime [59].

High doses of aminoglycosides are needed to overcome efflux pump resistance, so inhaled formulations of tobramycin are preferable as higher sputum concentrations are achieved without systemic toxicity [60]. Levofloxacin is often a better choice than ciprofloxacin. A reasonable starting point would be a combination of inhaled tobramycin, trimethoprim-sulfamethoxazole, or minocycline with meropenem or ceftazidime, but up to five agents may be necessary.

Novel Strategies to Manage Bcc

Novel Antibiotics

Cefiderocol is a siderophore cephalosporin with activity against carbapenem-resistant and multidrug-resistant Gram-negative bacilli [61–63], as is meropenem-vaborbactam [64, 65]. While both show promise as potential therapies for resistant organisms, specific efficacy data is yet to be confirmed with regard to the *Burkholderia* species.

Cysteamine

This molecule has been investigated as a potential enhancer of antimicrobial therapy against Bcc due to its ability to disrupt disulfide bonds, thus achieving mucolytic activity and improving biofilm penetration. This, in turn, enhances the activity of tobramycin, ciprofloxacin, and trimethoprim-sulfamethoxazole [66]. This molecule has also been shown to restore cystic fibrosis transmembrane conductance regulator (CFTR) protein function [67].

OligoG

OligoG is a low-molecular-weight oligosaccharide demonstrated in vitro to improve the efficacy of antibiotics used in combination via the perturbation of bacterial biofilms and improvements in mucus properties via the chelation of calcium. The results of a randomized double-blind, placebo-controlled study (NCT02453789) to assess Bcc sputum load are awaited [28].

Phage Therapy

Bacteriophages are viruses that infect and replicate within bacteria. Aerosolized phages decrease Bcc airway load and have been demonstrated to work synergistically with meropenem and ciprofloxacin in vitro [28, 67].

Other Potential Therapies

Inhaled nitric oxide (NCT02498535), cationic antimicrobial peptides, quorum-sensing inhibitors, fish oils, essential oils, and glycol-polymers are all the subject of ongoing Bcc research [28].

Conclusion

Burkholderia species represent potent human systemic pathogens, particularly concerning in the lung transplant population due to establishment of chronicity in the airways and resistance to antibiotics. Bpc, or meliodosis, is uncommonly reported in the transplantation setting which likely reflects the epidemiology of both meliodosis and access to organ transplant. *B. gladioli* is emerging as a contaminant pathogen in the setting of CF, critical illness, and the immune-compromised host. Bcc can be a contaminant and has a predilection to significant clinical infection in patients with CF and CGD. The virulence of Bcc varies with species and, within *B. cenocepacia*, with strain type, and determination of species and strain requires genotyping. Infection with *B. cenocepacia*, in particular the ET12 strain in the setting of lung transplantation, is associated with high morbidity and mortality.

The ability of *Burkholderia* species to survive in harsh macro- and microenvironments and against our best therapies will likely increasingly challenge microbiologists and clinicians. On the other hand, the very broad research being undertaken as a result of these challenges may also provide collateral insights and therapeutic agents against many other pathogens. In the context of transplantation, the high virulence of these organisms challenges us to continue to evolve novel ways of supporting host immunity and avoid, or at least minimize, systemic immunosuppression.

We have definitely not heard the final word regarding this bacterium.

Key Points

- *Burkholderia* species are associated with significant human disease – particularly in an immunosuppressed transplant patient.
- Speciation, and even identification to strain level, has relevance to virulence, prognosis, and therapeutic strategy.
- Bpc causes melioidosis in endemic areas, but if diagnosed is treatable with relatively standard intravenous antibiotics.
- *B. gladioli* is a soil organism and is emerging as a serious pathogen which is challenging to treat with antibiotics.
- Bcc, and in particular *B. cenocepacia*, are associated with serious infection, particularly in patients with suppurative lung disease, and a considered clinical and antibiotic strategy is required if transplantation is being considered or has already been undertaken.

Introduction

Tuberculosis (TB) in solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients can present a diagnostic challenge due to the immunosuppressed state of the patients, their comorbid conditions, and multiple concomitant medications. Screening and treatment of latent or subclinical TB prior to transplantation is critical in prevention of active TB after transplant, but has diagnostic limitations due to imperfect tests [1–3]. Donor-derived TB is a unique challenge in SOT patients, which requires a high index of suspicion. Treatment of TB after transplantation can be very difficult due to medication interactions, especially with immunosuppressive medications used to prevent rejection in SOT or treat graft-versus-host disease in HSCT [4–7].

Since few studies of latent or active TB treatment have been performed in transplant, clinicians have to rely on consensus guidelines based on expert opinion

[2, 8–16]. New diagnostics and guidance on therapeutic strategies are sorely needed in the area of TB in transplantation.

Disease Epidemiology

TB is caused by members of the *Mycobacterium tuberculosis* complex, most commonly *M. tuberculosis* (MTB), and it is estimated that about 1/3 of the world's population is infected [17]. The pathogen is ubiquitous, often remains latent in the human host, and is spread by airborne exposure [18]. The World Health Organization reported ten million incident cases of TB and 1.57 million TB deaths worldwide in 2017. TB is the leading cause of death from a single infectious agent [19].

In highly endemic areas, the prevalence of TB in transplant recipients is reported as high as 12%, with the prevalence in most developed countries between 1.2 and 6.4% [1, 20]. The highest incidence rates are reported in studies from Asia, with rates of 4 to nearly 30 times that of the general population [21–25]. This increased incidence is noted even when matched to similar non-transplant patients with end-stage organ failure [26]. Among organ transplant recipients, those who receive a lung transplant are at highest risk of TB [24]. While rates of TB in HSCT recipients are not as high as in SOT recipients, HSCT recipients who are from TB-endemic areas are at an increased risk of active disease [27–31]. Overall frequencies of active TB are reported as 2.3%, with the majority of HSCT cases in allogeneic transplant recipients [32].

A transplant recipient can develop active TB through the following mechanisms: [1] reactivation of latent or healed untreated primary TB, [2] undergoing transplant while already having unidentified active TB, [3] transmission of TB through the donated organ, or [4] new exposure to TB leading to primary infection after transplant [10]. Most cases are thought to occur through the first mechanism, endogenous reactivation of latent TB after transplant [25]. Unfortunately the TST reaction or IGRA results prior to transplant may not be a reliable predictor of reactivation post-transplant, likely due to anergy seen in end-stage organ failure [33, 34]. While donor-derived TB is rare (<5% of cases of post-transplant TB), it can cause severe illness or be fatal. TB transmission is reported most frequently through lung transplantation, but has also occurred via kidney, liver, and heart transplant [25, 35–37]. When there is exposure, primary TB infection can be acquired after transplant, and rare nosocomial transmission has been reported on a hospital transplant ward [38].

Risk factors for the acquisition of TB include disease incidence in one's country of birth or prior residence, close contact with persons with TB, medical risks such as diabetes mellitus, malnutrition, chronic kidney disease, and social risk factors such as cigarette smoking, homelessness, incarceration, or institutional residence. Specifically in the transplant setting, risk factors include a history of untreated TB, prior residence in TB-endemic areas, chest imaging with evidence of prior TB, and enhanced immunosuppressive treatment of allograft rejections, especially T-cell-depleting antibodies [10, 24, 39]. Risks specific to kidney transplant include hepatitis

C and duration of hemodialysis pre-transplant [40]. Recipients of lung transplants have the highest risk of active TB post-transplant compared to recipients of other organs. Increased age has been shown to be a risk factor in areas where rates of latent TB are higher in older cohorts [24]. In HSCT, presence of chronic graft-versus-host disease (GVHD) is a risk factor for the development of TB, likely related to the need for more intense immunosuppressive therapy [27, 31, 41].

Clinical Impact in Transplantation

Initial exposure to MTB can lead to primary disease, clearance of the organism, or latent infection with the possibility of reactivation disease many years later. Reactivation occurs in 5–10% of immunocompetent hosts but is much more common in immunocompromised patients [3, 42, 43]. The classic presenting symptoms of TB may be absent in transplant recipients. Fever was seen in 64% of patients with focal disease and 91% of those with disseminated infection in one study of transplant recipients [3]. Imaging findings can be quite varied, and pulmonary cavitary lesions may not be present [44, 45]. While pulmonary disease is still the most common manifestation, SOT patients have rates of extrapulmonary disease and disseminated disease of 30% and 16%, respectively [3, 25]. Similarly, in HSCT patients 34% of TB diagnoses are reported to be extrapulmonary and 23% disseminated [32]. Unusual manifestations of disease can be seen in immunosuppressed patients, including but not limited to cutaneous ulcers, musculoskeletal disease such as pyomyositis or tenosynovitis, and even gastrointestinal tract involvement. Allograft-specific infection can be seen, such as liver abscess in liver transplant or urinary tract involvement in kidney transplant [25].

Lung, heart, and liver transplant recipients have a median time to presentation of 6–11 months, which is shorter than kidney recipients. More than two-thirds of active TB cases in this group occur in the year following transplantation [3, 46]. In kidney transplant recipients, the median time to presentation is greater than 1 year post-transplant, thus requiring an ongoing high index of suspicion in this patient population [25]. As one would expect, donor-derived TB manifests earlier, at a median of less than 3 months [47]. A majority of TB cases seen after HSCT also occur within a year of transplant. In a review of HSCT cases from the last decade, the median time to clinical presentation was 4.6 months (range 3–12.9 months), and one third of cases presented within the first 100 days after HSCT [32].

TB mortality is increased post-transplant, most notably in patients with disseminated disease, prior graft rejection, or receipt of anti-T-cell antibodies [1, 3]. Prior estimates of crude mortality in post-transplant TB have been between 20 and 30% [3, 48], with an attributable mortality of 10% [24]. A recent comprehensive review of reported cases of TB after organ transplant calculated a 19% all-cause mortality and a 15% rate of allograft loss with TB therapy [25]. In HSCT patients, the mortality rate was reported as 28%, with a TB-attributable mortality of 8.5% [32].

Diagnostic Strategies and Screening

Because of the higher frequency of extrapulmonary or disseminated disease and the variability of symptoms and imaging findings, the diagnosis of active TB disease is frequently delayed after transplant unless a high index of suspicion is maintained. Hospitalized patients should be placed in airborne isolation, and three expectorated or induced sputum specimens should be obtained for smear and acid-fast stain, such as Ziehl-Neelsen, and cultured for acid-fast bacilli. If available, sputum should be tested by nucleic acid amplification techniques, such as Xpert MTB/RIF (Cepheid Inc.), an automated molecular test for MTB and resistance to rifampin (RIF). This can increase the sensitivity compared to microscopy alone and decrease the time to diagnosis since MTB can take 4–8 weeks to grow on solid culture media [17, 49]. Of note, a diagnostic invasive procedure is often required to make a diagnosis of TB. With pulmonary TB this may involve bronchoscopy with bronchoalveolar lavage or lung biopsy, or biopsy of skin lesions or lymph nodes, or sampling of abscess fluid in patients with deep collections. In addition to microbiologic exams for smear and culture, specimens should be sent for histopathological evaluation, looking for granulomatous inflammation [17]. Transplant candidates with suggestive symptoms such as fevers, cough, night sweats, and weight loss should be evaluated for active TB. If diagnosed, the candidate should be treated for active TB prior to proceeding with transplantation [11]. Ideally treatment should be completed prior to transplantation; however, this decision needs to be individualized based on the urgency of transplant and response to therapy. There are reports of successful liver transplantation in patients who developed liver failure due to TB medications requiring urgent transplant prior to completion of treatment [50].

Screening for latent TB infection is standard prior to transplant in order to determine the need for LTBI therapy. In patients without signs, symptoms, or chest imaging consistent with active TB, a diagnosis of latent TB is made by documenting a current or prior untreated positive TST or IGRA. IGRAs, including QuantiFERON-TB Gold and Gold Plus (QFT, QFT-Plus, Qiagen) and T-SPOT.TB (Oxford Immunotec Ltd), are currently used as alternatives to the TST in the general population [51]. Diagnostic tests such as the TST and IGRA do not distinguish latent TB infection from active disease, and both can yield falsely negative or indeterminate results in immunosuppressed patients [52]. Therefore, screening for LTBI should be done prior to administration of immunosuppression, and some patients with negative or indeterminate results may be considered for LTBI therapy. In fact, in HSCT patients, screening ideally should be done prior to the receipt of cytotoxic chemotherapy for their underlying malignancy. While TB screening prior to HSCT is not done routinely at most centers, in a review of HSCT patients who developed TB post-transplant, those screened with IGRA or TST pre-transplant had negative test results [32]. It should be noted that QFT and T-SPOT.TB tests are highly specific; therefore, a positive test should be considered evidence of MTB infection.

A thorough history is critical in all transplant candidates, to determine exposure to family members or close contacts with active TB, prior residence or extended travel to areas highly endemic for TB, and a history of prior TST or IGRA results. Any

history of treatment for active or latent TB should be documented, as well as details regarding the length and type of treatment. When a TST is used, it should be considered positive if there is ≥5 mm of induration at 48–72 h [17]. Based on a Spanish study of patients awaiting liver transplant which showed a 4% increase in positive TST when a two-step process is used, a second skin test 2 weeks after may be considered in patients with negative TST who may have had remote exposure to TB if feasible [41]. Many transplant programs prefer IGRA over TST because [1] TST requires 48–72 h follow-up for a read; [2] unlike the TST, results of the IGRA will not be falsely positive due to prior BCG vaccination; (3) IGRA testing appears to be more sensitive in transplant candidates with end-stage renal or liver disease; and [4] IGRA may have a slightly greater predictive value (albeit low) for reactivation of TB post-transplant [34, 53].

Routine screening with chest X-ray (CXR) should be done as part of the pre-transplant evaluation. Based on history, those with epidemiologic risk for latent or asymptomatic active TB should be considered for CT evaluation regardless of TST and IGRA results [39, 54]. A Korean study of patients who received liver transplants showed that CT scans with evidence of prior healed TB were more predictive of post-transplant TB than CXR [55]. Since none of the available screening tests are completely accurate in diagnosing latent or active MTB infection, the decision to treat should be individualized based on the clinical likelihood of infection. Patients with recent conversion of TST or IGRA should be treated for latent TB as promptly as possible. A current negative screening test, especially in patients with organ failure awaiting transplantation or those who have received cytotoxic chemotherapy, does not negate a prior positive test result. Individuals having a documented or reliable prior history of appropriately treated active TB disease or treated LTBI need not undergo further testing with TST or IGRA. However, these individuals should be screened for active TB.

Living organ donors should undergo an evaluation similar to that described for transplant candidates [37]. For living donors, the TST should be interpreted as positive or negative according to CDC guidelines for the general population, or an IGRA should be performed. If either is positive, and symptoms or chest imaging is indicative of TB, active disease should be ruled out. Treatment of LTBI should be considered prior to organ donation if feasible, especially with recent TST or IGRA conversion [10]. With deceased donors, a history of prior TB exposure, active disease, and treatment should be obtained from the family as TST and IGRA are not feasible in deceased donors. Treatment of the recipient for latent TB should be considered, as should recipient monitoring for development of active TB with early diagnosis and treatment as appropriate [37]. If active TB disease is present in either living or deceased donors, organs should not be used due to the high risk of transmission to the recipient. In the rare cases where active TB in the donor is diagnosed post-mortem and transplant has already occurred, treatment of active TB in the recipient should be initiated [37, 56]. Since TB has not been reported to be transmitted by HSCT, guidelines do not recommend routine screening in HSCT donors; however, screening is recommended in recipients who are at high risk of TB exposure [57].

There are many shortcomings of available diagnostics, namely, false-negative or indeterminate TST or IGRA, low predictive value to identify those with latent TB who will develop active TB, inability to distinguish latent from active TB, and lack of quantification of response to therapy. Therefore emerging diagnostics for TB are being developed. Some experts argue that these diagnostics need to be region-specific due to the variability of drug susceptibility patterns of MTB around the world [58]. Urine and serum tests detecting TB biomarkers such as lipoarabinomannan (LAM) and early secretory antigenic target 6 (ESAT6) are being developed for ease of point-of-care testing [59]; cell-free MTB DNA from both urine and blood look promising for diagnosis of active TB [60]. Recently, a novel 3-gene signature of host responses to TB that can be measured in blood has been shown to predict progression of LTBI to active TB up to 6 months prior to sputum conversion. This new assay can detect active TB with high sensitivity and specificity and identify treatment failure [61, 62]. These promising new diagnostics need to be studied in transplant candidates and recipients.

Treatment of Active TB

Standard drug treatment for active TB disease can be found in published guidelines on treatment of TB [8, 11]. While treatment success is achievable, the transplant clinician must plan for drug-drug interactions, additive toxicities to other transplant medications, and the need for dose adjustment with renal dysfunction.

In general, intensive phase treatment with a standard four-drug regimen is recommended for drug-sensitive TB including isoniazid, a rifamycin (rifampin or rifabutin), pyrazinamide, and ethambutol for the first 2 months. Once the susceptibility to isoniazid, rifampin, and pyrazinamide is confirmed, ethambutol can be stopped. This is followed by a continuation phase of isoniazid and the rifamycin for a minimum of 4 additional months [8]. There are some caveats to keep in mind when treating immunosuppressed transplant patients. Due to the risk of progression or dissemination, when the likelihood of TB is high, one may consider starting empiric therapy for active TB while awaiting diagnostic results, given the slow growth of MTB in cultures. Importantly, daily dosing of active TB therapy is recommended since twice- or thrice-weekly administration of TB therapy can increase the risk of relapse [63]. Pyridoxine should be administered daily as comorbid conditions may increase the risk of isoniazid-related neurotoxicity in transplant patients [8]. Transplant patients on treatment should be monitored carefully at least monthly for side effects and laboratory testing. Directly observed therapy (DOT) programs have been shown to improve adherence and outcomes in TB patients and are recommended for transplant recipients. Whenever possible, the involvement of a TB expert is recommended in managing the treatment of active disease, especially in post-transplant patients. Such expertise is essential in caring for patients whose TB is complicated by drug resistance or drug intolerance.

The potential for hepatotoxicity and major drug-drug interactions involving rifampin and immunosuppressive medications are major challenges in treating TB

in transplant recipients. However, rifamycins have potent MTB sterilizing activity, and their use is recommended if possible [17]. Rifampin is a potent inducer of the microsomal enzymes (P450-3A4) that metabolize immunosuppressive agents such as calcineurin inhibitors and mTOR inhibitors, used in both SOT and HSCT. Rifampin may also interfere with corticosteroid metabolism. Allograft rejection occurring in conjunction with rifampin use has been reported due to inadequate levels of immunosuppression resulting from drug-drug interactions with rifampin [25]. Doses of cyclosporine, tacrolimus, and sirolimus need to be increased at least two- to fivefold and therapeutic drug levels followed carefully during concomitant rifampin use in transplant patients [25]. It is possible to replace rifampin with rifabutin given its similar activity against MTB. Since it is a less potent inducer of cytochrome P450-3A4 enzymes, calcineurin inhibitor and mTOR inhibitor levels are somewhat easier to maintain with careful monitoring and dose adjustment [64]. While published clinical reports using rifabutin for TB after transplant are limited [65], clinical experience in patients with HIV infection and TB has shown equal efficacy between regimens containing rifabutin and those contacting rifampin [17, 66, 67]. It should be noted that with the use of either rifamycin, therapeutic drug monitoring (TDM) of immunosuppressants should be used, with appropriate dose adjustment at both the start and end of rifamycin therapy. There are reports of successful use of a non-rifamycin-based regimen for management of post-transplant TB, especially where rifabutin is not available [25, 68, 69].

In many SOT and HSCT recipients, the use of mold-active azoles are quite common, which also poses a challenge due to drug-drug interactions with rifamycins. Rifamycins reduce the serum levels of mold-active azoles; careful TDM is required for achieving therapeutic levels of voriconazole or posaconazole. Isavuconazole may need to be avoided due to lack of widely available TDM. One should note that rifabutin levels increase with the use of mold-active azoles, due to the bidirectional interactions which can pose an additional challenge [70].

Fluoroquinolones including moxifloxacin and levofloxacin have potent activity against MTB in vitro and are currently listed as second-line agents for active TB treatment [8]. These medications may be used in transplant patients with poor liver function and with those who develop hepatotoxicity on standard TB therapy [8]. Although systematic studies of second-line TB therapy in transplant recipients are not available, published case reports indicate that capreomycin, cycloserine, and moxifloxacin have been successfully used [71–73]. Recently, a WHO workshop examined the evidence for dosing of second-line agents for TB. Where there were gaps in knowledge, analyses using pharmacokinetics, pharmacodynamics, and computational and artificial intelligence algorithms were used to generate data to provide guidance on drug combinations and effective dosing [74].

When planning medical therapy for the treatment of active TB, a careful review of all drug-drug interactions is recommended. The hepatotoxicity of isoniazid, rifampin, and pyrazinamide used in combination is greater than isoniazid alone and noted to be particularly severe in liver recipients [75]. A recent review noted overall hepatotoxicity with TB therapy of 20% across all organs and 27.5% in liver transplant recipients [25]. For this reason, liver function tests should be closely

monitored in all transplant recipients during treatment of TB. If pyrazinamide is omitted due to severe baseline liver disease, treatment should be extended to 9 months; if both isoniazid and pyrazinamide are avoided, one could use rifampin, ethambutol, and levofloxacin or moxifloxacin with the regimen extended to 12 months [8]. Of note, among first-line drugs, ethambutol and pyrazinamide require dose adjustment with renal insufficiency, and aminoglycosides used as second-line drugs can cause renal dysfunction.

The recommended duration of treatment for transplant patients is similar to other patients, although longer durations should always be considered if the response to treatment is slow. Extended treatment durations are strongly recommended if second-line drugs are used or if resistance to rifampin and other drugs is documented. Uncomplicated pulmonary TB with sputum clearance before the completion of 2 months of treatment can complete therapy at 6 months; however, bone and joint disease (6–9 months), central nervous system disease (9–12 months), and severe disseminated disease (6–9 months) are treated longer. In cases of cavitary pulmonary TB with persistent TB culture-positive sputum at 2 months, 9 months of treatment is recommended. [17]. Treatment durations of TB after SOT reported in the literature range between 7.3 and 18 months [25]. Fortunately, to date multidrug- and extremely drug-resistant TB remains rare in the transplant population [25]. Recommended durations for treatment of MDR and XDR TB are 20 months long; shorter durations of 10 months have recently been shown to be non-inferior, but have not been studied in transplant recipients [76].

Prevention/Treatment of Latent TB

Identifying and treating latent TB in the setting of transplantation is an important public health measure to reduce the incidence of TB reactivation in transplant recipients. Active TB in the post-transplant setting is difficult to diagnose and treat, can be transmitted to other immunosuppressed contacts, and contributes to morbidity and mortality after transplant [48, 77–79]. In highly endemic areas where TB transmission occurs in the community, universal isoniazid prophylaxis for the first year post-SOT has been studied to prevent TB acquisition during the period of maximum immunosuppression [14]. Please refer to Table 1 for treatment options for latent TB which currently have the greatest amount of data supporting their use;

Table 1 Regimens used for treatment of LTBI [92, 95, 96]

First-line regimens:	**Alternative regimens with disadvantages relative to first-line regimens:**
9H (INH x 9 months) [95]	6H (INH x 6 months) [95]
4R (RIF x 4 months) [95]	RFB x 4 months [95]
3HP (weekly INH/RPT x 12 doses) [95]	3HR (INH/RIF x 3 months) [92, 96]
	4HR (INH/RIF x 4 months) [96]

INH isoniazid, *RIF* rifampin, *RPT* rifapentine, *RFB* rifabutin

however, there is still a paucity of information regarding use in transplant candidates [78, 80–82].

The mainstay of LTBI treatment is isoniazid, with data showing a low risk of isoniazid-related hepatotoxicity in renal transplant recipients without serious underlying liver disease [83] and in patients with compensated liver disease awaiting liver transplantation [84, 85]. Isoniazid preventive treatment for 9 months confers additional benefit over 6 months [78]. Pyridoxine (vitamin B6) 25–50 mg daily should be administered with isoniazid to decrease the risk of neurotoxicity. A 4-month course of rifampin monotherapy can be used for the treatment of latent TB [86, 87] and may be preferred in patients with some underlying liver disease who can complete therapy prior to transplantation. It is limited by drug-drug interactions that preclude continuation of treatment post-transplant for LTBI therapy. A fairly new regimen for treatment of LTBI is a 12-week course of isoniazid and rifapentine [88]. It has been used successfully in renal transplant candidates, with close monitoring of blood pressure due to drug interactions with antihypertensives [89]. Use of this regimen after transplantation is still limited by severe drug interactions between rifamycins and immunosuppressive agents. A clinical trial of levofloxacin for LTBI therapy in transplant candidates was stopped due to development of tenosynovitis; therefore, quinolones are not recommended as first-line therapy [15]. Recently, a 1-month regimen of isoniazid and rifapentine was studied in patients with HIV infection in a TB-endemic region [90]. This has yet to be studied in transplant candidates. Finally, if no treatment is possible, then careful clinical follow-up with prompt diagnostic attention to protracted fever or pulmonary symptoms may be the best course.

The timing of LTBI therapy must be individualized based on the urgency and anticipated timing of transplant and risk of progression to active TB. LTBI treatment should be considered more urgently in those with recent exposure to TB and conversion of the TST or IGRA within the previous year. Since those on hemodialysis are at increased risk for active TB and renal transplant candidates awaiting deceased donor transplants often have long waiting times, they should generally be treated prior to transplant [91]. In patients with chronic lung disease awaiting lung transplantation, it is often preferable to begin treatment prior to transplant once active disease is ruled out [92]. While LTBI treatment is safe in many liver transplant candidates with compensated cirrhosis [84, 85], in those with decompensated liver disease, it may be preferable to delay the administration of isoniazid until after transplantation, when liver function is improved [93]. It should be noted that liver transplant recipients treated with isoniazid who present with elevated serum transaminase levels should be evaluated for a specific diagnosis with liver biopsy, if necessary, without automatically ascribing the effect to isoniazid. HSCT recipients could be started or resumed on LTBI therapy after resolution of mucositis.

Regular clinical and laboratory monitoring of transplant candidates and recipients being treated for LTBI is extremely important. When isoniazid treatment is initiated, it is suggested to obtain at least a blood test for ALT at 2-week intervals for 6 weeks, followed by monthly testing. If transaminases are elevated to 1.5–3 times normal, isoniazid does not require immediate discontinuation, but needs ongoing frequent

laboratory monitoring. If transaminases are increased threefold with signs and symptoms of hepatotoxicity, or there is an asymptomatic fivefold elevation, LTBI treatment should be discontinued [78, 80]. Organ transplantation does not need to be delayed until completion of LTBI therapy. Latent TB treatment with isoniazid can be resumed after transplant once medically possible and the course of therapy can be completed.

Conclusion

Development of diagnostic tests for LTBI that do not rely on an intact T-cell response in the face of organ failure and immunosuppression would greatly improve diagnosis and clinical management, especially in the case of donor-derived infections. Hence, development of new diagnostics based on TB biomarkers, cell-free DNA, and host response gene signatures are very promising. Another important advance would be the development and/or clinical validation of antituberculous drugs that are free of significant organ toxicities and drug-drug interactions. New treatment regimens are on the horizon, including potent drugs that may have the potential to shorten and simplify anti-TB therapy [4]. Evaluation of these in transplant candidates and recipients may provide useful treatment alternatives for this population in the future. Lastly, new TB vaccines are being studied with some promising results, which may eventually lead to more effective prevention strategies [94].

Introduction

Nontuberculous mycobacteria (NTM) are widespread in the environment, especially in water-associated biofilms [1]. Rapidly growing mycobacteria (RGM) are a subset of NTM species capable of growing in the laboratory within 7 days. For discussion of other mycobacteria, refer to ▶ Chaps. 18, "*Mycobacterium tuberculosis* in Transplantation," and ▶ 20, "Slow-Growing Nontuberculous Mycobacteria in Transplant." While overall rare, prevalence of RGM infections has increased in recent years both in the United States and throughout the world [2–4]. Immunosuppression and high rates of airway colonization among patients with underlying structural lung disease increase risk of RGM infection among transplant recipients [5, 6]. Transplant patients commonly acquire RGM from the community; however, several recent healthcare facility-associated RGM outbreaks highlight increasing potential for transmission within the modern healthcare system [7–9]. Outbreaks have generated important questions regarding the need for healthcare facility surveillance and infection prevention measures to decrease risk of RGM transmission, particularly for high-risk transplant recipients. Outbreaks have also helped us to better understand diagnosis and management strategies in the immunosuppressed host.

RGM infections classically cause pulmonary disease in patients with abnormal lung architecture, as well as postoperative skin and soft tissue infections [10]. Diagnosis of RGM infection is often challenging, especially in transplant recipients, due to highly variable and indolent clinical presentations. Accurate species identification and susceptibility testing of RGM requires special expertise but provides important data to guide therapy and should be pursued where laboratory capability exists. Treatment is complex, typically requiring months of prolonged combination antimicrobial therapy. Adjunctive surgical management plays an important role in cases of soft tissue disease, osteomyelitis, and involvement of prosthetic material or, at times, for localized pulmonary disease. Clinical outcomes are often poor and can be complicated by antibiotic resistance and toxicities, drug interactions, treatment failure, relapse of infection, and need for long-term step-down or suppressive therapy. A few novel antibiotics with activity against RGM have shown promise *in vitro* or in small clinical studies; however, additional clinical data and treatment options are needed for transplant recipients with RGM infections. We will discuss many of these options in this chapter, highlighting available data and limitations.

Disease Epidemiology

RGM (recognized in some classifications as Runyon group IV) consist of more than 75 described species, classified within 6 major groups: *M. fortuitum, M. chelonae/M. abscessus*, *M. smegmatis, M. mucogenicum*, *M. mageritense/wolinskyi*, and the pigmented species [1, 11]. *M. abscessus* contains three related subspecies: subspecies *abscessus* (formerly *M. abscessus*), *massiliense*, and *bolletii* [1]. RGM are widely distributed in the environment, especially water and soil, are adept at forming

biofilms, and are highly resistant to many common disinfectants and antibiotics [1]. While case reports implicate species from each of the six major RGM groups as potential pathogens, the majority of RGM infections are caused by *M. abscessus*, *M. chelonae*, and *M. fortuitum*. See Table 1 for a detailed listing of recognized clinical syndromes.

RGM cause a wide range of infections, including pulmonary and extrapulmonary infections. Common extrapulmonary infections include skin and soft tissue infection, surgical site infections, osteomyelitis, and disseminated disease, including mycobacteremia. In addition, RGM adhere to foreign material and can cause infections involving prosthetic material, such as central line-associated bloodstream infections (CLABSI) [45], peritoneal dialysis catheter infections [55], and infections of cardiac devices, including ventricular assist devices and other implantable electronic devices [56, 57].

Infections caused by RGM occur worldwide. Variable definitions of incidence or prevalence hinder direct comparisons across regions; however, one of the more widely-available measures is the proportion of RGM among NTM pulmonary isolates, which ranges from 4% to 28% in South America, 6% to 62% in Europe, 9% to 59% in the Middle East, 20% to 60% in Asia, 5% to 10% in Australia, and 5% to 21% in North America [58]. Within the United States, prevalence of *M. abscessus* and *M. chelonae* is highest in the West and South [59]. Several recent studies have suggested that the prevalence of disease caused by RGM is increasing [3, 4]. For example, a US single-site longitudinal survey reported a threefold increase in cutaneous NTM infections from 2000 to 2009, with *M. abscessus* and *M. chelonae* comprising nearly 32% of isolates. Approximately 10% of patients analyzed in this study were solid organ transplant (SOT) recipients.

Defining the true prevalence of RGM infection among transplant patients is challenging, in part because NTM frequently colonize the respiratory tract in the absence of invasive pulmonary infection. However, mycobacteria found in other tissues constitute invasive infection. Epidemiologic studies have been limited by small cohort sizes and inconsistent definitions of disease, stratification of NTM rates by species, and rate calculations. Among transplant recipients, lung and heart transplant patients have the highest rates of NTM infection [60]. Two recent cohort studies of lung transplant recipients reported prevalence rates for RGM pulmonary disease of 1–2%, with a median time to diagnosis between 2 and 3 years post-transplant [5, 12]. Both cohorts found that greater than 80% of NTM pulmonary isolates obtained from lung transplant recipients represented transient colonization and did not require antimicrobial therapy. When invasive infection does occur in lung transplant recipients, pleuropulmonary disease from *M. abscessus* is most common [6, 33, 61]. Prevalence rates of NTM infection reported for heart transplant recipients range from 0.2% to 3%; extrapulmonary infection, including disseminated disease, is more common than isolated pulmonary infection [60, 62].

Compared to lung or heart transplant recipients, the risk of RGM infection is lower for other SOT and hematopoietic cell transplantation (HCT) recipients. Prevalence rates of NTM infection, including both rapidly and slow-growing NTM, have been reported at $<0.1\%$ in liver transplant recipients, $<0.2\%$ in renal transplant

Table 1 Types of rapidly growing mycobacteria and associated clinical syndromes

Group	Species	Pathogenicity	Types of infections
M. chelonae/abscessus	*M. abscessus* subsp. *abscessus*	Commonly reported [7, 12–19]	Pulmonary, lymphadenitis, soft tissue/bone, disseminated
	M. abscessus subsp. *bolletii*	Commonly reported [20]	Pulmonary
	M. abscessus subsp. *massiliense*	Commonly reported [21–26]	Pulmonary, disseminated
	M. chelonae	Commonly reported [12, 27–30]	Pulmonary, lymphadenitis, soft tissue/bone, disseminated
	M. immunogenum	Sporadically reported [31]	Disseminated, pseudo-outbreaks
	M. franklinii	Rarely reported [32]	Sinopulmonary disease
M. fortuitum	*M. fortuitum*	Commonly reported [33–35]	Pulmonary, soft tissue/bone, disseminated, CLABSI
	M. peregrinum	Rarely reported [36]	Pulmonary
	M. senegalense	Rarely reported [37]	CLABSI
	M. porcinum	Rarely reported [38]	Pulmonary
	M. boenickei	Rarely reported [39]	Soft tissue/bone
	M. houstonense	Rarely reported [39]	Soft tissue/bone
	M. brisbanense	Rarely reported [40]	Pulmonary
	M. septicum	Rarely reported [39]	CLABSI
	M. setense	Rarely reported [41]	Soft tissue/bone
M. smegmatis	*M. smegmatis*	Rarely reported [42]	Soft tissue/bone
	M. goodii	Rarely reported [43, 44]	Device infections
M. mucogenicum	*M. mucogenicum*	Sporadically reported [34, 45, 46]	Disseminated, CLABSI
	M. phocaicum	Rarely reported [47]	CLABSI
M. mageritense/wolinskyi	*M. mageritense*	Sporadically reported [48–50]	Skin/soft tissue, CLABSI, prosthetic valve infections
	M. wolinskyi	Rarely reported [51]	Surgical site infections, device infections
Pigmented group	*M. canariasense*	Rarely reported [45]	CLABSI
	M. cosmeticum	Rarely reported [52]	Prosthetic joint infections
	M. monacense	Rarely reported [53]	Soft tissue
	M. bacteremicum	Rarely reported [54]	CLABSI
	M. neoaurum	Rarely reported [34]	CLABSI

CLABSI central line-associated bloodstream infection, *subsp.* subspecies

patients, and <0.5% in HCT patients [5, 60]. Risk of specific clinical syndromes also varies depending on transplant type. For example, RGM infection among HCT recipients commonly manifests as CLABSI (16,18).

Community acquisition of RGM occurs via a variety of mechanisms (Table 2). The municipal water supply is a well-known reservoir of NTM, and molecular epidemiologic studies have isolated the same genotype of RGM from patients with respiratory disease and their residential water outlets [63]. Notably, NTM are relatively chlorine tolerant, and many commonly used water treatment strategies do not prevent NTM colonization of water distribution systems [67]. Cutaneous RGM infections have been linked to a range of other exposures, including acupuncture, pedicures, tattooing, and cosmetic procedures [64, 65, 68, 69].

Hospital acquisition of RGM occurs most commonly when vulnerable patients are exposed to hospital water sources or equipment colonized with NTM (Table 2) [70, 71]. For example, investigators traced one US RGM outbreak occurring among pediatric HCT recipients to colonized ice machines, sinks, and showers [8, 9]. Similarly, a cluster of RGM CLABSIs among adult HCT patients receiving care at a hematology-oncology ward in Japan was linked to a hospital water supply colonized with RGM [45]. Multiple RGM outbreaks of surgical site infections have also been linked to contaminated hospital water sources, but some investigations have been unable to elucidate mechanisms of patient acquisition. A recent cluster of wound infections that occurred in patients who returned to the United States after undergoing cosmetic procedures in the Dominican Republic highlights the risk of postoperative infection and challenges of RGM outbreak investigations [72].

A recent, large, single-hospital outbreak of *M. abscessus* occurred in two distinct phases and affected numerous transplant recipients [7]. The first phase predominantly affected lung transplant patients with respiratory colonization or infection. Molecular fingerprinting confirmed that clinical *M. abscessus* isolates matched environmental isolates taken from biofilms of hospital water sources, including ice machines, water faucets, and showerheads. Use of sterile water, rather than tap water, for patient care tasks potentially associated with aerodigestive water exposure mitigated this phase of the outbreak. The second phase of the outbreak affected cardiac surgery patients, including heart transplant recipients, who developed mediastinal or bloodstream infections from *M. abscessus* after undergoing cardiopulmonary bypass. Infections were suspected to be caused by aerosolization of *M. abscessus* in the operating room from heater-cooler units (HCUs) that were filled with water taken from the colonized plumbing system. This phase of the outbreak resolved after institution of several interventions, including an enhanced disinfection protocol for HCUs and use of sterile water in these devices. Although risk of infection after cardiac surgery related to HCU colonization has been more widely reported for the slow-growing *M. chimaera* [73], *M. abscessus* outbreaks in cardiac surgery patients have demonstrated that RGM can be transmitted by the same mechanism.

Acquisition of RGM has historically been thought to occur via independent transmission events from the environment to patients; however, some recent studies have postulated indirect patient-to-patient transmission of *M. abscessus* [66]. In one large study, global whole genome sequencing (WGS) of *M. abscessus* isolates showed that a

Table 2 Summary of selected community and healthcare facility surveys and outbreak investigations involving rapidly growing mycobacteria

Setting	RGM sources	Study design	Methods/ description	Conclusions
Community	Municipal drinking water	Environmental survey [63]	Survey of *M. abscessus* isolates ($n = 74$) from potable water sources and human clinical isolates; all strains genotyped by rep-PCR	*M. abscessus* drinking water isolates were genetically similar to clinical isolates
	Tattoo ink	Outbreak investigation [64]	Analysis of a cluster of *M. chelonae* infections ($n = 19$) among tattoo recipients; clinical and tattoo ink isolates were compared by PFGE and genomic sequencing	Clinical isolates were identical to *M. chelonae* isolates obtained from premixed tattoo ink, confirming the ink as the outbreak source
	Pedicure baths	Post-outbreak systematic surveillance [65]	Surveillance conducted among pedicure salon clients following a series of cases of pedicure-associated RGM furunculosis ($n = 40$ cases); included comparison of clinical and salon environmental samples	Clinical outbreak consisted of predominantly *M. chelonae/ abscessus*, while multiple different RGM were recovered from salon pedicure baths Presence of biofilms and inadequate cleaning were strongly associated with infection risk
Healthcare-associated	(1) Ice machines (2) Water	Outbreak investigation followed by process improvement intervention [8, 9]	Outbreak investigation of RGM infections among pediatric hematopoietic	RGM isolates were traced to ice and water sources on hospital wards Use of bottled water for consumption and

			patients in Japan (n = 5); 16S sequencing used to match strains with environmental isolates	Isolates from tap water sources were matched to clinical isolates by 16S sequencing
	(1) Fomites (2) Aerosols (3) Clinic environment	Multicenter cluster analysis using whole genome sequencing [66]	Multicenter network study of clinical isolates from cystic fibrosis patients coupled with patient-level metadata	Genotyping demonstrated a wide circulation of a limited number of *M. abscessus* clones Embedded proof of concept studies suggested that fomites, aerosols, and clinic environment contamination may have contributed to transmission
	Clinic environment	Outbreak investigation [21]	Molecular epidemiologic investigation of *M. abscessus* subspecies *massiliense* outbreak at a lung transplant/ cystic fibrosis center (n = 5); strains genotyped by rep-PCR and PFGE	All clinical isolates were identical by rep-PCR and PFGE Sole source of shared contact appeared to be an outpatient pulmonary clinic, suggesting indirect transmission via environmental contamination

PFGE pulsed-field gel electrophoresis, *rep-PCR* repetitive element palindromic polymerase chain reaction, *RGM* rapidly growing mycobacteria

large proportion of patients with cystic fibrosis in the United States, Europe, and Australia shared a small number of very closely related *M. abscessus* strains. The authors concluded that widespread transmission of common *M. abscessus* clones may have occurred via fomites, surface contamination of the clinical environments, and generation of aerosols by cystic fibrosis patients. A smaller clonal outbreak of *M. abscessus* subspecies *massiliense* among five cystic fibrosis patients at a single

center similarly implicated contamination of the clinic environment as the most likely mechanism of transmission [21]. Due to concerns over possible healthcare-associated transmission of pulmonary *M. abscessus*, some centers segregate infected patients in single-use outpatient rooms and utilize negative pressure rooms for inpatient care [74]. However, other recent studies analyzing WGS of *M. abscessus* isolates concluded that patient-to-patient transmission of *M. abscessus* is quite uncommon [75, 76]. Hospitals and clinics do not commonly employ specialized infection control practices designed to decrease RGM transmission, and the benefit of such practices has not been proven.

Diagnosis

Diagnostic Challenges

Several factors make diagnosis of RGM infections difficult. First, infections are often indolent, have variable clinical presentations, and can involve a wide range of body sites [1]. Clinical manifestations include pulmonary disease, skin and soft tissue infection, lymphadenitis, osteomyelitis, tenosynovitis, catheter-associated infection, and disseminated disease [77]. Pulmonary disease commonly presents with chronic cough and dyspnea, often accompanied by nodular opacities, bronchiectasis, or cavities on chest imaging. Manifestations of skin and soft tissue RGM infections are particularly diverse and can include cellulitis, delayed surgical site infections, nonhealing ulcers, nodular lesions, lymphadenitis, folliculitis, or furuncles [78]. Particularly for immunosuppressed patients, presenting symptoms and exam findings are often insidious, appearing to represent superficial or limited infection despite the presence of invasive or disseminated disease (Fig. 1).

A second factor complicating RGM diagnosis is the difficulty in differentiating airway colonization from invasive pulmonary infection. The American Thoracic Society (ATS) criteria for NTM lung disease [10] require both clinical and microbiologic evidence of infection. Clinical criteria require that other diagnoses have been appropriately excluded and that patients have pulmonary symptoms, nodular or cavitary opacities on chest radiography, or bronchiectasis and multiple small nodules on high-resolution computed tomography imaging. Microbiologic criteria include either positive sputum cultures from two or more samples, positive culture from at least one bronchoalveolar lavage (BAL), or positive culture from a lung biopsy with consistent histopathologic features (e.g., granulomatous inflammation or acid fast bacilli [AFB] present on tissue stains). These criteria are difficult to apply to transplant recipients, especially lung transplant recipients who have high baseline prevalence of unrelated respiratory symptoms and abnormal lung imaging. Therefore, in addition to considering ATS criteria, we review a number of additional clinical factors to help differentiate NTM colonization from lung disease in transplant recipients, including the number of positive BAL specimens, smear positivity, and degree of immunosuppression.

Third, isolation of RGM in culture typically requires AFB-specific media, designed to inhibit the growth of more common bacteria, as well as prolonged

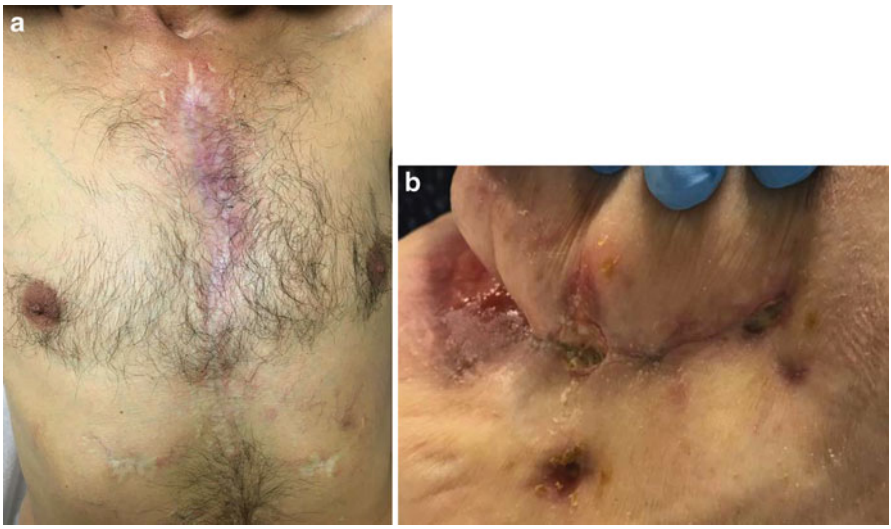

Fig. 1 Appearance of *M. abscessus* surgical wound infections. (**a**) Sternal wound infection following orthotopic heart transplantation. (**b**) Surgical wound infection of clamshell incision following lung transplantation. (Images courtesy of Eileen K. Maziarz, MD, Duke University School of Medicine, Division of Infectious Diseases)

incubation. Even AFB-specific cultures of fluid and tissue samples have limited sensitivity, however, and obtaining samples for histopathology evaluation can be required for diagnosis and should be encouraged [1, 10]. Histopathologic evaluation of NTM infection often reveals granulomatous inflammation. While organism burden may be low, AFB staining can help to confirm the presence of bacilli within tissue samples. Therefore, clinical suspicion of possible NTM infection is needed to ensure appropriate collection and processing of clinical samples for both microbiologic and histopathologic evaluation.

Species Identification

Despite the imperfect sensitivity of culture, isolation of RGM remains critical for species-level identification and subsequent susceptibility testing. In cases of mycobacteremia, RGM tend to grow well with most current blood culture systems; however, the prolonged incubation period used for mycobacterial isolator tubes may still provide increased sensitivity [79]. For specimens that may contain other contaminating organisms (e.g., respiratory samples), processing within one hour is ideal; refrigeration can be used if sample processing is delayed [10]. BAL has higher sensitivity and specificity than sputum samples. For fluid or tissue specimens, either surgical collection or sterile aspiration is preferred over swabs [10]. Culture is often performed on both solid media (either Lowenstein-Jensen or Middlebrook 7H10/11) and broth (usually a modified Middlebrook 7H9 broth) if sufficient specimen is available [10].

RGM species identification traditionally relied on the evaluation of growth rate, colony morphology, pigmentation, and biochemical testing [1]. However, traditional methods fail to separate several RGM beyond the group level (e.g., *M. chelonae/abscessus* group). Due to the difficulty in distinguishing RGM, many clinical laboratories do not identify RGM to the species level. Because antimicrobial susceptibility patterns vary even among closely related species, clinicians or laboratory staff may need to engage reference laboratories to ensure accurate and timely identification. For example, the activity of macrolide antibiotics (azithromycin or clarithromycin) as well as certain aminoglycosides (amikacin and tobramycin) can often be predicted from a more detailed understanding of the species.

Many different biochemical or molecular methods have been developed to promote rapid and accurate species-level identification of RGM. Most methods have had limited clinical utility due to extensive similarities between closely related RGM and lack of widespread availability of specialized testing. High-performance liquid chromatography (HPLC), for example, has been used to analyze mycolic acid signatures but is only capable of accurately identifying a few species [80]. A variety of molecular methods have been developed in reference labs, including restriction fragment length polymorphism (RFLP) analysis of select genes, such as *hsp65* or *rpoB*; however, these tests are not commercially available or approved by the US Food and Drug Administration (FDA). 16S rRNA sequencing has also been used but has limitations. For example, commercial sequencing often analyzes only the first 500 base pairs, which is insufficient to distinguish between closely related RGM, and many commercial databases have limited representation of NTM [1]. Furthermore, the *M. abscessus* subspecies are identical throughout the entire 16S rRNA sequence and cannot be identified to the subspecies level by 16S rRNA sequencing alone.

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) may expedite presumptive identification of some RGM. A recent study found that MALDI-TOF could typically identify the *M. fortuitum* group and distinguish between *M. abscessus* and *M. chelonae*; however, in this analysis, MALDI-TOF could not discriminate species within the *M. fortuitum* group, nor could it fully resolve the *M. abscessus* subspecies [81–83]. Whole genome sequencing shows increasing promise for the future, offering maximal discriminatory capacity both for subspecies identification and delineation of outbreaks, but currently remains under development and is limited to reference laboratories.

Management

Treatment of RGM *infections* requires prolonged therapy with multiple antibiotics. Choice of regimen depends on species identification, antimicrobial susceptibilities, site of infection, and patient tolerance of antibiotics associated with multiple potential toxicities.

Table 3 Antimicrobial susceptibilities for commonly isolated rapidly growing mycobacteria[a]

Antimicrobial	*M. abscessus* complex (%)	*M. chelonae* (%)	*M. fortuitum* (%)
Amikacin	90–94	50–80	100
Cefoxitin	70–83	0	50–80
Ciprofloxacin[b]	0–5	20	96–100
Clarithromycin	20–100[c]	100	50–80[c]
Doxycycline	1–5	20–25	40–50
Imipenem	50–60[d]	50–60[d]	100
Linezolid	23–50	54–90	60–90
Trimethoprim-sulfamethoxazole	–	–	100
Tobramycin	–	83–100	–
Tigecycline[e]	99	92–100	100

References: [10, 85–87]

[a]Percentages represent the proportion of isolates with minimum inhibitory concentrations (MICs) in the intermediate to susceptible range

[b]Moxifloxacin and levofloxacin susceptibilities may differ from ciprofloxacin susceptibility for some RGM isolates; susceptibility testing for multiple fluoroquinolones may be considered [88]

[c]*erm*-mediated, inducible macrolide resistance can occur in *M. abscessus* subspecies *abscessus*, *M. abscessus* subspecies *bolletii*, and *M. fortuitum*. Extended incubation or direct assessment for the *erm* gene is needed to ensure accurate results for macrolide susceptibilities. In contrast, *erm*-mediated inducible resistance is not seen with *M. abscessus* subspecies *massiliense*

[d]Imipenem susceptibility testing is problematic in *M. abscessus* and *M. chelonae* due to lack of reproducibility

[e]MIC <1.0 mcg/mL is used as a proxy for tigecycline susceptibility. No widely-accepted interpretable criteria for susceptibility exist

Susceptibility testing often guides therapy, but for most antibiotics with activity against the RGM, there is limited clinical evidence linking *in vitro* susceptibilities to treatment success [84]. Broth micro-dilution remains the gold standard method for antimicrobial susceptibility testing. Presence of multiple organisms on culture, poor isolate growth, strict time windows for accurate minimum inhibitory concentration (MIC) interpretation, and interlaboratory inconsistencies complicate resistance testing [85]. E-tests in particular have shown poor interlaboratory agreement and are discouraged [86]. Due to these complexities, only experienced laboratory personnel should perform RGM antimicrobial susceptibility testing. Susceptibility data are commonly reported for *M. abscessus*, *M. chelonae*, and *M. fortuitum* (Table 3); among less frequently encountered species, data are sparse and less reliable [84].

The following subsections outline the important role of macrolide antibiotics in treating RGM and then address species-specific antibiotic options, including treatment considerations for pulmonary and extrapulmonary disease (Table 4). We also discuss unique challenges encountered in treating RGM infections in transplant recipients, including the often-difficult decision regarding which patients to treat with antibiotic therapy (see section "Management Considerations Unique to Transplant Recipients"). There is a distinct lack of randomized controlled trial data to guide treatment of RGM

Table 4 Antibiotics commonly used to treat rapidly growing mycobacterial infections

Pathogen	Commonly used antibiotics by route
M. abscessus complex	IV: Amikacin Cefoxitin or imipenem Tigecycline PO: Azithromycin/clarithromycin[a] Tedizolid Linezolid Clofazimine Bedaquiline Inhaled: Amikacin
M. chelonae	IV: Tobramycin Imipenem Tigecycline PO: Azithromycin/clarithromycin Fluoroquinolones Tedizolid Linezolid
M. fortuitum	IV: Cefoxitin or imipenem Amikacin PO: Azithromycin/clarithromycin[a] Fluoroquinolones Doxycycline Trimethoprim-sulfamethoxazole
M. mucogenicum	IV: Cefoxitin or imipenem PO: Azithromycin/clarithromycin Doxycycline Fluoroquinolones Trimethoprim-sulfamethoxazole

[a]Inducible resistance to macrolides mediated by the *erm* gene can occur for *M. abscessus* subspecies *abscessus, M. abscessus* subspecies *bolletii*, and *M. fortuitum.* Macrolides are preferred oral agents for these species only if isolates remain susceptible after prolonged incubation

infections, in particular for transplant patients. Guidelines and the following recommendations are therefore largely based on retrospective cohort studies, case series, *in vitro* data, and expert opinion.

The Role for Macrolides

Azithromycin and clarithromycin are often attractive components of multidrug regimens used to treat RGM infections given their high oral bioavailability and

relatively low toxicity. Furthermore, in contrast to other antibiotic options, macrolide susceptibility has been associated with microbiologic response in treatment of NTM disease [22, 89–91]. However, clinicians must be wary of the potential for inducible macrolide resistance: *M. abscessus* subspecies *abscessus, M. abscessus* subspecies *bolletii*, and *M. fortuitum* can express an inducible *erm* gene, which mediates macrolide resistance through ribosomal methylation [92–94]. As a result, MICs may appear low in the first 3–5 days of incubation but rise with extended incubation as *erm* expression increases (i.e., by 14 days). Therefore, accurate macrolide susceptibility testing in these three species requires extended incubation, with or without adjunctive molecular testing for functional *erm* genes.

In contrast, other RGM, such as *M. abscessus* subspecies *massiliense, M. chelonae*, *M. immunogenum*, and *M. mucogenicum*, generally lack a functional *erm* gene and do not exhibit inducible resistance [95]. Nonetheless, isolates without functional *erm* genes can still exhibit macrolide resistance through other mechanisms, such as ribosomal RNA mutations [85]. Detection of non-*erm* gene-mediated macrolide resistance does not require extended incubation.

In vitro and animal model data suggest that compared to clarithromycin, azithromycin is a weaker inducer of the *erm* gene [92]. Furthermore, azithromycin exhibits less inhibition of CYP3A4 compared to clarithromycin and typically is associated with less significant interaction with calcineurin inhibitors [96, 97]. Furthermore, our patients have tolerated a 250 mg daily dose of azithromycin better than clarithromycin or higher doses of azithromycin. Therefore, although clinical studies to definitively inform macrolide preference have not been performed, we favor azithromycin as the macrolide of choice to treat RGM infection in transplant recipients. Importantly, we recommend against monotherapy with a macrolide (or other antibiotic) for induction or maintenance therapy due to high risk of development of resistance and treatment failure [98].

Species- and Site-Specific Treatment Considerations

M. abscessus Complex

Although taxonomically related, the *M. abscessus* complex subspecies have different antimicrobial resistance patterns, particularly for macrolides (Table 3). Macrolides are favored components of regimens used to treat susceptible isolates of *M. abscessus* subspecies *massiliense* and the minority of *M. abscessus* subspecies *abscessus* isolates with a nonfunctional *erm* gene [89]. The utility of macrolides in treating *M. abscessus* complex species possessing an inducible *erm* gene is unclear, but azithromycin may retain more activity than clarithromycin [92]. *M. abscessus* complex species generally have low to intermediate range MICs for cefoxitin. Among the carbapenems, imipenem typically has the best *in vitro* activity, but results of susceptibility testing are inconsistent [86]. Isolates from treatment-naïve patients are usually susceptible to amikacin, but amikacin may not be active against isolates from patients with extensive prior

aminoglycoside exposure (e.g., cystic fibrosis patients) [10]. Widely accepted susceptibility criteria are not available for tigecycline, but MICs typically are low [99].

Several additional antibiotics have been evaluated *in vitro* against *M. abscessus* isolates. Linezolid shows *in vitro* activity for up to 50% of isolates [10], and tedizolid, which shares the same mechanism of action, also has favorable *in vitro* activity [87]. Novel antituberculous agents clofazimine and bedaquiline lack established susceptibility criteria but also demonstrate *in vitro* activity [100, 101]. New semisynthetic tetracyclines with *in vitro* activity against *M. abscessus* have also recently been developed, including omadacycline and eravacycline [102, 103]. *M. abscessus* is almost always resistant to doxycycline and the fluoroquinolones [10].

Many patients fail typical treatment regimens for *M. abscessus* or require a combination of oral antibiotics for long-term suppression. In these scenarios, clinicians are often forced to rely on antibiotics with favorable *in vitro* data but published clinical data that are limited to small cohorts and case reports. For example, although prolonged use of tigecycline is often limited by toxicity, clinical use in treatment of RGM, especially extrapulmonary disease, has become common. An analysis of a small cohort of patients who failed initial therapy for *M. abscessus* or *M. chelonae* infection reported clinical improvement in over 60% of patients who continued tigecycline as part of combination therapy for longer than 1 month [27]. For linezolid and tedizolid, clinical data describing treatment of *M. abscessus* and other RGM are limited to case reports. Compared to linezolid, long-term use of tedizolid may have less toxicity, particularly from myelosuppression and peripheral neuropathy [104].

Limited case series also report use of novel antituberculous agents clofazimine or bedaquiline as salvage therapy for *M. abscessus* [99, 105, 106]. In one observational cohort of patients with NTM infection, inclusion of clofazimine as part of combination therapy resulted in a 50% sputum clearance rate [107]. Notably, patients in this study received aggressive combination therapy with a median of three additional agents for prolonged durations, and the cohort did not include transplant recipients. Another case series reported clofazimine-based combination therapy to be reasonably well-tolerated among five SOT recipients with *Mycobacterium avium* complex (MAC) infection [108]. Bedaquiline was similarly assessed in a small case series of patients with either macrolide-resistant *M. abscessus* or MAC pulmonary disease who had failed prior treatment. Although transplant recipients were excluded, nearly 60% of patients achieved clinical improvement, and 50% converted to negative sputum cultures [100].

Poor outcomes for *M. abscessus* infections, particularly in SOT recipients, highlight the growing need for more effective and better-tolerated therapies [13, 14, 109, 110]. While new antibiotics with activity against *M. abscessus* and other RGM have been developed, clinical effectiveness and impact remain uncertain. Investigators have recently developed and utilized bacteriophage therapy targeting *M. abscessus*, which could represent a treatment option if subsequent clinical data also support use of mycobacteriophage [111].

Pulmonary Disease

M. abscessus is the RGM most frequently isolated from pulmonary specimens [33, 112]. Pulmonary infection from *M. abscessus* is difficult to treat, although likelihood of microbiologic response is at least partly dependent upon the presence of an inducible *erm* gene [89]. For macrolide-susceptible isolates (such as *M. massiliense* and a minority of *M. abscessus* subspecies *abscessus* isolates), optimal therapy includes azithromycin or clarithromycin. We recommend choosing two additional agents from the following: intravenous amikacin (or inhaled amikacin if only intrapulmonary disease is present), cefoxitin (or imipenem), and tedizolid (or linezolid if tedizolid is not available) [10]. Patients with *M. massiliense* or macrolide-susceptible *M. abscessus* have demonstrated sputum conversion rates as high as 80–90%, although larger case series have typically not included transplant recipients [23, 89].

In contrast, *M. abscessus* subspecies *abscessus* isolates with inducible *erm* genes are associated with worse clinical outcomes for pulmonary infections [22, 90, 92]. Optimal combination therapy for transplant patients with macrolide-resistant isolates is not known. Based on our experience, we recommend initial therapy with three-drug regimens, chosen based upon susceptibility results and often including cefoxitin (or imipenem), inhaled or intravenous amikacin, and either azithromycin (despite *in vitro* resistance), tedizolid (or linezolid), or tigecycline.

Use of inhaled amikacin for transplant recipients with *M. abscessus* pulmonary disease may represent a viable alternative to intravenous amikacin with less risk of ototoxicity and nephrotoxicity. However, clinical data are limited to small cohorts, and systemic absorption and associated toxicity can occur with inhalational therapy [13, 113, 114]. Therefore, we recommend surveillance of serum amikacin levels for transplant recipients receiving inhalational therapy who have abnormal renal function or for whom clinical concern of toxicity develops. When random serum amikacin levels are detected, clinicians should decrease the frequency or amount of inhaled amikacin doses.

In the United States, the FDA recently approved a liposomal formulation of inhaled amikacin (amikacin liposome inhalation suspension) for treatment of refractory *M. avium* complex (MAC) based upon improved culture conversion after addition of this agent to standard of care regimens [115, 116]; however, culture conversion was less common for a small subset of patients with *M. abscessus*. Therefore, further study of inhaled amikacin for *M. abscessus* pulmonary disease is needed.

We treat transplant recipients with pulmonary *M. abscessus* infection for a minimum of 6–12 months, but treatment duration depends upon clinical response and tolerance of antibiotics. For patients who exhibit symptomatic and radiographic improvement with good tolerance of antibiotics, we may extend therapy for up to 12 months beyond sputum culture conversion [10]. However, many patients do not achieve culture clearance or are unable to tolerate long durations of therapy, and disease recurrence after cessation of antibiotics is common [117]. In refractory cases, clinicians may revert to periodic courses of therapy lasting approximately 3–6 months with a goal of providing symptomatic management rather than cure.

In other cases, surgery may offer the best opportunity for cure if the infection is localized and resectable [15, 109, 118]. Potential surgical candidates with localized disease must be carefully selected to have sufficient pulmonary reserve to withstand planned resections. However, many transplant recipients present with diffuse, bilateral pulmonary disease and are not candidates for adjunctive surgical therapy.

Extrapulmonary Disease

Skin or soft tissue infection from *M. abscessus* is generally treated with combination antibiotics for 4–6 months. Surgical debridement significantly improves chances of successful therapy, particularly in cases with more extensive disease, necrotic tissue, or abscess formation. We suggest induction therapy with 4–6 weeks of combination therapy, including intravenous therapy for serious disease. Choice of subsequent multidrug maintenance regimens depends upon susceptibilities, extent of infection, surgical source control, patient comorbidities, and clinical response [10].

Bone infections are typically treated for at least 6 months following surgical debridement. Experts recommend induction therapy with three agents (two of which are typically parenteral) for 8–12 weeks before considering oral combination maintenance therapy, based upon susceptibilities [10]. Induction therapy for disseminated *M. abscessus* infection usually consists of 3–4 active agents, including either cefoxitin or imipenem. Induction regimens often include various combinations of the following antibiotics: azithromycin, amikacin, cefoxitin (or imipenem), tigecycline, and tedizolid (or linezolid) [10]. Particular antibiotic combinations depend upon comorbidities, potential for drug interactions, susceptibilities, and patient tolerance. Combination maintenance regimens for severe disease typically include intravenous therapy and are continued for at least 6 months. Many disseminated *M. abscessus* infections are not curable, even with aggressive surgical and medical management. Therefore, maintenance or suppressive regimens are occasionally required, at times including newer oral agents, such as clofazimine or bedaquiline.

M. chelonae

M. chelonae does not express *erm* and is generally susceptible to macrolides (Table 3) [93]. *M. chelonae* is typically resistant to cefoxitin, and, similar to *M. abscessus,* imipenem MIC testing tends to be inconsistent; however, imipenem is often a component of treatment regimens. Tobramycin has excellent *in vitro* activity against most isolates of *M. chelonae* and is the aminoglycoside of choice for treating serious infections from this species. Tigecycline has been used with some success as a component of salvage therapy [27]. Among oral agents, in addition to macrolides, fluoroquinolones and linezolid exhibit good activity for some isolates.

Pulmonary Disease

M. chelonae is a much less frequent cause of pulmonary disease than *M. abscessus*. Treatment duration is similar to other RGM and can extend up to 12 months beyond culture clearance. Combination therapy usually consists of a macrolide plus two additional agents, including parenteral therapy for at least the first 4–6 weeks. Some

providers subsequently transition to maintenance regimens including a macrolide plus two active oral agents, if susceptibilities allow [10].

Extrapulmonary Disease

Similar to *M. abscessus*, skin or soft tissue disease from *M. chelonae* is generally treated for a total of 4–6 months. Surgical debridement is often critical to successful treatment of resectable disease. Patients frequently initiate therapy with 4–6 weeks of combination therapy, including intravenous therapy for serious disease. They may transition to 2–3-drug oral therapy thereafter, based upon susceptibilities, surgical source control, and clinical response [10].

Therapy for bone infection is generally continued for at least 6 months. Similar to treatment of *M. abscessus* osteomyelitis, experts recommend initial therapy with a macrolide plus 2 parenteral agents for 8–12 weeks, followed by conversion to 2–3 active oral agents thereafter [10].

Disseminated infection from *M. chelonae* typically requires at least 6 months of combination therapy. Induction therapy generally includes a macrolide, tobramycin, and an additional active agent for the first 4–6 weeks. Susceptibilities and clinical response help to determine combination maintenance regimens [10].

M. fortuitum

Although variable between isolates, *M. fortuitum* generally exhibits increased susceptibility to oral agents compared to other RGM (Table 3) [10]. Frequently used agents include the fluoroquinolones, trimethoprim-sulfamethoxazole, doxycycline, and, in the absence of *erm* expression, azithromycin. Among parenteral agents, cefoxitin, amikacin, and imipenem are typically active. In contrast to *M. abscessus* and *M. chelonae*, imipenem MICs tend to be reproducible with *M. fortuitum* [10].

Pulmonary Disease

M. fortuitum pulmonary infection is relatively uncommon and can be associated with emesis or aspiration. We recommend initial therapy with three agents, including azithromycin only after excluding *erm*-mediated macrolide resistance. Similar to treatment of pulmonary disease from other RGM, treatment can continue for up to 12 months beyond culture clearance [10].

Extrapulmonary Disease

Treatment duration for skin and soft tissue infection from *M. fortuitum* is typically 4–6 months. Due to favorable susceptibility data for oral agents, it is often possible to treat with combination oral therapy once susceptibility results are available. As with other RGM, surgical debridement of deep infections is key.

For bone infections, we recommend three-drug induction therapy, including at least one parenteral agent, for at least the first 6 weeks. Transitioning to 2–3 active oral drugs to complete a total duration of 6 months thereafter is usually possible [10].

Disseminated disease typically requires at least 6 months of therapy. Induction therapy consists of 4–6 weeks of parenteral therapy, often followed by conversion to oral agents thereafter [10].

Role for Surgery in Extrapulmonary RGM Disease

Due to high rates of drug resistance and a tendency to form biofilms, surgical debridement is recommended for any RGM infection with associated abscess, bony involvement, or extensive tissue involvement [10]. Repeat debridements are often required because the margins of involved tissue can be difficult to ascertain, and obtaining adequate source control from a single debridement may not be possible. One review of cardiac surgical site infections with *M. chelonae*, including deep infections such as mediastinitis, found that nearly all successfully treated patients had undergone surgical debridement [119]. Similarly, any infected prosthetic material should be removed because the retention of foreign material confers a high risk of treatment failure or recurrence. In one small case series of two *M. chelonae* infections involving left ventricular assist device (LVAD) driveline infections, extended courses of combination therapy coupled with repeated debridement were unsuccessful; cure was achieved in both cases only after LVAD removal [56]. A separate analysis of 32 RGM infections of implantable electronic devices reported device removal in all but 3 cases [57].

Catheter-Associated Infections

Catheter-associated RGM infections are common. Regardless of the site or type of infection, catheter removal remains essential to successful treatment given the high risk of biofilm formation. In the setting of isolated CLABSI, catheter removal followed by a short course of therapy may be effective. In one oncology center's experience with 116 RGM CLABSIs, consisting predominantly of *M. mucogenicum* or *M. fortuitum* infections, the majority of patients achieved clinical cures with a median of only 4 weeks of therapy, provided the line was promptly removed [34, 120].

RGM infection of peritoneal dialysis catheters also occurs. These infections can present as culture-negative or treatment-refractory peritonitis. As with CLABSIs, successful treatment requires catheter removal [55]. Duration of therapy for peritoneal dialysis catheter infection with peritonitis is poorly defined. Among published cases, treatment courses after catheter removal ranged from several weeks to 12 months. We suggest at least 3–6 months of therapy for transplant recipients with peritoneal dialysis catheter-related invasive RGM infections.

Treatment of Less Common RGM Isolates

Due to their overall rarity, treatment of less common RGM, such as *M. mucogenicum* or *M. immunogenum*, is often inferred from experience with the more common isolates. One key difference, however, is that susceptibility data are sparse, making the selection of empiric therapy challenging. Initial regimens are generally chosen based upon published susceptibility data, and therapy is individualized according to patient response and susceptibility profile of the specific clinical isolate.

Management Considerations Unique to Transplant Recipients

Treatment of RGM infections in transplant recipients presents several unique challenges. First, the decision to pursue aggressive treatment versus observe off of therapy is often complex. On one hand, some heavily immunosuppressed patients with positive respiratory cultures but a lack of compelling symptoms or radiographic findings indicative of infection may benefit from several months of aggressive combination therapy designed to provide secondary prophylaxis against invasive pulmonary infection. For example, lung transplant recipients with peri-transplant respiratory colonization from RGM may benefit from 3 to 6 months of post-transplant three-drug therapy to decrease risk of chronic RGM infection of the transplanted graft. Ideal duration of therapy in this scenario is not clear and depends upon evaluation of explanted lung histopathology for stigmata of invasive RGM infection, post-transplant surveillance BAL culture results, antibiotic tolerance, and potential for decrease in immunosuppression with time after transplant. On the other hand, some transplant recipients with confirmed invasive or even disseminated infection may benefit from symptom palliation rather than aggressive medical or surgical therapy due to poor overall clinical status, high risk for antibiotic-related toxicities, and lack of potential for cure [121].

Next, transplant recipients who decide to initiate antibiotic therapy for RGM infection are likely to develop clinically significant antibiotic toxicities. A recent study analyzed 55 patients with a variety of underlying diseases who were treated for *M. abscessus* infection [122]. Many patients in this cohort developed clinically significant toxicities related to antibiotics, including 23 (42%) patients with gastrointestinal toxicity. Another recent study of 82 SOT recipients treated for pulmonary ($n = 48$) or extrapulmonary ($n = 34$) *M. abscessus* infection found that 55 (67%) patients developed antibiotic toxicities severe enough to require changes in therapy [13]. Transplant recipients may be at particularly high risk to develop nephrotoxicity from intravenous aminoglycosides, especially given prevalence of pre-existing renal disease and use of concomitant nephrotoxic medications, including calcineurin inhibitors. Potential for drug-drug interactions, such as macrolide inhibition of CYP3A4 and consequent increased calcineurin inhibitor levels, also increase risk of treatment-related adverse events and require close clinical and drug-level monitoring (Table 5).

Duration of therapy decisions are also difficult and must be individualized for transplant recipients with RGM infections. Shorter courses of antibiotics may be appropriate for patients with a removable source of infection, such as a central line, lack of confirmed invasive infection, antibiotic toxicities, or untreatable disease. However, relapsed disease from invasive RGM infection is common, and in some cases, long-term suppressive oral antibiotics can prevent recrudescence of infection and need for re-induction therapy with intravenous antibiotics and surgical debridement.

Several treatment strategies may decrease risk of toxicity from antibiotic regimens commonly used to treat RGM infections (Table 5). For example, patients receiving intravenous aminoglycoside therapy should undergo baseline and

Table 5 Dosing, common adverse effects, and drug interactions for antibiotics commonly used to treat rapidly growing mycobacterial infections

Antimicrobial/dose	Common adverse effects	Transplant-relevant drug interactions
Aminoglycosides		
Amikacin 10–15 mg/kg IV three times per week[a] Adjust dose to maintain trough level <1 μg/mL Amikacin 250–500 mg inhaled daily (free amikacin) Liposomal amikacin 590 mg inhaled daily	Ototoxicity, nephrotoxicity	Potentiates risk of nephrotoxicity with CNI
Tobramycin 7 mg/kg IV three times per week[a] Adjust dose to maintain trough level <1 μg/mL	Ototoxicity, nephrotoxicity	Potentiates risk of nephrotoxicity with CNI
Carbapenems		
Imipenem 500 mg IV Q6h or 1000 mg IV Q12h	GI upset Reduced seizure threshold Hepatitis Hematologic toxicity[b]	May increase CSA levels
Cephalosporins		
Cefoxitin 8–12 g IV daily, in divided doses or via continuous infusion	Artificial increase in creatinine[c] Hematologic toxicity[b]	
Fluoroquinolones	Applicable to all fluoroquinolones:	
Ciprofloxacin 500–750 mg PO twice daily Levofloxacin 500–750 mg PO daily Moxifloxacin 400 mg PO daily	*Clostridioides difficile* infection Tendonitis Aortic aneurysm Prolonged QT	Mildly increases CNI levels Mildly decreases MMF levels
Macrolides	Applicable to all macrolides:	
Azithromycin 250 mg PO daily Clarithromycin 500 mg PO twice daily	GI upset Prolonged QT Ototoxicity	Mildly increases CNI, mTORi levels Increases CNI, mTORi levels

Oxazolidinones		
Linezolid 600 mg PO daily	Peripheral neuropathy Hematologic toxicity[b] Serotonin syndrome	Risk of serotonin syndrome if co-administered with serotonin re-uptake inhibitors or other serotonergic medications
Tedizolid 200 mg PO daily	May have lower risk of the adverse effects associated with linezolid	
Tetracyclines		
Doxycycline 100 mg PO twice daily	Sun sensitivity, esophagitis	
Minocycline 100 mg PO twice daily	GI upset, skin pigmentation	
Tigecycline 50 mg IV daily or Q12h[d]	GI upset	May increase CSA levels
Sulfonamides		
Trimethoprim-sulfamethoxazole 800–1600 mg sulfamethoxazole component PO twice daily	Hyperkalemia Increase in serum creatinine Hematologic toxicity[b]	
Novel agents		
Bedaquiline 400 mg PO daily for 2 weeks and then 200 mg PO three times per week	QT prolongation	
Clofazimine 100 mg PO daily	GI upset Skin pigmentation changes QT prolongation Rare visceral crystallization	

References: [10, 17, 123]

Antibiotic doses provided assume normal renal function and may require adjustment for renal insufficiency

CSA cyclosporine, *CNI* calcineurin inhibitor, *GI* gastrointestinal, *MMF* mycophenolate mofetil, *mTORi* mammalian target of rapamycin inhibitor

[a]Once-daily dosing may be considered, but daily dosing may increase risk of side effects, especially with prolonged use

[b]Hematologic toxicity may include anemia, thrombocytopenia, or leukopenia

[c]Cefoxitin may interfere with the Jaffe method for creatinine measurement; artifactual creatinine elevation can be avoided if blood draws are performed 2–4 h after the last cefoxitin dose, assuming normal renal function

[d]Once-daily tigecycline dose may have less GI toxicity than traditional Q12h dosing

surveillance audiology assessments [124], in addition to close monitoring of renal function and drug levels. We prefer three-times-weekly dosing of amikacin and tobramycin, targeting undetectable trough levels, to decrease risk of toxicity associated with prolonged treatment courses. We also suggest N-acetylcysteine supplements during intravenous aminoglycoside therapy, which may decrease risk of ototoxicity [125]. Reducing dosing frequency for tigecycline to 50 mg once daily [27] and for linezolid to 600 mg once daily [126] may also decrease risk of toxicity. Tedizolid may prove to have similar efficacy as linezolid with improved long-term tolerance [104].

Finally, while immunosuppression is one of the key risk factors for RGM infection, few data are available to guide the management of immunosuppressive medications in the setting of known infection. Reports of immune-reconstitution inflammatory syndrome are exceedingly rare among SOT recipients with NTM infections [127]. Therefore, when feasible, we reduce immunosuppression when treating RGM infections. For SOT recipients, we often decrease the dose or stop the antimetabolite agent (e.g., mycophenolate mofetil or azathioprine).

Prevention

Transplant recipients are at increased risk for community-acquired RGM infection. While RGM are ubiquitous in the environment, municipal water colonization likely represents the most important reservoir for community acquisition [63]. Guidelines recommend that transplant recipients avoid hot tubs due to potential for aerosolization of high concentrations of NTM [128]; however, few data are available to guide outpatient tap water use related to risk of RGM acquisition. Based on our experience, we recommend that recent SOT recipients avoid tap water contact to the surgical wound until it is well-healed and sutures or staples have been removed. For lung transplant recipients living in a geographic area with endemic RGM, we recommend home use of sterile or boiled water for oral care, enteric tube flushes, and consumption, at least until functional status has improved and risk of micro-aspiration of tap water has presumably decreased [7].

Transplant recipients also acquire RGM from healthcare facilities, and recent RGM outbreaks among hospitalized transplant recipients have led to increased scrutiny of hospital water use and equipment that contacts tap water [129]. Tap water should not contact unhealed surgical wounds, central lines, and other catheters or drains that exit the skin [10]. Furthermore, transplant centers should perform clinical surveillance for RGM infections. Suspected healthcare-acquired cases of RGM require investigation of potential mechanisms of transmission, particularly via direct or indirect tap water contact. In the outbreak setting, environmental sampling of biofilms from healthcare facility water sources can help to elucidate mechanisms of transmission; however, given low sensitivity and delays inherent in performing mycobacterial cultures of environmental samples, avoidance of tap water sources or medical equipment potentially responsible for transmission of RGM should occur prior to source confirmation. Tap water avoidance has successfully mitigated RGM

outbreaks at several hospitals [7, 8, 45, 130]. Another potential mitigation measure is use of 0.2 micron filters at distal water outlets. Finally, more proximal interventions on the healthcare facility plumbing infrastructure can improve water flow and disinfectant levels, which may decrease RGM concentration in water [7]. Guidelines for screening healthcare facility water systems for RGM or building new hospital plumbing systems that have intrinsically lower risk for RGM contamination need to be developed, especially for transplant centers.

Clinical Impact in Transplant

RGM infections have unique impact upon transplantation. These infections affect patients undergoing evaluation to assess transplant candidacy, transplant recipients, and transplant centers located in areas where RGM are endemic.

Impact on Transplant Candidacy

The majority of data on pre-transplant RGM infection come from experience with lung transplantation, in particular for patients with cystic fibrosis and *M. abscessus* infection. Pre-transplant RGM infection, most notably from *M. abscessus*, likely increases risk of lung transplantation; therefore, many authorities consider *M. abscessus* infection to be a relative contraindication to lung transplantation [131–134]. Nonetheless, despite risk of recurrent post-transplant RGM infection and related complications, transplantation may offer transplant candidates with complicated RGM infections the best chance for long-term cure. In fact, multiple transplant centers have reported successful transplantation for small cohorts of patients with *M. abscessus* infections [61, 135, 136]. For example, one hospital analyzed clinical courses of 13 patients with cystic fibrosis and positive respiratory cultures for *M. abscessus* prior to transplant and found that 5-year post-transplant survival for this cohort was not different from survival of cystic fibrosis patients without *M. abscessus* who underwent transplantation [135]. In our experience, lung transplant candidates with RGM infection associated with large pulmonary cavities, suspected pleural involvement or risk of soiling during surgery, or poor tolerance of RGM antimicrobial regimens are at highest risk of progressive infection after transplant and may therefore be poor transplant candidates. More data are needed to allow accurate risk stratification of lung transplant candidates based upon clinical characteristics of RGM infection and subspecies identification (e.g., *M. massiliense* vs. *M. abscessus*) [137].

Lung transplant candidates with RGM infection should begin treatment prior to transplant listing with specific therapies chosen based upon species identification, susceptibility patterns, and patient tolerance of particular multidrug therapies [132]. Lung transplant recipients with invasive pulmonary RGM infection at the time of transplant require at least several months of combination therapy after transplant, as well as close clinical and microbiologic surveillance for recurrent or refractory infection.

Pre-transplant evaluation of heart transplant candidates with RGM infections, in particular VAD-associated infections, also presents unique management challenges with minimal data available for guidance. Some centers exclude LVAD recipients with RGM infection from transplantation, but two limited reports describe successful heart transplantation in three patients with chronic, disseminated *M. abscessus* infections involving LVADs [56, 138]. At our center, active intrathoracic RGM infection would likely exclude a patient from transplant due to potential for worsening of infection with immunosuppression. RGM infections limited to LVAD drivelines can be considered for transplantation, however, because LVAD removal would provide surgical source control and opportunity for cure. After LVAD explantation and heart transplantation, we recommend post-transplant antibiotic courses of 6–12 months.

Fewer data are available to help guide management of patients with hematologic malignancy with active RGM infection and potential for HCT. Akin to management prior to SOT, initiation of combination antibiotic therapy to gauge tolerance and clinical response prior to augmentation of immunosuppression is ideal but sometimes not possible due to chemotherapy or transplant timelines. Like SOT candidates, HCT candidates often continue prolonged treatment courses after transplantation.

Impact on Transplant Recipients and Transplant Centers

Substantial morbidity and mortality is associated with RGM infections in SOT or HCT recipients, best studied for *M. abscessus* in the SOT literature [13, 14, 109, 110]. Antibiotic toxicities related to prolonged combination antimicrobial therapy are common, and despite long courses of antibiotics that are difficult to tolerate, failure to achieve cure and relapsed infection occur frequently. Transplant patients are also at increased risk for drug-drug interactions and require close clinical and laboratory surveillance while on therapy. However, despite risks associated with therapy, heavily immunosuppressed patients may be at highest risk for progression from colonization to infection and for development of complications related to infection. Therefore, when level of immunosuppression is highest, such as early after transplant or during treatment for rejection, the relative benefits of aggressive RGM therapy or secondary prophylaxis may be greatest.

Healthcare facility outbreaks of RGM can disproportionately affect transplant recipients due to presence of immunosuppression and frequent healthcare exposures, such as increased number of procedures and need for invasive devices [7]. In addition to causing substantial illness in patients with infection, outbreaks of RGM can profoundly impact SOT and HCT programs, including outcome statistics and other performance metrics [8, 9, 45, 139]. Healthcare facility-associated outbreaks of RGM affecting transplant recipients emphasize the importance of infection prevention, particularly with regard to principles of hospital water safety [70, 129].

Conclusion

RGM are widespread in the environment and well-adapted to form biofilms. While RGM infections are relatively rare, prevalence appears to be increasing, and transplant patients are at elevated risk. RGM infections in transplant recipients are difficult to diagnose due to atypical clinical presentations and limitations of diagnostic testing. Culture using AFB media remains the gold standard for diagnosis and promotes species identification and susceptibility testing, which require specialized laboratory expertise. Treating RGM infections is also challenging because transplant recipients with serious infections require months of combination antibiotic regimens that frequently cause important toxicities. Furthermore, particularly for extrapulmonary infections, patients often require multiple surgical debridements. The high morbidity and mortality associated with RGM infections in transplant patients emphasizes the importance of clinical surveillance and infection prevention strategies. Poor treatment outcomes also underscore the growing need for new treatment agents and approaches.

Key Points

- RGM commonly form biofilms and survive in community and healthcare facility water systems.
- Diagnosis of RGM infection in transplant recipients is difficult because patients often present with atypical symptoms and have indolent clinical courses.
- Culture remains the gold standard for diagnosis, but presence of AFB or granulomatous inflammation on histopathology can provide early evidence of infection.
- Treatment typically requires prolonged courses of combination antibiotic therapy, adjusted based upon susceptibility results, patient tolerance, and clinical response.
- For extrapulmonary infections, removal of infected prosthetic material and debridement of infected tissue is essential for treatment success.
- Transplant can offer cure for some transplant candidates with RGM infections, but active RGM infection also increases risk of complications after transplant.
- Transplant recipients with RGM infections often have poor outcomes and do not achieve cure despite aggressive medical and surgical management.
- To decrease risk of infection, transplant patients living in areas with endemic RGM should avoid high-risk tap water contact in the community and at healthcare facilities.

Introduction

Nontuberculous mycobacteria (NTM) are ubiquitous environmental organisms found in soil and water. Although clinical infections with NTM are rare, epidemiologic studies suggest an increase in their incidence in the last four decades [1–3]. Factors such as the continuous expansion of the immunocompromised population, more widespread environmental exposure to these organisms (inhalation of shower-produced aerosols), and improvements in mycobacterial detection and diagnosis have contributed to an increased awareness of NTM as human pathogens and the emergence of these infections in transplant recipients.

Due to impaired cell-mediated immunity, these patients are at increased risk of infection and have higher associated morbidity and mortality. The diagnosis and management of NTM infection in the transplanted host pose a particular challenge to clinicians. Disease manifestations can be protean and nonspecific, invasive infection is often difficult to recognize because of the ubiquitous nature of the organisms, and microbiological diagnosis is frequently delayed. In addition, the necessity of prolonged treatment with multidrug regimens associated with significant drug toxicities and the need to consider drug-drug interactions between antimicrobials and immunosuppressants add to the complexity of managing transplant recipients with NTM.

Our understanding of NTM infections in the immunocompromised host is based on case reports and case series [3–9]. To date, of the over 180 NTM species that have been identified, only 25 are known to have caused disease in transplant recipients [10]. These include rapid and slow-growing NTM, classified as such based on whether the species isolates require less or more than 7 days to form mature colonies on subculture, respectively. This chapter will discuss the epidemiology, clinical presentation, diagnosis, and management of the most common slow-growing NTM described in solid organ transplant (SOT) and hematopoietic stem cell transplant recipients (HSCT) (Table 1).

Epidemiology

Slow-Growing Mycobacteria: Organisms and Mode of Transmission

Approximately 18 species of slow-growing mycobacteria (SGM) are known to cause infection in transplant patients (Table 1). *Mycobacterium avium* and *Mycobacterium intracellulare* (together known as *Mycobacterium avium* complex [MAC]) are the most common NTM species in the United States and are the most common species isolated in SOT recipients [11], followed by *M. kansasii*, *M. haemophilum*, *M. marinum*, *and M. xenopi*. In HSCT recipients, the most frequent species are MAC, *M. haemophilum, M. gordonae*, *and M. xenopi* [3, 7, 12].

NTM are ubiquitous saprophytic organisms widely distributed in the environment, in sources including soil and natural and treated water (e.g., M. *kansasii*,

Table 1 Slow-growing mycobacteria reported in transplant recipients and associated clinical syndromes (SOT, HSCT) [7, 11, 31]

M. ulcerans; M. conspicuum have not been reported in transplant recipients
SOT solid organ transplant, *HSCT* hematopoietic stem cell transplant

M. *xenopi*, and *M. simiae* are recovered almost exclusively from municipal water sources) and also dust, aerosols, plant material, animals, and birds [13, 14]. Most infections arise following environmental exposure. These organisms can be resistant to disinfection and thus can be recovered from drinking water distribution systems. Nosocomial cases due to contaminated surgical equipment, solutions, and cleaning devices and hospital outbreaks from contaminated water systems and hemodialysis units have been reported [15, 16]. In recent years, a global outbreak of disseminated *M. chimaera* (until recently, identified as *M. avium intracellulare* by most laboratories) has been ongoing, associated with contaminated Sorin 3T heater-cooler devices used in open-chest surgery requiring cardiopulmonary bypass. It has affected patients with ventricular-assist devices and heart transplant recipients [17–19]. This outbreak has raised awareness of the emergence of *M. chimaera* as a pathogen, prompting the development of specific guidelines [19] addressing the diagnosis, management, and prevention of infections with this organism. Another pseudo-outbreak of *M. chimaera* originating in aerators and hand-washing machines of a HSCT unit was also recently reported [20]. Recent epidemiologic and genetic evidence of *M. abscessus* spread between individuals with cystic fibrosis (CF) has contested the historical belief that person-to-person transmission of NTM does not occur [21, 22]. The exact mechanism of transmission remains unclear but is thought to be indirect, through contaminated fomites and long-lived infectious aerosols rather than direct human-to-human spread. Moreover, this form of transmission with other NTM species has not been demonstrated. In SOT recipients, transmission from donor to recipient via the allograft can occur but is rare [23].

Incidence of NTM in Transplant Recipients

NTM infection posttransplant is relatively infrequent. However, this disease is on the rise in both the general and transplant population [2, 24–26]. Exact data regarding the incidence of NTM infections in SOT and HSCT recipients is lacking, since reporting of these infections is not mandatory. A large single-center study of SOT recipients of all organ types noted an incidence of NTM infection, defined as any positive culture for NTM, of 1.5%. For slow-growing NTM infection specifically, the incidence was 1% [27]. Among SOT recipients, the incidence of NTM infection varies based on transplanted organ, the highest being reported in lung transplant patients. The only study of NTM infections in liver transplant recipients reported the lowest incidence, of 0.04% [28], which could be reflective of the local epidemiology, underdiagnosis, or true diminished susceptibility to NTM. Among other SOT recipients, studies suggest an incidence of 0.16–0.38% in kidney transplant, 0.24–2.8% in heart transplant, and 0.46–8% in lung transplant recipients. An incidence of 0.4–4.9% has been observed in HSCT patients [3, 7, 26, 29]. Studies have included all NTM species: rapid, intermediate, and slow-growing. Therefore, the incidence of slow-growing NTM is even lower than in these reports.

Timing of Infection

The timing of infection after transplantation varies significantly in the published literature. In general, studies have evaluated infection with all NTM species, and specific data on slow-growing mycobacteria (SGM) is lacking. In a series of 82 SOT recipients with NTM infection, diagnosis was made at a mean of 48 months after transplant (range 10 days to 269 months) [6]. A smaller study of 34 SOT recipients (55% of which had SGM) reported a median time of diagnosis of 8-month post-transplant but in a bimodal distribution, with 18% of infections occurring within 3 months and 44% after 3 years posttransplant [30]. A recent review of NTM infections in SOT recipients reported shorter median times of onset in lung transplant recipients (13 months) than in liver, kidney, and heart recipients (24, 27, and 33 months respectively) [31].

Among 30 allogeneic HSCT recipients with NTM infection, 77% of which were with SGM [MAC ($n = 14$; 46.7%), *M. xenopi* ($n = 8$; 26.7%), *M. gordonae* ($n = 1$; 3.3%)], the median time to diagnosis of NTM infection was 343 days (range 19–1967), and in 83% of patients, the diagnosis was made within 2 years of allogeneic HSCT [26]. In a review of published cases of NTM infection in HSCT recipients, Knoll et al. described a shorter time of onset in this population, with a median onset of 5 months (range 3–11 months) [7].

Risk Factors

Infections with NTM result from the interaction of multiple factors including the type and load of the exposure, the virulence of the pathogen, as well as host-specific factors [32]. As species vary in distribution between regions and across different latitudes and water sources, a determined exposure in a geographic location can predispose to a specific NTM infection. For instance, *M. marinum* infection, commonly known as "fish tank granuloma," is closely related to direct injury from fish or shrimp fins or bites or after cutaneous trauma and subsequent exposure to contaminated saltwater or freshwater from cleaning of fish tanks or swimming pools. *M. kansasii* or *M. avium complex* have been found to be more frequent in states near coastal swamps and estuaries [33]. Certain SGM species such as *M. kansasii* or *M. malmoense* are regarded as being more virulent than others like *M. gordonae* and *M. terrae complex*, usually considered contaminants [11]. However, in the transplanted host, severe infections with species not traditionally considered pathogenic are increasingly reported [23, 34], underscoring the importance of host immune factors.

In the general population, several host-specific predisposing factors for NTM infection have been identified. Structural or preexisting pulmonary diseases such as chronic obstructive pulmonary disease (COPD), bronchiectasis, alpha-1 antitrypsin deficiency, pneumoconiosis, sarcoidosis, pulmonary tuberculosis, and CF have been strongly associated with a risk of pulmonary NTM infection. NTM are recovered in 6.6–20% of CF patients [3], and therefore, these patients are routinely screened for NTM when lung transplantation is considered. Individuals with gastroesophageal

reflux and other esophageal dysmotility syndromes, rheumatoid arthritis, low vitamin D, low body mass index, and malnutrition are also at risk. Nonsmoker elderly females with certain phenotypic features like a slender body type, scoliosis, pectus defects, or mitral valve prolapse (Lady Windermere syndrome) are known to be prone to pulmonary bronchiectatic disease. Immunosuppressed patients are at increased risk of opportunistic infection with NTM. In HIV-infected individuals, a CD4 T-cell count less than 50/μL is associated with an increased risk of disseminated infection [11]. A number of immunodeficiencies have been associated with NTM infection, including inherited disorders and targeted therapies with biologics affecting the IFNγ-IL12 pathway [35], cytokine signaling (e.g., STAT mutations), or the macrophage and dendritic cell function (e.g., GATA2, NRAMP1) [36]. Treatment with corticosteroids and antitumor necrosis factor agents also predisposes to NTM infections [35, 37–40].

In the transplanted host, the disruption of mucosal barriers during surgery or via vascular catheterization can serve as a portal of entry for NTM. Structural abnormalities, notably in lung transplant candidates and recipients, facilitate colonization with NTM. Finally, the net state of immunosuppression in transplant recipients promotes the progression to disease in those who have been environmentally exposed or colonized. Taking this into consideration, it is not surprising that NTM infections are more commonly seen in lung transplant recipients.

Longworth et al. identified lung transplantation and biopsy-proven acute cellular rejection as important risk factors for NTM infection in SOT recipients [30]. Among lung transplant patients, CF, pretransplant NTM infection, and the use of rabbit antithymocyte globulin have been identified as significant risk factors of post-transplant NTM. However, in a different single-center study, African American race and high-risk CMV mismatch status emerged as risk factors, and there was no difference in the incidence of NTM infection among those with and without pre-transplant NTM infection [41].

For HSCT recipients, Beswick et al. identified CMV viremia and chronic graft-versus-host disease as independent risk factors of NTM infection, both surrogate markers of overall immunosuppression [26]. An earlier study suggested total body irradiation (TBI) as a risk factor of cutaneous NTM in this population [12].

Clinical Impact

The clinical impact of SGM depends on the site of culture positivity. A positive culture from a sterile site is considered clinically significant. However, because these organisms are ubiquitous in the environment, it is often a challenge to determine clinical relevance if the organism is isolated from a non-sterile site such as sputum or bronchoalveolar lavage fluid. In this setting, particularly relevant to the lung transplant population, a positive culture is not always indicative of disease and could simply signify transient growth or colonization. Colonization of the airway by NTM is 10 times more common than invasive infection in lung transplant patients, comprising 75–89% of cases with positive culture (the majority of which were

SGM) in two single-center studies [8, 42]. The same percentage of pulmonary colonization was noted among all organ types in the SOT population (75%) [30].

Similar findings have been observed in HSCT patients. A small single-center study found that 20% of patients with NTM isolated in respiratory sample had proven or probable pulmonary infection requiring treatment [34]. Another found that 44% of HSCT patients with NTM isolated on sputum cultures met criteria for NTM pulmonary disease requiring treatment [25]. Based on these studies, positive NTM respiratory culture in HSCT patients represented colonization 56–80% of the time. Underlying GVHD as well as coinfection with additional pathogens such as *Aspergillus* is common in HSCT patients who grow NTM from respiratory cultures, making it difficult to pinpoint the exact cause of symptoms and the effect of NTM specifically [43]. Thus, a positive culture must be interpreted in the context of the patient's overall status to determine the clinical impact of these organisms.

NTM infections are often difficult to treat. Disease cure rates in the literature for all NTM infections range from 32% to 44%, although a greater number of patients do have some clinical improvement without complete resolution of infection on NTM therapy [3]. Outcomes in transplant patients with NTM disease are highly variable and depend on the extent of infection, virulence, and susceptibility of the organism and level of immunosuppression of the host [3, 4, 42]. Studies of the impact of NTM infection on patient outcome show varied results, likely in part due to small numbers of patients examined in single-center studies. Early infection within the first year posttransplant has been associated with decreased survival in SOT patients (half of which were infected with SGM), although NTM infection itself was listed as a cause of death in a minority [44]. The impact of early NTM infection on survival is complex. Multiple factors likely contribute to increase in mortality including indirect immune modulation, transplant rejection, or development of secondary infections [44]. Among lung transplant patients specifically, there are mixed results regarding NTM infection impact on mortality, with one single-center study showing that NTM infection (both colonization and pulmonary disease) at any time point is associated with increased mortality (although in no patients was death a direct result of NTM infection) and another showing no effect of NTM infection on mortality[41, 42]. Both studies showed no significant independent increased risk of bronchiolitis obliterates syndrome (BOS) when controlling for other potential contributing factors.

Interestingly, in HSCT patients, definite NTM infection has been associated with excellent prognosis, while possible and probable infection was associated with increased mortality [12]. This suggests other underlying host factors associated with positive NTM cultures, such as pulmonary disease or GVHD, may have more of an impact on survival than the NTM infection itself. It's also worth noting that there were different pathogens and areas of disease involvement between these two groups, with cutaneous and musculoskeletal *M. haemophilum* in the former vs. pulmonary MAC in the latter, which may have confounded results [12]. Chronic airway colonization with any bacteria in HSCT patients with BOS has been associated with decreased survival, more rapid decline of lung function, and progression of CT findings. A small number of patients with NTM were included in this study [45].

Further study into the impact of positive NTM cultures on the trajectory of GVHD itself is needed.

Data regarding the lung microbiome and its impact on pulmonary health and infection are emerging [46]. Further study into how NTM fit into this niche environment, interact with the usual commensal microbiome, and therefore potentially contribute to pulmonary pathology would be enlightening.

Presentation and Diagnosis

Clinical Presentation

The clinical manifestations of NTM infection in transplant recipients are protean, and constitutional symptoms like fever, weight loss, and night sweats are often absent. Thus, clinicians must maintain a high index of suspicion for these infections and a low threshold to obtain diagnostic specimens for mycobacterial culture.

NTM infections classically cause one of six clinical syndromes: pleuropulmonary disease, skin and soft tissue infection, musculoskeletal infection, catheter-associated disease, lymphadenitis, or disseminated disease (Table 1).

Pleuropulmonary disease is the most common presentation of NTM infection after SOT, and lung transplant recipients are the most commonly affected [8, 30, 42]. Patients typically manifest with cough, dyspnea, sputum production, and occasionally, hemoptysis. Disease can be fibrocavitary, nodular/bronchiectatic, or a combination of both. Computed tomography of the chest may show pulmonary nodules, tree-in-bud opacities, bronchiectasis, and/or consolidations. *M. avium* complex (MAC), *M. kansasii*, *Mycobacterium xenopi* are together with the RGM *M. abscessus*, the most common NTM-causing pulmonary disease [47]. *M. kansasii*, in particular, can cause aggressive disease in lung transplant recipients and often develops into cavitary infiltrates with an upper-lobe predilection, mimicking tuberculosis reactivation [11].

Non-lung SOT recipients most commonly present with cutaneous lesions, tenosynovitis, or septic arthritis [31]. Dissemination to noncontiguous areas is already present at the time of diagnosis in half of these patients. These forms of infection are most frequently caused by RGM (*M. chelonae*, *M. fortuitum*) but also common with *M. haemophilum* and *M. marinum*, owing to their predilection for cooler body sites like the extremities [48]. Skin lesions are typically papules or painful erythematous or violaceous subcutaneous nodules that can form abscesses and/or ulcerate, usually after 2–3 weeks. Severe complications may include osteomyelitis, tenosynovitis, and arthritis of the joints. *M. marinum* rarely disseminates and classically presents with a localized lesion at the inoculation site after exposure to fresh or saltwater ("fish tank granuloma"), spreading in a lymphangitic distribution resembling sporotrichosis (Fig. 1) [1, 9].

Disseminated infections are not uncommon; approximately 50% of patients with pulmonary disease demonstrate dissemination at the time of diagnosis [10]. In these patients, constitutional symptoms are more often described. Sites of

Fig. 1 *M. marinum* infection in a renal transplant recipient following a puncture wound at the tip of the index finger while hunting ducks in a lake

dissemination can include skin, lymph nodes, bone marrow, visceral organs, and musculoskeletal sites. *M. kansasii* and MAC are the most common SGM-causing disseminated disease. Interestingly, the primary involvement of the allograft has been described with MAC infection and has been reported to cause acute interstitial nephritis in renal transplant recipients and hepatic infection in liver transplant recipients [49, 50]. *M. haemophilum* and *M. genavense* less commonly cause disseminated disease in SOT recipients [51, 52]; intestinal involvement may occasionally occur [52, 53].

In recent years, infections with *M. chimaera* have emerged as part of a global outbreak originating in heater-cooler devices used in surgeries requiring

cardiopulmonary bypass. The incubation period of *M. chimaera* can range from 6 weeks to more than 6 years and can present with initial symptoms that may be very subtle. Thus, a high index of suspicion and awareness of the most frequently described manifestations is key to promptly diagnose and treat this infection. Common reported symptoms are prolonged fever, weight loss, generalized malaise, and night sweats. Eventually, patients may develop sternal/wound infections, mediastinitis, or cardiovascular infections (prosthetic valve endocarditis, aortic graft infection, myocarditis, infected pseudoaneurysms, infections of implantable and ventricular-assist devices). Disseminated disease with bacteremia may involve a variety of organs, including the lung (pneumonitis), spleen (splenomegaly), bone marrow (cytopenias), kidney (nephritis), liver (hepatitis), brain (vasculitis, encephalitis), skin, or bone (spine involvement). More importantly, the presence of choroidal lesions and chorioretinitis – which may be asymptomatic – has been found to be a hallmark of disseminated *M. chimaera* infection [19].

In HSCT recipients, catheter-related infections are the most frequent form of NTM infection, although the organisms most typically involved are RGM, followed by *M. haemophilum* [7, 12, 34, 54]. Skin and soft tissue and pulmonary infections are also common [7]; lymphadenitis is less frequent. In a recent study, Beswick et al. reported 30 NTM infections in HSCT recipients, 28 of which were pulmonary and 2 disseminated (pulmonary and an additional site, 1 skin, 1 blood). Twenty-three of these infections were caused by SGM (MAC, *M. xenopi, M. gordonae*) [26].

Diagnosis

Maintaining a high index of clinical suspicion and considering mycobacteria in the differential diagnosis of infection are key to promptly recognize NTM infection in the transplant host.

There is currently no serological test to diagnose SGM infections. However, it is worth mentioning that, while the interferon-gamma release assays (IGRA) have no role in the diagnosis, the antigens used in these assays cross react with *M. marinum*, *M. kansasii,* and *M. szulgai* and possibly other unrecognized NTM.

Patients in whom pleuropulmonary NTM is suspected should be evaluated with a chest computed tomography scan and with at least two mycobacterial sputum (expectorated or induced) cultures collected on separate days. If the latter cannot be obtained or cultures are negative, yet clinical suspicion remains, bronchoscopy for bronchial washings and cultures should be pursued [11, 47]. The diagnosis of pulmonary NTM disease, notably the distinction of invasive infection and colonization, can be particularly challenging, especially in lung transplant recipients. The American Thoracic Society (ATS) jointly with the Infectious Disease of America (IDSA) [11, 36] and more recently the British Thoracic Society (BTS) [36] have formulated in their guidelines specific clinical, radiographic, and bacteriologic criteria that need to be met to establish a diagnosis of pulmonary NTM infection (Table 2). These criteria are not specific to the immunocompromised population and fit best with MAC and *M. kansasii*.

Table 2 Criteria for the diagnosis of NTM lung disease. Adapted from the American Thoracic Society/Infectious Diseases Society of America guidelines [11]

Clinical criteria (1 and 2)
1. Pulmonary symptoms, nodular or cavitary opacities on chest radiograph, or a high-resolution computed tomography scan that shows multifocal bronchiectasis with multiple small nodules (strong, high)
and
2. Appropriate exclusion of other diagnosis (strong, high)
Microbiological criteria
1. Positive culture results from at least two separate expectorated sputum samples (strong, moderate). If the results are nondiagnostic, consider repeat sputum AFB smears and cultures (weak, low)
or
2. Positive culture result from at least one bronchial wash or lavage (weak, low)
or
3. Transbronchial or other lung biopsy with mycobacterial histopathologic features (granulomatous inflammation or AFB) and positive culture for NTM or biopsy showing mycobacterial histopathologic features (granulomatous inflammation or AFB) and one or more sputum samples or bronchial washing that is culture positive for NTM (strong, moderate)
Other considerations (weak, low)
1. Expert consultation when NTM are recovered that are either infrequently encountered or that usually represent environmental contamination 2. Follow patients who are suspected of having NTM lung disease but do not meet the diagnostic criteria until the diagnosis is firmly established or excluded 3. Making the diagnosis of NTM lung disease does not, per se, necessitate the institution of therapy, which is a decision based on potential risks and benefits of therapy for individual patients

Nevertheless, they serve as a useful reference for the diagnosis of pulmonary infection in transplant recipients, even though they should be applied with caution.

For extrapulmonary disease, clinical suspicion should be raised whenever a transplant recipient presents with unexplained febrile illness, nonhealing wound (s), or cutaneous lesions, septic arthritis, bone infection, or lymphadenitis, especially when routine bacterial cultures are nondiagnostic. In this situation, clinical specimens and tissue from the involved sites should be sent for mycobacterial staining and cultures, as well as histopathology. Repeated sampling may be required to establish the diagnosis. Recovery of an NTM from a sterile source (e.g., blood, synovial fluid, bone) provides straightforward evidence of invasive disease. If disseminated disease is suspected, mycobacterial blood cultures should be obtained.

On histopathology, the visualization of granuloma is characteristic of NTM infection. However, granulomatous responses may be impaired in the transplanted host and thus may not be present.

The recommended method for microscopy staining of NTM is the auramine-phenol stain, and it is preferred over the Ziehl-Neelsen and Kinyoun methods owing to its improved sensitivity [36, 55].

Table 3 Common slow-growing mycobacteria with special requirements for culture

	Optimal growth temperature	Special media for fastidious NTM	Incubation time
M. haemophilum	28–30 °C	Ferric ammonium citrate, hemin, hemoglobin	
M. marinum	28–30 °C		
M. conspicuum	22–30 °C, 37 °C in liquid media		
M. ulcerans	25–33 °C	Egg yolk	
M. genavense		Mycobactin J, acidic pH (pH 5.5)	8–12 weeks
M. malmoense			8–12 weeks
M. xenopi	42–45 °C		
M. gordonae			3 weeks or longer

NTM: nontuberculous mycobacteria

Mycobacterial cultures should be performed on both solid and liquid (broth) media. Liquid culture systems are more sensitive and rapid. However, solid media allow for the evaluation of colony morphology and quantification, growth rate, and identification of mixed infections and also serve as a backup when liquid media cultures are contaminated [11, 36]. Quantification of colonies in sputum samples is a useful tool to distinguish colonization and infection and can be followed to monitor response to therapy.

Most clinically significant SGM grow well at 35 to 37 °C. However, certain species need lower-than-standard temperatures or special media for optimal recovery [11, 55, 56] (Table 3). *M. marinum* and *M. haemophilum* grow at 28–30 °C, *M. conspicuum* at 22–30 °C, and only at 37 °C in liquid media, and *M. ulcerans* grows at 25–33 °C. As a general rule, all skin, joint fluid, and bone specimens should be cultured at 28–30 °C and at 35–37 °C. In addition, fastidious NTM species like *M. haemophilum*, *M. genavense,* or *M. ulcerans* require special supplementation of the media for growth to occur. *M. haemophilum* needs iron-containing compounds such as ferric ammonium citrate, hemin, or hemoglobin. *M. ulcerans* may be optimally recovered with egg yolk supplementation. *M. genavense* needs mycobactin J and can take 8–12 weeks to grow. Thus, when these pathogens are suspected, the laboratory should be notified so that specimens are incubated appropriately to maximize organism recovery.

In general, NTM should be identified to the species level for the optimization of treatment. For MAC, species-level identification is generally not required with the exception of *M. chimaera*, if suspected.

Rapid molecular methods have replaced conventional phenotypic testing (e.g., growth rate, colony morphology, and pigmentation) for more accurate and rapid mycobacterial identification (Table 4). When these techniques are not available locally, isolates should be referred to a reference laboratory [55].

High-performance liquid chromatography (HPLC) can rapidly identify NTM by species by the analysis of mycolic acids. However, HPLC has a limited library of

Table 4 Advantages and disadvantages of molecular diagnostics for SGM

Diagnostic test	Advantages	Disadvantages	Comments
Direct probe assays	Rapid – 2 h From solid and liquid media	From positive culture Only available for MTB, MAC, *M. gordonae*, and *M kansasii* Sensitivity 85–100% Cross-reactivity	
16 s sequencing, Sequencing ITS, rpoB, secA, hsp65	Rapid – 1.5 h Can be performed from liquid media	From positive culture 16 s: Unable to distinguish *M. avium* subspecies, *M. kansasii* and *M. gastri*, *M. marinum* and *M. ulcerans*, and *M. malmoense* and *M. szulgai*	
MALDI-TOF MS	Rapid – 90 min	From positive culture Mostly from solid media Database dependent	Rapid turnaround but slowed by the need of growth
NGS	Rapid: 2–4 days for plasma cell-free DNA NGS in plasma, can be done noninvasively and without need of growth	Technology needs further investigation Cost	

MTB: Mycobacterium tuberculosis, MAC: *Mycobacterium avium complex*, *MALDI-TOF MS:* matrix-assisted laser desorption ionization-time-of-flight mass spectrometry, *NS:* next-generation sequencing

mycobacteria and thus has also been replaced by the newer molecular methods [11].

Direct probe hybridization assays are commercially available for MAC, *M. gordonae*, and *M kansasii (AccuProbe; Hologic, San Diego, CA)* [55]. This technique is based on the release of target 16S rRNA from the organism, identifying the species from solid or liquid culture media within 2 h, with 100% specificity but a sensitivity of 85–100%. Cross-reactivity (e.g., *M. celatum*) has been described [11].

Sequence-based identification, most commonly with the 16S rRNA gene as the target, is increasingly being used. One advantage of this approach is the ability to perform sequencing directly from a positive liquid media culture and its rapid turnaround time (~1.5 days). However, initial growth of an isolate is still required. In addition, some mycobacteria are indistinguishable by 16S rRNA gene sequencing, like the *M. avium* subspecies, *M. kansasii* and *M. gastri*, *M. marinum* and *M. ulcerans*, and *M. malmoense* and *M. szulgai*. Nevertheless, most of these organisms can be differentiated by sequencing of other genes, such as the internal transcribed spacer (ITS), rpoB, secA, or hsp65 [57–59].

In recent years, matrix-assisted laser desorption ionization-time-of-flight mass spectrometry (MALDI-TOF MS) has emerged as a method to reliably identify NTM [60, 61]. It is relatively inexpensive, and results can be obtained within 90 min. Like

16S rRNA gene sequencing, the accuracy of MALDI-TOF MS also depends on the robustness of the database. One caveat is that SGM are often extracted after 14–21 days of growth. Furthermore, the MALDI-TOF MS identification of mycobacteria has been studied mainly using isolates on solid media, which delays significantly the time of reporting compared to sequencing techniques. Although identification directly from broth media looks promising, more studies are needed to determine the appropriate scores to use for the acceptability of species-level identifications [60, 62].

Finally, whole-genome next-generation sequencing (NGS) technologies have emerged as a promising diagnostic platform, but data in the transplant population are lacking. In a recent study evaluating the performance of NGS for mycobacterial detection in liquid cultured clinical samples compared to that of liquid probe assay, the concordance rate of detection was 99.2% (98.7–99.5%). NGS overall sensitivity and specificity were 94.2% (88.4–97.6%) and 99.4% (99–99.7%), respectively [63]. Plasma microbial cell-free DNA NGS has also been used to noninvasively detect mycobacteria, including *M. chimaera*, with rapid turnaround time (~2–4 days) [64, 65]. Further investigation of this technique and clinical experience are needed to better understand its clinical applications and result interpretation.

Management

General Principles

Individual treatment regimens for SGM vary based on the species, but there are a few principles that are common in management. More than one active agent should be used for the treatment of these infections to avoid development of resistance. Susceptibility testing for a particular antimicrobial is proven to be clinically predictive in few instances. Among SGM species, drug susceptibilities are predictive of clinical response only for clarithromycin and amikacin against MAC and rifamycin against *M. kansasii* [11, 47, 66]. There is otherwise no clear correlation between treatment efficacy and susceptibility of other medications in patients treated for SGM with a multidrug regimen.

Recommendations for species-specific treatment of SGM in the transplant population are the same as in immunocompetent individuals with a few notable exceptions. Interactions between NTM therapy and immunosuppressive medications complicate the treatment of this disease for the transplant patient. Azithromycin is the preferred macrolide for the treatment of SGM over clarithromycin since it is a less potent inhibitor of cytochrome P450 (CYP450) and, thus, has less of an impact on calcineurin inhibitor (CNI) and mammalian target of rapamycin (mTOR) levels. Rifampin is a potent inducer of CYP3A4 resulting in decreased CNI and mTOR levels which can lead to organ rejection. Rifabutin exhibits less of this effect and is thus the preferred rifamycin in transplant recipients. Close monitoring of drug levels, medication side effects, and allograft

function during treatment for NTM infection is critical. Careful consideration should be given to the appropriateness of intermittent or three-times-a-week therapy in this population given the potential for fluctuating levels of immunosuppression if thrice-weekly antibiotics are administered and also the potential absorption issues in this population for various reasons (i.e., complications of lung transplantation or GVHD in HSCT patients).

Whenever possible, a reduction in the intensity of immunosuppression should be employed as part of the treatment of SGM infection. However, similar to *Mycobacterium tuberculosis* in transplant patients, paradoxical immune reconstitution inflammatory syndrome (IRIS) is possible. This has been described in a kidney patient with *M. kansasii* infection [67]. In a patient being treated with appropriate antibiotic therapy and reduction in immunosuppression with initial improvement, a clinical deterioration in the absence of positive culture results should prompt consideration of IRIS. An increase in immunosuppression led to favorable response in the abovementioned case.

In addition to lowering immunosuppression as able and treating with antibiotics, surgical debridement is sometimes utilized for NTM infection and should be considered for localized lesions, such as cutaneous disease.

MAC

Drug susceptibility should be performed for MAC against clarithromycin (susceptible $\leq$8 μg/mL, intermediate 16 μg/mL, and resistant $\geq$32 μg/mL) at baseline, if previously treated and if persistent culture positivity despite 6 months of effective therapy [11]. More recently, amikacin MICs have also been shown to be predictive of clinical response; however, breakpoints have not been adopted by the Clinical Laboratory Standards Institute (CLSI). In vitro data from over 400 MAC isolates showed an amikacin MIC $\leq$16 ug/mL was susceptible, 32 ug/mL intermediate, and $\geq$64 ug/mL resistant [68]. Resistance to both of these agents can be acquired while on therapy. Macrolide resistance results from 23S rRNA mutation. Risk factors for acquired resistance include treatment with macrolide monotherapy or macrolide plus a fluoroquinolone alone; therefore, these suboptimal treatment regimens should be avoided [66]. Resistance to amikacin is associated with mutations in 16SrRNA and similarly can develop if a patient is not on a robust treatment regimen [68].

Guidelines suggest treatment with three active agents including a macrolide, ethambutol, and rifamycin for both pulmonary and extrapulmonary MAC infection [11]. Macrolides are the backbone of therapy targeting MAC. There has not been a head-to-head comparison between clarithromycin and azithromycin, but retrospective data shows no difference in response between the two agents for pulmonary disease [69]. A prospective noncomparative trial also showed azithromycin is an effective agent [70]. As mentioned above, azithromycin is the favored macrolide based on better tolerability and lesser drug interactions; the latter is especially pertinent to the transplant population. Rifabutin is the favored

rifamycin in transplant patients to minimize drug interactions [47]. Previous studies of therapy for disseminated MAC infection in AIDS patients showed success with macrolide plus ethambutol combination therapy [71, 72]. Although the data for addition of rifamycin is not strong, this is generally recommended [11, 71, 72]. Case reports of disseminated MAC in transplant patients have shown good outcomes with daily triple antibiotic therapy as per these recommendations [73, 74]. A small open-label study in immunocompetent patients with pulmonary disease suggested dual therapy with macrolide plus ethambutol is non-inferior to guideline-based triple antibiotic therapy [75]. A larger randomized controlled trial is ongoing to further evaluate this finding (clinicaltrials.gov NCT03672630). Notably this study does not include immunocompromised patients, so results may not be applicable to the transplant population.

Addition of intravenous amikacin upfront should be considered for cavitary pulmonary disease or extensive/severe disease [11]. A recent study evaluating patients with pulmonary cavitary disease suggested that those patients that received over 3 months of intravenous amikacin had better treatment outcomes, although this had no impact on rates of recurrence [76]. The decision to initiate aminoglycoside therapy and the treatment duration should be individualized since nephrotoxicity and ototoxicity can be significant. This is particularly relevant to the transplant population who are often receiving other nephrotoxic medications. Liposomal inhaled amikacin has recently been approved for treatment of refractory pulmonary MAC disease (defined as positive cultures for $\geq$6 months). A randomized trial showed that addition of inhaled liposomal amikacin to failing guideline-based therapy resulted in higher rates of culture clearance compared to continuation of guideline-based therapy alone (30% compared to 9%). Adverse events included dysphonia, dyspnea, and hoarseness which generally were more pronounced in the first month of therapy and then dissipated [77].

Treatment of macrolide-resistant MAC is challenging and requires multidrug therapy with little data to support various agents. There are promising novel agents for consideration in the treatment of resistant disease or in those patients who fail to tolerate first-line treatment. Clofazimine has good in vitro activity against slow-growing NTM and has in vitro synergistic activity in combination with amikacin or clarithromycin against MAC [78]. It has been used as part of a salvage regimen and is reported to be safe for use in SOT patients, although this is based on very small numbers [79]. Data in pulmonary MAC disease in non-transplant patients shows a 40% culture conversion rate when added to standard regimen for treatment refractory disease. The most commonly reported side effects in this cohort were related to the skin including discoloration, photosensitivity, and dryness as well as gastrointestinal upset [80]. Fluoroquinolones are additional agents with activity against MAC. A retrospective study of patients with pulmonary MAC who failed first-line therapy showed a 30% microbiologic clearance rate after addition of moxifloxacin to standard therapy [81]. Oxazolidinones can also be utilized to treat MAC. Tedizolid has been shown to have more favorable in vitro MIC values compared to linezolid and thus appears to be a preferred treatment option [82]. Of note, side effects of long-term use of tedizolid appear to be similar to that of linezolid [83]. Bedaquiline is an

option with low in vitro MICs even in clarithromycin- and amikacin-resistant isolates [84]. Preliminary clinical data for treatment-experienced pulmonary MAC including with macrolide-resistant isolates appear promising. Ten patients (six with MAC and four with *M. abscessus*) with refractory NTM pulmonary disease received bedaquiline as part of a multidrug regimen, and a microbiologic response (defined as improvement in semiquantitative sputum culture) was achieved in 60% of patients. Common side effects included nausea, arthralgias, anorexia, and subjective fever [85]. The novel beta-lactam ceftazidime/avibactam also appears to have some activity against MAC [86]. A combination of ceftazidime/avibactam, tedizolid, moxifloxacin, and rifabutin was found to have similar activity in vitro to standard therapy [87]. Further clinical studies involving these potential therapies are needed.

M. chimaera

Recent guidelines for the treatment of *M. chimaera* infection following cardiac surgery with cardiopulmonary bypass suggest combination therapy with azithromycin, ethambutol, and rifamycin. Intravenous amikacin is recommended for at least the first 6–12 weeks with continuation for as long as tolerated. Resistance is rare, but if confirmed, addition of clofazimine is recommended. Even in the absence of resistance to clarithromycin or amikacin, a fifth agent such as clofazimine is often added due to the severity of these infections. Moxifloxacin or linezolid are alternate agents, although they have limited data supporting their use. Revision surgery with the removal of all cardiovascular prosthetic material is recommended for source control. The duration of therapy is not clearly defined, but some experts treat for 12 months after conversion of blood cultures to negative. For those patients who are not candidates for surgery, long-term suppressive antibiotic therapy should be considered [19].

M. kansasii

For *M. kansasii*, rifampin susceptibility has clinical relevance and should be performed routinely at the onset of therapy [11, 47]. The recommended treatment regimen includes a combination of rifampin, isoniazid, and ethambutol [11]. A case series of *M. kansasii* disease in renal transplant patients, including disseminated, cutaneous, and isolated pulmonary infection, showed a 87.5% cure rate with a rifabutin-containing drug regimen. The remaining agents varied, but all patients were treated with at least two drugs with the majority of cases receiving three or more antibiotics [88]. Recently, a retrospective study compared a macrolide-containing regimen to an isoniazid-containing regimen in immunocompetent individuals with pulmonary disease. There was no difference in outcome found between the two groups, suggesting substitution of a macrolide for isoniazid is a reasonable treatment alternative [89].

Other Slow-Growing NTM

There is little data to guide treatment of other slow-growing NTM species. Treatment is based on expert opinion and case reports and is summarized in Table 5 for the most commonly isolated organisms. Table 6 lists medications used in the treatment of SGM with doses, side effects, and notable interactions with immunosuppression.

Duration of Therapy

The optimal duration of therapy in this patient population is not clear. Guidelines recommend 12 months of therapy from date of culture clearance for pulmonary disease and at least 4–6 months for soft tissue disease or bone disease, respectively. Due to underlying immunosuppression, the duration of therapy may need to be longer in transplant patients. It is reasonable to consider these recommended durations as the minimum in this patient population [3, 47]. Relapse is possible after

Table 5 Initial Antibiotic regimens for treatment of common slow-growing NTM infections[a]

NTM species	Recommended regimen	Alternative agents	Considerations
MAC	Azithromycin Rifabutin Ethambutol +/− Amikacin	Clarithromycin Rifampin Amikacin Moxifloxacin Clofazimine Bedaquiline	Amikacin should be included in initial regimen if pulmonary cavitary disease present or considered in setting of severe or disseminated disease
M. haemophilum	Azithromycin Rifabutin Ciprofloxacin	Rifampin Clarithromycin Amikacin Sulfonamides Doxycycline	Not susceptible to ethambutol
M. kansasii	Rifabutin Ethambutol Isoniazid	Rifampin Clarithromycin Azithromycin Moxifloxacin Amikacin Sulfonamides	Macrolide could be substituted for isoniazid
M. marinum	Azithromycin Ethambutol +/− Rifabutin	Rifampin Clarithromycin Azithromycin Sulfonamides Doxycycline Minocycline	Rifabutin can be considered for extensive disease
M. xenopi	Azithromycin Ethambutol Rifabutin +/− Amikacin	Moxifloxacin Amikacin	Similar to MAC, amikacin can be considered for cavitary pulmonary disease or severe disease

[a]Adapted from ATS/IDSA and AST guidelines for treatment of NTM infections [11]

Table 6 Antibiotics used to treat slow-growing mycobacteria

Drug	Dose	Requires renal adjustment	Side effects	Interactions
Amikacin	10–15 mg/kg IV daily or 20–25 mg/kg IV 3x week	Yes	Vestibular/ ototoxicity, renal toxicity	Possible potentiation of renal failure with CNI
Liposomal amikacin inhaled	590 mg inhaled daily	No	Dysphonia, bronchospasm, ototoxicity	None
Azithromycin	250–500 mg PO daily	No	Ototoxicity, QTc prolongation, hepatotoxicity	Increased CNI, CsA, mTOR, and rifamycin levels
Bedaquiline	Load with 400 mg PO daily for 2 weeks, followed by 200 mg PO 3x week	No	Increased risk of death, QTc prolongation, hepatotoxicity, GI upset, headache, chest pain, arthralgias	Rifamycins Potentiation of QTc prolongation with CNI, co-administration with rifampin decreases bedaquiline levels and should be avoided
Ciprofloxacin	500 mg PO twice daily	Yes	GI upset, tendonitis, insomnia/agitation, QTc prolongation, possible aneurism formation	May potentiate nephrotoxic effect of CsA
Clarithromycin	500 mg PO twice daily	Yes	GI upset, hepatotoxicity, QTc prolongation	Increased CNI, CsA, mTOR, and rifamycin levels
Clofazimine	50–100 mg PO daily	No	Skin hyperpigmentation, enteropathy, nausea, and vomiting, QTc prolongation	Potentiation of QTc prolongation with CNI
Doxycycline	100 mg PO twice daily	No	GI upset, photosensitivity, pill esophagitis	None
Ethambutol	15 mg/kg PO daily	Yes	Optic neuritis, peripheral neuropathy	None
Isoniazid	5 mg/kg PO daily (up to 300 mg daily)	No	Hepatotoxicity, taken with vitamin B6 to avoid neuropathy	None
Levofloxacin	500–750 mg PO daily	Yes	GI upset, tendonitis, insomnia/agitation, QTc prolongation,	Increased CNI, CsA levels

(continued)

Table 6 (continued)

Drug	Dose	Requires renal adjustment	Side effects	Interactions
			possible aneurism formation	
Linezolid	600 mg PO daily	No	GI upset, cytopenias, peripheral neuropathy, optic neuritis, serotonin syndrome	None
Minocycline	100 mg PO twice daily	No	GI upset, photosensitivity, vertigo/dizziness	None
Moxifloxacin	400 mg PO daily	No	GI upset, tendonitis, insomnia/agitation, QTc prolongation, possible aneurism formation	None
Rifabutin	300 mg PO daily. If <50 kg, 150 mg daily	Yes	Arthralgias, myalgias, leukopenia, anterior uveitis	Decreased CNI, mTOR inhibitor levels
Rifampin	600 mg PO daily. If <50 kg, 450 mg PO daily	Yes	Orange discoloration of secretions, GI upset, hepatitis, drug-drug interactions	Decreased CNI, mTOR inhibitor levels
Tedizolid	200 mg PO daily	No	Thrombocytopenia, no serotonin syndrome risk	None
Trimethoprim/ sulfamethoxazole	8–12 mg/kg/d of TMP component PO divided twice daily (max 320 mg/d)	Yes	Nephrotoxicity, cytopenias, rash	Possible potentiation of renal failure with CNI

PO: per os, *CNI:* calcineurin inhibitors, *CsA:* cyclosporine, *GI:* gastrointestinal, *TMP:* trimethoprim

completion of therapy, especially in the setting of ongoing immunosuppression, so patients should have ongoing clinical and, if possible, microbiologic monitoring.

Prevention

Since these organisms are found in the environment, transplant patients should be counseled on lifestyle modifications which may reduce the risk of SGM exposure. They should wear gloves while cleaning fish tanks and during gardening. Hot tubs,

saunas, and ultrasonic humidifiers should be avoided [7, 90]. Sterile water should be used for sinus and respiratory care [90]. Maintaining the house water heater temperature greater than 130 degrees Celsius has been associated with less NTM growth in the water circuit [13]. Monthly shower head cleaning with bleach should be considered [90]. Providers should optimize management of other comorbidities that are associated with pulmonary NTM disease such as gastroesophageal reflux and aspiration.

The management of transplant candidates who are colonized or infected with NTM organisms pretransplant can be challenging. This occurs most commonly in the lung transplant population as many of these transplant candidates have structural lung disease, such as CF or COPD, which is a risk factor for the presence of NTM. NTM infection incidence in the CF population is as high as 20% [24]. The significance of colonization with SGM including MAC pre-lung transplant is unclear. Practices vary from no treatment with monitoring to pretransplant and/or peritransplant anti-mycobacterial therapy. The American Society of Transplantation recommends that lung transplant candidates colonized or infected with MAC should be treated with multidrug therapy prior to transplant [47]. However, others suggest observation without treatment may be reasonable based on the finding that most cases of MAC pulmonary disease occur later posttransplant, suggesting environmental acquisition rather than early recolonization of allograft with host flora [7, 8].

Azithromycin secondary prophylaxis is sometimes considered based on experience with AIDS patients, although there is no data backing this in transplant patients. In support of this practice is the observation that CF patients with their first episode of NTM growth on culture were less likely to have received chronic macrolide therapy within the last year [91]. Routine screening for NTM should be performed in patients who are maintained on azithromycin as secondary prophylaxis due to concerns for the development of macrolide resistance. An additional caveat of long-term azithromycin use is the potential for polypharmacy-related adverse events. Given these disadvantages, close monitoring after completion of therapy is preferred over extended macrolide therapy [90]. Relapse of NTM disease is fairly common and may be more so in the setting of need for ongoing immunosuppression [69]. Therefore, it is important to monitor patients closely for relapsed or recurrent disease.

Conclusion

Slow-growing NTM infection is relatively rare posttransplant, but the incidence is increasing. In transplant recipients, NTM infections can be difficult to recognize, but carry significant associated morbidity and mortality. Clinicians should maintain a high index of suspicion for this disease, so it can be diagnosed and monitored or treated accordingly. Advances in mycobacterial diagnostics, notably in molecular testing, hold promise for rapid and accurate identification of these NTM. Further research is needed to better understand NTM infections in this population, to improve diagnostic and preventive strategies, and to investigate new and more tolerable therapeutic regimens.

Key Points

- Slow-growing NTM infections are relatively rare posttransplant, but the incidence is increasing.
- In the transplanted host, clinical manifestations of NTM infection may be protean, and NTM classically cause one of six clinical syndromes: pleuropulmonary disease, skin and soft tissue infection, musculoskeletal infection, catheter-associated disease, lymphadenitis, or disseminated disease.
- Molecular diagnostic techniques are emerging and replacing traditional methods for rapid and accurate identification of NTM.
- The clinical impact of the presence of slow-growing NTM depends on the site and extent of involvement, host immune status, and comorbidities.
- Treat with a multidrug regimen based on current guidelines. Treatment will often need to be individualized to the patient based on drug-drug interactions and tolerance of therapy.

Introduction

Nocardia species are ubiquitous Gram-positive bacteria belonging to the *Actinomycetaceae* family and are responsible for opportunistic infections in humans. While nocardiosis may affect immunocompetent individuals, the disease is more commonly seen in immunocompromised patients such as recipients of solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients. The most common sites of infection include the lung, skin, and central nervous system. Disseminated disease affecting multiple organs may occur in 40% of transplant recipients with nocardiosis and is associated with a high mortality. In this chapter, we will review the disease epidemiology of *Nocardia* species and clinical impact of infection and give an overview of diagnosis and management strategies, with special consideration given to the solid organ and hematopoietic stem cell transplant recipient.

Disease Epidemiology of *Nocardia*

Routes of Infection

Nocardia spp. are ubiquitous environmental organisms found in stagnant water, decaying plants, and soil. As the organism is readily aerosolized, the main portal of entry for this bacterium is inhalation into the lung, although direct ingestion and inoculation via skin injury are other forms of recognized entry sites for the bacteria [1–3]. Given the potential for this bacterium to be aerosolized, clusters of infections have been reported in immunocompromised patients related to occupational exposures with soil [4] and nosocomial infection from construction work [5].

Nocardia Species Responsible for Infection in Humans

Over 80 species of the genus *Nocardia* have been identified to date, with at least 40 species implicated in human infection. In the last decade, the use of novel molecular technology such as PCR-restriction enzyme analysis and 16S ribosomal RNA (rRNA) sequencing has greatly enhanced our ability to identify *Nocardia* species that are predominantly responsible for human infection [1]. These include *Nocardia asteroides*, *N. nova*, *N. farcinica*, *N. otitidiscaviarum*, *N. transvalensis*, *N. brasiliensis*, *N. brevicatena*, *N. abscessus*, *N. cyriacigeorgica*, *N. veterana*,

N. paucivorans, *N. wallacei*, *N. blacklockiae*, *N. elegans*, *N. concava*, and *N. cassostreae.*

N. farcinica and *N. nova* complex have been identified as the major species responsible for disease in SOT recipients accounting for over 50% of cases in one study in which isolates were identified with sequencing of 16S rRNA or hsp65 gene [6]. Isolates less commonly found responsible for infection in this particular study were *N. cyriacigeorgica*, *N. abscessus*, *N. veterana*, *and N. beijingensis*. *Nocardia* species responsible for infection in the HSCT population are less well-characterized, but in a study from MD Anderson Cancer Center of 132 patients of which 30% received a stem cell transplant, 27 species of *Nocardia* were identified as being responsible for infection with the most prevalent being *N. nova*, *N. cyriacigeorgica*, *N. farcinica*, *and N. abscessus* [7].

Incidence and Risk Factors for Nocardiosis in Solid Organ Transplant Recipients

Given that T cell-mediated immune responses are protective against infection with *Nocardia*, transplant recipients, persons living with HIV, and those on systemic corticosteroid immunosuppression are at higher risk of infection. In SOT recipients, the incidence of nocardiosis is estimated to be between 0.04% and 3.5% [8–10] and highest in heart and lung transplant recipients [9, 10] likely reflecting the differences in the net state of immunosuppression among organ transplant subtypes and respiratory portal of entry for the bacterium. Onset of infection typically occurs within the first 2 years of transplantation, with infection within the first month considered to be very rare [6, 10, 11] and late infection (greater than 2 years posttransplant) also rare, but still possible. In a large retrospective case-control study of solid organ transplant recipients [6], high level of immunosuppression preceding or at the time of diagnosis was identified as the main risk factor for nocardiosis following solid organ transplant. *Cytomegalovirus* disease 6 months prior [10] has also been associated with nocardiosis, but it is not clear whether this finding represents coinfection due to high level of immunosuppression or a causal immunomodulatory factor increasing susceptibility to *Nocardia* infection. Overall risk factors for nocardiosis in SOT recipients are summarized in Table 1.

Incidence and Risk Factors for Nocardiosis in Hematopoietic Stem Cell Transplant Recipients

Fewer studies have characterized the epidemiology of nocardiosis in HSCT recipients. While nocardiosis can occur in autologous stem cell transplant recipients, it is allogeneic stem cell transplant recipients who are at higher risk with a reported incidence of 0.5–1.7% within the first 2 years of transplant [4, 12–14]. Late infections, with a median onset of 508 days HSCT, have been described in a small case series [15], but in these patients, the vast majority were receiving

Table 1 Risk factors for nocardiosis in solid organ transplant recipients

High-dose corticosteroids at the time of diagnosis
Use of tacrolimus
High calcineurin inhibitor trough level 1 month before diagnosis
Prolonged stay in intensive care unit after transplant
Patient age
Coinfections (*Cytomegalovirus*)

high-dose steroids for graft-versus-host disease. The small size of all of these studies in immunocompromised population did not permit a detailed analysis of independent risk factors for infection, but like their solid organ transplant counterparts, an augmented net state of immunosuppression is likely to be a contributory factor in the risk of infection.

Trimethoprim-sulfamethoxazole (TMP-SMX) is frequently used as prophylaxis following SOT and HSCT for the prevention of *Pneumocystis jirovecii* pneumonia. While this drug is active in vitro and in vivo against many *Nocardia* species, breakthrough infections have been reported in transplant recipients receiving TMP-SMX, and thus use of this drug should not be considered a protective factor in the evaluation of a patient with possible *Nocardia* infection [6, 10, 16].

Clinical Impact on Solid and Hematopoietic Stem Cell Transplantation

Mortality

Although infections with *Nocardia* spp. are considered to be rare, the mortality from this infection is high. In SOT recipients, historical mortality rates from small case series have been reported to be between 11% and 70% [10, 17–19]. A more recent, larger, European case-control study of 117 patients demonstrated a tenfold higher mortality in solid organ transplant recipients with nocardiosis compared to a control group without infection, with a 1-year, all-cause mortality rate of 17% [20]. Independent risk factors for mortality identified in this study included history of malignancy, history of invasive fungal infection, and donor age. Interestingly, in this same study, acute rejection in the year proceeding the diagnosis (with resultant intensification of immunosuppression) was associated with *reduction* in mortality. The authors speculated that this paradoxical finding may have been due to these patients receiving more vigilant surveillance for infection leading to earlier detection and treatment of *Nocardia* or possible benefits associated with the immunosuppression-associated modulation of inflammatory response from *Nocardia* infection. Mortality rates in HSCT recipients are less well-characterized, but several small case series have reported mortality rates in the range of 40–50% [4, 13, 15]. Further, larger studies in HSCT recipients are required for better estimation of mortality in this population.

Treatment-Associated Morbidity

Due to the antimicrobial-associated side effects of many first-line choices for nocardiosis, treatment-associated morbidity is important in solid organ transplant and stem cell transplant recipients. For several decades, sulfonamide-based therapy (e.g., trimethoprim-sulfamethoxazole) was established as the drug of choice for nocardiosis due to its widespread activity against many *Nocardia* species and ability to achieve high concentrations in affected tissues (including the brain, skin, and lung). However, gastrointestinal disturbances, bone marrow suppression, and nephrotoxicity have led to cessation of this antibiotic during *Nocardia* treatment in up to 50% of cases [21, 22]. Other antimicrobial-associated toxicities which should be noted are nephrotoxicity and ototoxicity with amikacin, seizures with carbapenem therapy, and bone marrow suppression, peripheral neuropathy, and lactic acidosis with linezolid. A special toxicity consideration in transplant patients is the use of calcineurin inhibitors (cyclosporine and tacrolimus) which may lead to additive renal injury [23] due to the concomitant use of antimicrobials such as TMP-SMX and amikacin. In addition, for any antimicrobial used, it is important to assess the potential impact of drug-drug interactions with immunosuppressive medications and monitor immunosuppression levels accordingly [24].

Graft Outcomes

Allograft rejection and graft-versus-host disease (GvHD) have been reported as outcome measures in studies of nocardiosis in transplant recipients. While the rates reported are typically high, 9–70% in solid organ transplant recipients [11, 19, 25] and 52–83% in HSCT recipients [4, 13, 26], it is unclear if these numbers represent a direct consequence of infection with *Nocardia* or representative of the aberrant immunological state of the host preceding the diagnosis of nocardiosis.

Disease Diagnostics and Clinical Evaluation of *Nocardia*

Pulmonary Nocardiosis

Given that inhalation remains the most frequent portal of entry for *Nocardia*, pulmonary disease is the most frequent clinical presentation of nocardiosis in transplant recipients, occurring at least 80% of the time [6]. The tempo of presentation in transplant recipients can be acute, subacute, or chronic, and symptoms may include dyspnea, cough (productive or nonproductive), chest pain, or hemoptysis [27]. Constitutional symptoms may be present such as fever, chills, and weight loss. A wide variety of radiographic presentations of nocardiosis have been described in the literature including lobar pneumonia (also multi-lobar involvement), diffuse interstitial pneumonia, and pleural effusions. However nodular and cavitary lesions

are most typical [28] and should immediately raise suspicion for infection with *Nocardia*. An analysis of *Nocardia* infection presentations in patients with a wide spectrum of immune competency found that pulmonary cavitation was a distinct clinical presentation of patients receiving immunosuppression compared to those that did not [29]. Isolation of the organism with sputum culture and bronchial alveolar lavage (BAL) are appropriate initial diagnostic steps. If diagnostic uncertainty persists following these initial tests, transbronchial biopsy or open surgical/percutaneous lung biopsy may be necessary.

Cutaneous Manifestations

Cutaneous manifestations of nocardiosis include nodular lesions, ulcers, mycetomas, cellulitis, and skin abscesses [2]. In studies of solid organ transplant recipients with nocardiosis, cutaneous manifestations represent approximately 10% of all presentations [10, 17, 18]. The mechanism of infection may be direct inoculation of the organism secondary to injury or trauma or by dissemination from other organs to the skin. As in pulmonary disease, the time course of presentation can be both acute and subacute. It is important to note that many of the cutaneous manifestations of nocardiosis can mimic other opportunistic infections in transplant recipients, such as fungal and mycobacterial infections [30]. Thus, obtaining a microbiologic diagnosis with tissue biopsy is essential. In addition, given that cutaneous manifestations may represent part of a disseminated process, imaging evaluation of the lung and brain should be performed routinely in patients presenting with skin disease.

Central Nervous System Manifestations

Brain involvement of *Nocardia* infection may occur in up to one third of cases of nocardiosis. In 30 cases of central nervous system (CNS) nocardiosis of solid organ transplant recipients reported by Coussement et al. [6], over 40% of these patients were asymptomatic, illustrating the importance of routine evaluation of the central nervous system (preferably with magnetic resonance imaging (MRI)) in *Nocardia* infection, regardless of symptoms. Infection of the CNS is believed to be a secondary dissemination by the bloodstream although positive blood cultures are rarely detected. Neurological manifestations of central nervous system nocardiosis include asymptomatic presentation, headache, focal neurological signs, seizures, and coma [31]. Radiographic findings of CNS nocardiosis typically include single or multiple brain abscesses that may involve both cerebral hemispheres. An example of nocardiosis presenting as a brain abscess is shown in Fig. 1. Additional CNS radiological presentations that have been reported in solid organ transplant recipients include ventriculitis and spinal cord abscesses. If a microbiologic diagnosis has already been obtained from another organ site (such as the lung or skin), it is reasonable to assume that the radiographic abnormalities seen in the brain are part of the same infective process. However in the absence of the clear microbiologic

Fig. 1 Coronal MRI (T1 post-contrast image) of a patient showing an abscess in the right cerebellar hemisphere. Surgical drainage of the abscess and culture later revealed the etiology of this infection as *Nocardia ignorata*

diagnosis, brain biopsy may be necessary to confirm the diagnosis of central nervous system nocardiosis [32]. Among the *Nocardia* species described, *Nocardia farcinica* has been associated with predilection for CNS infection [6, 33], although, as stated before, evaluation for CNS disease should be routinely performed regardless of *Nocardia* species.

Other Presentations of Nocardiosis

Disseminated nocardiosis is defined as *Nocardia* infection involving two organs that are not contiguous. It represents the most severe spectrum of disease conferring a high mortality and has been reported to occur in up to 40% of solid organ transplant recipients with nocardiosis. Other less common presentations of *Nocardia* infection that have been described included involvement of the eye, liver, kidney, and adrenal gland and spinal abscess.

The presentations and approaches to diagnosis of nocardiosis of the skin, lung, and brain are summarized in Table 2.

General Approach to Diagnosis of Nocardiosis

Isolation of *Nocardia* in culture from a suspected site of infection in a patient with clinically compatible disease is sufficient for the diagnosis of nocardiosis. Often, obtaining such cultures may entail invasive diagnostic and potentially risky

Table 2 Presentation and diagnoses of nocardiosis in transplant recipients

Skin	Presentation	Diagnosis
	Nodule Ulcer Mycetoma Cellulitis Abscess	Skin biopsy
Pulmonary disease		
	Consolidation Nodules Cavitary lesion Pleural effusion	Sputum sample Bronchoscopy with BAL Transbronchial biopsy Surgical or percutaneous biopsy
CNS disease		
	Brain abscess Meningitis Ventriculitis Spinal abscess	Brain biopsy (if no other Lesion can be biopsied) Spinal abscess biopsy Lumbar puncture (if deemed safe)

procedures including biopsy sampling of lung or brain tissue, but these are warranted given the antimicrobial toxicities associated with empiric treatment for *Nocardia* and need to exclude other opportunistic infections. *Nocardia* colonization of the respiratory tract is possible particularly in immunocompetent patients with structural lung disease, but the isolation of *Nocardia* from culture in a transplant recipient should generally be considered to be pathogenic unless there is substantive evidence that points to the contrary.

Nocardia can be detected on both Gram stain and modified acid-fast stain (Fig. 2). On Gram stain, *Nocardia* is seen as a filamentous Gram-positive branching rod. Isolation of the organism for culture, identification, and antimicrobial susceptibility can take anywhere from a few days to several weeks. While the organism can grow on nonselective media, recovery of the bacteria may be enhanced by longer incubation period and use of selective media such a Thayer-Martin agar.

Identification of *Nocardia* down to the species level can be incredibly helpful in guiding empiric antimicrobial therapy given the taxonomic association with

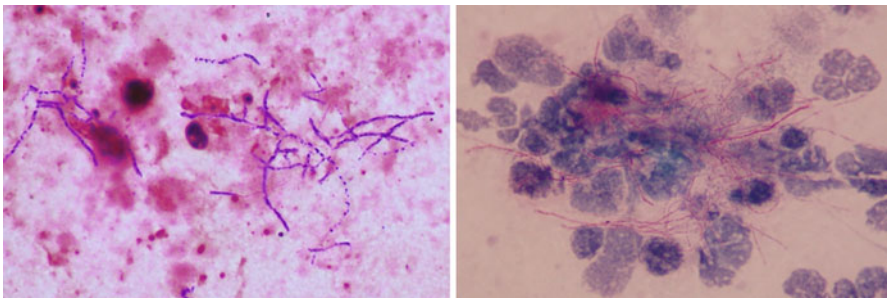

Fig. 2 On the left panel, Gram stain depicting filamentous Gram-positive branching bacteria later identified as *Nocardia* species (original magnification x 100). The right panel shows *Nocardia* species staining positive on modified acid-fast stain (original magnification x 100). (Courtesy of Dr. Dominick Cavuoti, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX)

antimicrobial susceptibilities (discussed later in this chapter). Identification of species is best performed with sequencing of the 16S ribosomal ribonucleic acid, hsp65, secA1, or gyrB genes [34, 35]. Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry is an alternative method of rapid identification with correct species-level identification reported between 75% and 95% [36–38], depending on the quality of the reference library used.

There has been a recent interest in the use of 16S PCR-based assay to detect *Nocardia* spp. from clinical samples. This may reduce time to diagnosis and may be especially useful in circumstances where the patient has received antibiotic therapy, potentially compromising the yield of traditional culture methods. In a recent study of 68 patients including 14 solid organ transplant patients and 14 allogeneic stem cell transplant recipients, the sensitivity and specificity of the test were 74% and 87%, respectively [39]. In a prospective of study of 21 lung transplant recipients, evaluating *Nocardia* PCR on BAL specimens, *Nocardia* PCR was positive from 5 BAL specimens performed for routine surveillance only. None of these patients developed clinical disease, and thus a major drawback of PCR-based diagnosis, particularly in respiratory samples, is the risk of detecting airway colonization [40].

Management

Empiric Therapy

After isolation of *Nocardia* spp. in the setting of suspected clinical infection, antimicrobial therapy remains the mainstay of therapy. However, there are a number of challenges associated with therapeutic decision-making. Firstly, each species of *Nocardia* has a unique antimicrobial susceptibility profile, and thus "empiric" antimicrobial decisions including the use of combination therapy with two or three

agents in severe disease may be needed until susceptibility testing is available. This may take up to several weeks due to slow-growing strains and technical challenges of performing susceptibility testing. Secondly, special consideration should be given with regard to the site and severity of disease to ensure appropriate penetration of antibiotics into the affected site. Lastly, minimization of drug interactions and antimicrobial toxicities is important given the need for long-term therapy to achieve clinical cure in these patients. When antimicrobial susceptibility testing is still pending, identification of *Nocardia* down to the species level can be helpful in designing empiric therapy given the previously reported taxonomic variances reported of *Nocardia* isolates. Particular attention should be paid to the following resistance patterns associated with *Nocardia* species, and these typical susceptibility patterns are reported in Table 3. For example, *Nocardia farcinica* is usually resistant to ceftriaxone and has variable susceptibility to TMP-SMX. Variable activity of amikacin has been described against *Nocardia transvalensis*, and variable activity of imipenem has been described against *Nocardia brasiliensis*, *Nocardia abscessus*, and *Nocardia otitidiscaviarum*.

In vitro susceptibility testing should be performed at a specialized laboratory experienced at testing *Nocardia* strains. Multiple antimicrobials should be tested up front given the potential need to adjust therapy including switch from intravenous to oral therapy or switch due to antimicrobial-associated toxicities. These include amikacin, amoxicillin-clavulanate, ceftriaxone, ciprofloxacin, clarithromycin, imipenem, linezolid, minocycline, trimethoprim-sulfamethoxazole, and tobramycin.

There are no randomized trials to guide optimal therapy for *Nocardia* infection including single versus combination antibiotic therapy and duration of therapy. For empiric therapy the following antimicrobials should be considered based on their widespread activity against *Nocardia* species and evidence supporting clinical use. These are TMP-SMX, carbapenems (imipenem and meropenem), amikacin, third-generation cephalosporins (ceftriaxone and cefotaxime), and linezolid. Table 4 gives a suggestion for empiric treatment (in the absence of *Nocardia* spp. identification or antimicrobial susceptibility testing) for each of the main clinical presentations of nocardiosis.

It is reasonable to consider monotherapy with TMP-SMX as a first-line agent for mild skin and pulmonary disease given that this drug has high bioavailability and widespread activity against *Nocardia* isolate. Likewise monotherapy with linezolid could also be considered for the same indications, but current data supporting this clinical use is lacking. The use of combination therapy has been suggested by many authors for severe pulmonary disease, disseminated disease, and central nervous system involvement [2, 9, 42]. Such practice has been based on the following premises: synergy data of combination antimicrobials from murine models (particularly with imipenem and amikacin), improved clearance of high-burden disease with addition of bactericidal drug to bacteriostatic drug (e.g., addition of imipenem to TMP-SMX), and life-threatening disseminated or CNS disease where, in the absence of susceptibility data, probability of effective therapy is increased by the use of multiple antimicrobials.

Table 3 Antimicrobial susceptibility of Nocardia spp.

Antibiotic	*N. abscessus*	*N. farcinica*	*N. nova* complex	*N. brasiliensis*	*N. transvalensis*	*N. otitidiscaviarum*	*N. cyriacigeorgica*

Table 4 Suggested approach to empiric therapy for *Nocardia* infection in transplant patients

Organ involved	Suggested empiric therapy	Alternative therapy
Skin	TMP-SMX	Linezolid
Lung	**For mild disease**: TMP-SMX **For severe disease**: TMP-SMX + imipenem Imipenem + amikacin	Imipenem + linezolid
Brain	TMP-SMX + imipenem TMP-SMX + imipenem + amikacin	Imipenem + amikacin +/− linezolid TMP-SMX + imipenem +/− linezolid
Severe disseminated disease	TMP-SMX + imipenem TMP-SMX + imipenem + amikacin	Imipenem + amikacin +/− linezolid TMP-SMX + imipenem +/− linezolid

Duration of Therapy

There are still important questions that remain unanswered with regard to ongoing antimicrobial therapy, timing of transition from intravenous to oral therapy, and optimal duration of therapy. The consensus regarding these questions differs and should not supersede clinical judgment and the patient's response to therapy.

Several authors have suggested the use of a minimum of 2 weeks of intravenous antibiotics for severe skin or pulmonary disease and up to 6 weeks for central nervous system disease [41, 42]. While this is a reasonable recommendation, we would add the caveat that assuming there is a suitable oral antibiotic available based on antimicrobial susceptibility testing, a switch from intravenous to oral antibiotic therapy is reasonable if the patient is able to tolerate oral medications without concern for malabsorption, and the antibiotic of choice has high bioavailability with appropriate penetration into the affected tissue site. Use of continuation combination therapy when antimicrobial susceptibility testing has resulted, although not proven to be superior versus single agent therapy, is a reasonable consideration in the following circumstances: high-burden disease and concern regarding pharmacokinetic and/or pharmacodynamic properties of a single antimicrobial.

Given the slow clearance of the organism on antimicrobial therapy and risk of relapse after cessation of therapy, durations of therapy have historically been set to be several months with at least 3 months for skin and soft tissue disease and 12 months recommended for disseminated or CNS disease. A suggested range of duration of therapy based on disease sites is listed in Table 5. It is important to note that shorter durations of therapy have been successful in solid organ transplant recipients including a study in heart transplant recipients where duration of therapy less than 3 months was successful [11]. At this present time, it is unclear which patients may be suitable for shorter-course therapy. After completion of therapy, the risk of relapse has been estimated to be around 5% in solid organ transplant recipients [16], and thus monitoring for recurrence should continue for up to 1 year.

Table 5 Suggested durations of therapy for nocardiosis depending on disease site

	Duration (based on clinical and/or radiographic resolution)
Skin	3 months
Mild pulmonary	6 months
Severe pulmonary	6–12 months
Disseminated and CNS disease	12 months

Drug Toxicity Monitoring

Specific monitoring for myelosuppression and kidney function is required, especially if agents such as TMP-SMX, linezolid, and amikacin are used. For several decades, the use of sulfonamide drug monitoring has been proposed (with a target 2-h post-dose peak level of 100–150 micrograms/ml deemed as safe and therapeutic) for *Nocardia* and other sulfonamide-responsive infections such as *Pneumocystis jirovecii* [43]. A recent study examining sulfamethoxazole use and drug monitoring for a variety of infections (predominantly *Pneumocystis jirovecii* and *Stenotrophomonas maltophilia*, but also including *Nocardia*) has not shown a correlation between the aforementioned drug level and therapeutic efficacy or toxicity [44]. Thus, the role of routine monitoring of sulfonamide levels in therapy of *Nocardia* is unclear. It may be considered in the setting of concern for malabsorption, therapeutic failure, or suspected sulfa drug-related toxicity.

The Role of Adjunctive Surgery

Surgical intervention in conjunction with antimicrobial therapy can be considered for high-burden skin disease and in cerebral abscesses [45, 46]. The optimal approach to management of CNS nocardiosis is not established. Criteria for neurosurgical intervention have been proposed by Mamelak and colleagues [32]. They propose conservative (nonsurgical) management for extra-neurological infection documented with minimal neurological deficit and small abscess (less than 2 cm) and for multiple abscesses where surgery would be technically challenging with poor potential outcome. Mamelak and colleagues suggest surgical intervention for abscesses greater than 2.5 cm, for failure to respond to clinical treatment, or in cases of diagnostic uncertainty.

Immunosuppression Reduction and Immune-Based Therapy

Given the impact of T cell-mediated immunosuppression on the risk of nocardiosis and related mortality, reduction of immunosuppression is extremely important in clearing of disease although this should be carefully weighed against the risk of allograft rejection and GvHD. Although autoantibody production to GM-CSF has been implicated in the disease pathogenesis of nocardiosis [47], therapy with GM-CSF has not been studied as an adjunctive therapy for nocardiosis.

Use of Oxazolidinone Antimicrobials in Therapy: Linezolid and Tedizolid

The oxazolidinone antibiotic class comprising of linezolid and more recently tedizolid represents a promising advance in the therapy for nocardiosis, due to universal in vitro activity of the drugs against all species of *Nocardia* and excellent bioavailability. An 84% cure rate was reported in 19 lung transplant recipients with nocardiosis that were treated with linezolid [48]. However, toxicities including myelosuppression, peripheral neuropathy, and lactic acidosis and serotonin syndrome (when concurrent selective serotonin reuptake inhibitor (SSRI) drugs are used) are documented risks of therapy. Tedizolid is a novel oxazolidinone with a wide spectrum of actions against Gram-positive organisms and nontuberculous mycobacteria. It has been shown to be two- to threefold more potent than linezolid in vitro against common species of *Nocardia* except for *N. nova* and *N. brasiliensis* [49]. Tedizolid has lower rates of myelosuppression and has a lower risk for SSRI-mediated drug-drug interactions and thus holds significant promise in the long-term treatment of nocardiosis. Tedizolid (in combination with TMP-SMX) was successfully used for 6 months to treat CNS nocardiosis in a patient with multiple myeloma without myelotoxicity [50]. CLSI breakpoints for tedizolid have not been established for *Nocardia* spp., and a theoretical concern exists with regard to use of tedizolid for CNS disease given higher protein binding and lower CNS penetration [51].

Prevention

As iterated earlier, breakthrough infections with *Nocardia* spp. in patients on TMP-SMX for opportunistic infection prophylaxis have occurred in SOT recipients. While TMP-SMX may confer partial protection against *Nocardia* or delay onset of infection, it should not be considered an absolute preventative measure for either primary or secondary prevention of *Nocardia* infection in this population. In the HSCT population, the preferential use of atovaquone over TMP-SMX has been reported in one center to lead to increased rates of nocardiosis although this observation is based on small numbers [15]. Like their solid organ transplant counterparts, breakthrough *Nocardia* infections have still been reported in stem cell transplant recipients receiving TMP-SMX as the primary prophylaxis [13]. Thus, the optimal approach for primary or secondary prophylaxis in both solid organ and stem cell transplant recipients thus remains uncertain.

Conclusion

Nocardiosis is a rare opportunistic infection in solid organ and stem cell transplant recipients associated with considerable morbidity and mortality. The most common type of presentation is pulmonary infection, and in all cases central nervous system infection should be ruled out with imaging. While the majority of presentations are within the first 2 years of transplant, late presentations are possible and often related

with a higher level of immunosuppression. Identification of the *Nocardia* down to the species level and antimicrobial susceptibility testing are imperative to guide antimicrobial therapy. Initial therapy may require use of combination of antimicrobials, and durations of therapy are often several months. Relapse of disease is possible after cessation of treatment. There is an ongoing need for novel antimicrobials that can be used against *Nocardia* spp., which are both effective and tolerable in the transplant recipients.

Key Points

- Nocardiosis is a rare but serious opportunistic infection in transplant recipients commonly affecting the lung, brain, and skin.
- Use of primary TMP-SMX prophylaxis for *Pneumocystis jirovecii* pneumonia should not be considered protective for *Nocardia* infection.
- For pulmonary disease, the diagnosis should strongly be considered in transplant recipients with nodular or cavitary lesions of the lung.
- Communication with the microbiology lab is essential in order to maximize the yield of culture specimens. Identification of *Nocardia* down to the species level and antimicrobial susceptibility testing and an experienced laboratory are strongly recommended.
- All transplant recipients should have brain imaging performed to rule out central nervous system disease.
- The use of empiric combination therapy (involving addition of beta-lactam such as imipenem to TMP-SMX or linezolid) can be considered for severe disease in immunocompromised hosts.
- Durations of therapy are variable and can be as short as 3 months for limited skin disease and up to 12 months for central nervous system disease.

Disease Epidemiology

Mycoplasma spp. and *Ureaplasma* spp. are cell wall-lacking bacteria that belong to the class of *Mollicutes*. The term genital mycoplasmas encompasses *Mycoplasma hominis*, *M. genitalium*, *Ureaplasma urealyticum*, and *U. parvum*. Genital mycoplasmas are sexually transmitted. *M. genitalium* is considered a true sexually transmitted disease, whereas *M. hominis*, *U. parvum*, and *U. urealyticum* can be found in both healthy and symptomatic individuals [1]. Asymptomatic carriage is common, and the majority of individuals does not develop symptoms. Ureaplasma infection has been associated with chorioamnionitis, preterm labor, and preterm birth [2, 3]. Beyond, vertical transmission during delivery seems frequent, and an association with bronchopulmonary dysplasia of the neonate has been described [4–6]. In

immunosuppressed patients, *M. hominis* can be a relevant pathogen in urogenital and extragenital infections [7]. A broad range of manifestations has been described encompassing bacteremia, vascular, wound, central nervous system, respiratory tract, and joint infections [7]. In hypogammaglobulinemic patients, joint infections were attributed to infection with *Ureaplasma urealyticum* [8]. It has been hypothesized that the origin of extragenital infections is frequently the urogenital tract.

M. pneumoniae most frequently affects the respiratory tract in the general population [9]. Extrapulmonary manifestations are present in up to 25% of individuals with *M. pneumoniae* infection and can infect the central nervous system, heart, kidney, gastrointestinal tract, ears, and/or bloodstream. Pneumonia is an uncommon presentation in children below 5 years of age and is most frequent among school-aged children, with a decline in adolescence. In elderly adults suffering from pneumonia, higher age was associated with an increase in *M. pneumoniae* infections [9]. Skin findings associated with *M. pneumoniae* infections are common, being present in up to 25% of infected individuals. The spectrum ranges from mild findings presenting as relatively transient rashes or urticaria to severe manifestations such as bullous exanthems, Stevens-Johnson syndrome, or involvement of mucous membranes [9–11]. Human-to-human transmission occurs via droplet infection. Notably, individuals can remain infectious even after resolution of symptoms. Children are a frequent reservoir due to what can commonly be an asymptomatic or mild course combined with prolonged shedding, even after treatment [12]. In closed or semi-closed settings, outbreaks have been described, such as in a residential facility for adults with developmental disabilities [13].

Clinical Impact in Transplant

Epidemiological data on solid organ and hematopoietic stem cell transplant recipients are scarce and predominantly limited to single-case reports or small case series, which we will review.

Lung, Heart, and Combined Heart-Lung Transplantation

Overall, *M. hominis* seems to be a rare pathogen in surgical site infections after lung and lung/heart transplantation. In a retrospective single center study of deep surgical site infections (SSI) after lung transplantation, a single case out of 31 cases with SSI was caused by *M. hominis* [14] which presented as pericarditis.

M. hominis infections after lung transplantation can be donor-derived. In a cluster of three lung transplant recipients with *M. hominis* infections, whole-genome sequencing indicated clustering of a donor-recipient pair, whereas the two other cases showed genetically unrelated *M. hominis* isolates [15]. At a center in the United States, seven cases of *M. hominis* infections after cardiothoracic transplantation were observed over a time span of 18 years [16]. Clinical presentations encompassed sternal wound infections, pleuritis, mediastinitis, and anastomosis

leaks. In this case series, all patients recovered. All but one patient underwent revision surgery. Antibiotic treatment was given to all affected patients, of which treatment duration varied widely ranging from days to lifelong therapy. Two cases received single lung transplants from the same donor, and multilocus sequence typing also suggested a donor-derived infection.

Isolated pericarditis caused by *M. hominis* was recently reported following lung transplantation [17]. The patient was successfully treated with pericardial drainage, which also enabled pathogen detection, and a 6-week course of doxycycline.

Another manifestation was a periaortic abscess formation caused by *M. hominis* without presence of a sternal wound infection following combined heart-lung transplantation. The authors highlighted the need for considering *M. hominis* as pathogen, once conventional microbiological identification and empiric treatment failed [18]. In this case, a combined approach of surgical revision and prolonged antimicrobial therapy (3 months) was successful.

A single case of empyema due to *M. hominis* after bilateral lung transplantation in a patient with prior HSCT was recently published [19]. The patient developed bilateral pleural effusions and progressive respiratory distress in the early post-transplant course. Interestingly, *M. hominis* was exclusively identified in the left-sided pleural effusion, but not right-sided. The patient received a 6-week course of doxycycline and clindamycin with a complete clinical response.

A study from Australia described a cluster of four cases of *M. hominis* infections within 3 weeks, affecting three cardiac and one lung transplant recipient [20]. In all cases, surgical site infections were observed. A nosocomial transmission seemed likely based on adjacent beds and provision of care for each shift provided by the same nurses. The authors did not identify a single nurse that took care of all affected patients. A donor-derived origin was considered unlikely, as samples gathered at time of organ harvest did not grow *M. hominis*. All affected cases were treated with surgical exploration and debridement combined with antibiotic therapy. The authors suggested that in mild wound infections or local pleuropericarditis a 2- to 3-week course of oral doxycycline and/or ciprofloxacin might suffice. For more severe infections 10 to 14 days of intravenous clindamycin followed by 3–6 weeks of oral doxycycline was proposed.

Several reports of hyperammonemia syndrome have been published, an uncommon but frequently fatal disorder, associated with *Ureaplasma* spp. infections following lung transplantation. In a recent report, an index case of a lung transplant recipient suffering from hyperammonemia syndrome associated with disseminated *U. urealyticum* infection triggered further investigations [21]. In three other lethal cases of hyperammonemia after lung transplant, workup detected *U. urealyticum* in two cases and one case of *U. parvum* and *M. hominis*. The authors described another two cases of lung transplant recipients suffering from hyperammonemia, which were used for prospective validation. Both cases recovered from hyperammonemia syndrome after initiation of quinolone treatment. At time of initiation of quinolone treatment, polymerase chain reaction of blood and airway samples of both cases tested positive for *U. parvum*. One case was retested after 1 week of treatment with negative results for *Ureaplasma* spp. Disseminated *Ureaplasma* spp. infections may

result in an excess of ammonia production due to hydrolysis of urea in carbon dioxide and ammonia.

Liver Transplantation

After liver transplantation, infections caused by *Mycoplasma* spp. or *Ureaplasma* spp. seem to be infrequent. In a small case series, two liver transplant recipients with intra-abdominal wound infections caused by *M. hominis* were described [22]. One patient died due to another infectious complication, whereas the second case was cured by abscess drainage and antibiotic treatment with ciprofloxacin for 12 days. In another case report, *M. hominis* was found in perihepatic hematomas [23]. Recently, following liver transplantation in a child, *M. hominis* was detected in a fluid collection on the cut surface of the allograft [24]. Cure was achieved by treatment with doxycycline and clindamycin for 25 days. A single case of peritonitis caused by *M. hominis* and *U. urealyticum* was published [25]. At 12 days posttransplant revision, laparotomy was performed due to an increase in inflammatory markers and purulent wound secretions. Intraoperatively a retroperitoneal hematoma and fecal peritonitis were detected. Cultures exclusively grew *M. hominis* and *U. urealyticum*. Notably, in this case an increase in ammonia levels was observed along with a mild brain edema. Treatment with ciprofloxacin was administered.

Kidney Transplantation

In a Swiss university hospital, ten kidney transplant recipients with identification of genital mycoplasmas in urine samples were observed over a 3-year period [26]. Five patients were asymptomatic; in four patients sterile pyuria was present, while the remaining patient was screened due to detection of genital mycoplasmas in her partner. Four out of these five asymptomatic patients received treatment with doxycycline. The clinical course was favorable in all asymptomatic patients. Out of the five symptomatic patients, three patients were diagnosed with pyelonephritis, one patient with recurrent dysuria and pain in the graft region along with localized swelling of the upper pole of the kidney, and the remaining patient suffered from dysuria, vaginal discomfort, and pyuria. All symptomatic patients received treatment with doxycycline, in one patient combined with metronidazole. Due to insufficient clinical response, doxycycline was replaced by clindamycin in one case resulting in cure. In one symptomatic case, infection was accompanied by T-cell-mediated rejection, which resulted in end-stage renal disease despite antirejection treatment.

In the early posttransplant course, wound infections can be caused by *U. urealyticum* and *M. hominis* [27–29]. A 49-year-old kidney transplant patient was found to have a large seroma as well as urinary leak due to a severely necrotic transplant ureter, which required a washout and ureteropyeloplasty with a native ureter [30]. Serum and urine PCRs for *M. hominis* and *Ureaplasma* spp. were sent, which returned positive for *M. hominis* from both samples. Although she completed

a course of antimicrobial therapy, neurological complications from hyperammonemia resulted in a prolonged hospital stay, and she eventually succumbed to aspiration pneumonia.

In a 38-year-old kidney transplant recipient, arthritis of the shoulder and the knee was attributed to *M. hominis* and *U. urealyticum* in the early posttransplant course [31]. Despite prolonged antibiotic treatment with doxycycline, the infective arthritis recurred.

A single case of *U. urealyticum* meningitis was reported after kidney transplantation [32]. Following a complicated early posttransplant course with graft explantation due to arterial bleeding, the patient suffered from increasing headaches and showed clinical signs of meningitis. The diagnosis of *U. urealyticum* meningitis was established by a broad-range PCR. Targeted therapy encompassed doxycycline and chloramphenicol. The patient improved rapidly and recovered completely.

Kidney-Pancreas Transplantation

Following combined kidney-pancreas transplantation due to diabetes mellitus type 1, a systemic infection caused by *M. hominis* was reported [33]. Ten days post transplant an intra-abdominal abscess was suspected, while the patient received antimicrobial treatment with imipenem/cilastatin and fluconazole. Due to further deterioration, empirical treatment with ciprofloxacin was added and resulted in rapid clinical improvement. *M. hominis* was repeatedly detected in wound drainage. The patient was treated with a combined approach consisting of revision surgery and antibiotics, resulting in a favorable outcome.

Recently, another case of multiple intra-abdominal abscesses after combined kidney-pancreas transplantation due to diabetes mellitus type 1 was described [34]. Specimens derived from abscess drainage prompted suspicion of *M. hominis* infection, which was confirmed by PCR. After detection of *M. hominis*, treatment with minocycline was initiated.

Hematopoietic Stem Cell Transplantation

Following treatment with rituximab and allogenic hematopoietic stem cell transplantation (HSCT), a patient with prolonged agammaglobulinemia and B-cell aplasia developed septic polyarthritis due to *U. urealyticum* [35]. Treatment consisted of doxycycline and substitution of intravenous immunoglobulins (IVIG). The clinical course was complicated, but the patient finally recovered.

Recently, a case of gross hematuria and scrotal swelling 1 month after haploidentical HSCT was described [36]. At presentation urine culture and urine testing for adenovirus and BK virus were performed with negative results. On day +52, the patient developed fever. Retesting for bacteria, adenovirus and BK were negative again. Testing for *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Mycoplasma genitalium*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, *Neisseria*

gonorrhoeae, and *Mycobacterium* spp. was prompted. PCR tested positive for *U. urealyticum*, and treatment with doxycycline was initiated with rapid clinical improvement. After 14 days of treatment, a repeat PCR for *Ureaplasma* spp. was negative.

Similar to case reports in lung transplant recipients, hyperammonemia in a patient after HSCT has been attributed to *U. parvum* infection [37]. Twelve days after HSCT, the patient developed an alteration in mental status without focal neurological findings. Despite treatment of hyperammonemia, the neurological condition worsened. At day +15, tracheal aspirations and blood samples were obtained prior to initiation of empiric treatment with azithromycin and levofloxacin. PCR of tracheal aspirations tested positive for *U. parvum*, whereas PCR of the blood did not detect *Ureaplasma* spp. An airway sample on day +24 tested negative for *Ureaplasma* spp. Following cessation of azithromycin and levofloxacin after 15 and 18 days, respectively, an increase in ammonia levels was noticed and prompted retreatment with levofloxacin resulting in therapeutic success.

An Italian case series on toxic epidermal necrolysis-like reaction (TEN-LR) after HSCT in children included an 11-year-old child that received treatment with clarithromycin for *M. pneumoniae* infection and *Pneumocystis* prophylaxis with trimethoprim-sulfamethoxazole at the time of onset [38]. The patient was treated with IVIG and high-dose steroids, while clarithromycin and trimethoprim-sulfamethoxazole were stopped. The authors discussed *M. pneumoniae* as potential etiology of TEN-LR. The patient fully recovered in the latter course. A single case of Steven-Johnson syndrome (SJS) was reported after HSCT in a 21-year-old patient. She presented with fever, throat pain, and dehydration on day +20. Histopathological findings of esophageal biopsies were interpreted as compatible with SJS. Considering the finding of oral and vaginal mucositis, dermatologists suspected SJS most likely caused by *M. pneumoniae*. IVIG was administered, and topical mupirocin was applied to the lesions. Serology confirmed presence of *M. pneumoniae* IgM. A 5-day course of levofloxacin was given with favorable clinical response.

Disease Diagnostics and Clinical Evaluation

In general, culture for *M. pneumoniae* is laborious, time-consuming (up to weeks), and expensive. Due to these limitations, culture techniques are rarely used. In *M. pneumoniae* infections, cold agglutinins can be frequently detected from the first week of illness and may persist for several months after illness. Nowadays, cold agglutinins are rarely used. Serological tests showing a fourfold or greater rise in paired specimens collected 2–3 weeks apart are considered indicative of current or recent infection [9]. In general, nucleic acid amplification tests (NAATs), with PCR being the most common method, may be positive much earlier in the course of infection [39]. NAATs are almost always showing superior sensitivity compared to conventional methods [40]. Correspondingly, these tests are more and more considered the gold standard and are widely applied [40], as they are able to provide timely results. Several in-house as well as commercially available NAATs with a broad

range of different methods have been described in literature [40, 41]. Real-time PCRs offer the advantages of quantification and increased sensitivity compared to conventional PCR [42]. Dumke R. and Jacobs E. tested four commercially available PCRs and compared these to an in-house PCR; all PCRs detected at least 20CFUs/5 μl, whereas the in-house PCR was able to detect 0.2CFUs/5 μl [43]. Commercial multiplex assays detecting "atypical bacteria" and respiratory viruses that might show similar clinical presentation are increasing. However, multiplex assays might be hampered by a lower sensitivity [40]. Recently, assays that combine detection of *M. pneumoniae* with identification of macrolide resistance-associated mutations have been developed [40]. Suitable specimens for detection of *M. pneumoniae* respiratory tract infections include nasopharyngeal or oropharyngeal swabs, sputum, tracheal aspirates, lung tissue, pleural fluid, and bronchoalveolar lavage fluid. Samples from various extrapulmonary sites such as blood, cerebrospinal fluid, or tissue samples were tested in studies only [39].

Genital mycoplasmas require specialized media for optimal in vitro growth. *M. hominis* can be grown with methods routinely used in clinical laboratories, but sensitivity is poor. The extremely slow growth of *M. genitalium* renders culture methods impractical [42]. PCR methods are considered more sensitive than culture and are less time-consuming. Until recently, no commercially available test for diagnosis of *M. genitalium* infection was cleared by the US Food and Drug Administration (FDA), while several tests were CE approved in Europe [44]. In January 2019, the FDA permitted marketing of the transcription-mediated amplification test Aptima *Mycoplasma genitalium* assay (Hologic, San Diego, CA, USA) [45]. Syndromic multiplex tests for sexually transmitted diseases might also include testing for *M. genitalium* and *U. urealyticum*, such as the STD-Finder 2SMART (PathoFinder, Maastricht, Netherlands). In a study from 2011, sensitivity and specificity of a previous version of this assay were reported each 100% for detection of *M. genitalium*. Notably, a combination assay that detects *M. genitalium* and provides information on macrolide resistance-associated mutations has been described [44]. Considering the frequent detection in healthy individuals, serological tests for *M. hominis*, *M. genitalium*, and *Ureaplasma* spp. are hard to interpret and lack standardization [3, 42]. Specimens can be urogenital tract samples, but also blood, airway samples or biopsies [42].

Ammonia levels should be determined if a transplant recipient develops a neurological deterioration, especially if there is no alternative explanation and suspicion of an infection. Attention needs to be given in pre-analytics of ammonia measurement. EDTA should be used as anticoagulant for plasma samples; samples should be transported on ice and processed ideally within 1 h [46–48].

Management

Depending on the extent of infection, either a conservative, i.e. antibiotic treatment, or a combined approach consisting of antibiotic treatment and drainage or operative debridement should be chosen. In general, with abscess formation or extensive, life-threatening infection, an interventional or operative procedure for reduction of the

pathogen load would be indicated. As *Mycoplasma* spp. and *Ureaplasma* spp. lack a cell wall, these organisms are generally resistant to beta-lactam antibiotics. Empiric treatment for *M. pneumoniae* and genital mycoplasmas is often recommended with macrolides, tetracyclines, or quinolones. Notably, *M. hominis* is resistant against macrolides, but susceptible to clindamycin (Fig. 1) [49]. Resistance of *Mollicutes* against macrolides, quinolones, as well as tetracyclines has been described and should be considered, if treatment response is insufficient [50]. Susceptibility of *Mollicutes* largely varies by local epidemiology (Table 1). For *Ureaplasma* spp., a study from China reported resistance rates for ciprofloxacin, doxycycline, and azithromycin of 94%, 5%, and 39% [51], respectively, whereas Swiss isolates were found to be resistant for ciprofloxacin, doxycycline, and azithromycin in 19%, 0%, and 1%, respectively [52, 53]. A high prevalence of multidrug-resistant *M. genitalium* infections was identified among men who have sex with men in Alabama [54], while a report from the Netherlands published in the same year described one of the first cases of multidrug-resistant *M. genitalium* infections in Europe [55]. Duration of antibiotic treatment widely varied among the reports. Treatment duration should be guided by both general principles in treatment of infections, e.g. prolonged antibiotic treatment in case of affection of poorly perfused structures such as bone or cartilage and overall response (clinical, laboratory, and occasionally repeated imaging).

Respiratory infections caused by *Mycoplasma* spp. should prompt infection control measures, i.e. initiation of droplet precautions in addition to standard precautions for the duration of illness [56]. Nosocomial outbreaks have also been reported outside of transplant wards. In outbreak settings, postexposure prophylaxis

can be considered, especially in vulnerable populations such as lung transplant recipients. A few reports support an enhanced outbreak control approach through a combined method of infection control measures and azithromycin prophylaxis [13, 57]. In a setting of high macrolide resistance, tetracyclines might be an effective alternative [58, 59]. The role of infection control measures in *Mycoplasma* spp. infections that do not primarily affect the respiratory tract is less clear. However, as highlighted in the study by Hopkins PM et al., a nosocomial clustering of surgical site infections caused by *M. hominis* has been suggested [20]. Measures to reinforce standard precautions seem prudent.

To our knowledge, no approved vaccinations against *Mycoplasma* spp. or *Ureaplasma* spp. are available.

Conclusions

In general, infections caused by *Mycoplasma* spp. and *Ureaplasma* spp. after solid organ transplantation or hematopoietic stem cell transplantation seem to be rare. The most commonly reported manifestation is surgical site infection following solid organ transplantation. Urogenital infections in kidney and hematopoietic stem cell transplant recipients have been also attributed to these pathogens. Beyond, an

association of infections caused by genital mycoplasmas and increased ammonia levels is postulated. *M. pneumoniae* may be associated with severe dermatologic manifestations. For diagnosis, NAAT, most commonly PCR, is considered gold standard. Depending on extent of infections, management is either conservative with antibiotic therapy or combined with a surgical procedure.

Key Points

- Common manifestations encompass surgical site infections after solid organ transplant and urogenital infections after kidney and hematopoietic stem cell transplant.
- An association with hyperammonemia syndrome has been described.
- *M. pneumoniae* might be relevant in severe dermatologic manifestations after HSCT.
- Consider *Mycoplasma* spp. and *Ureaplasma* spp., if routine diagnostics do not identify causative pathogens.
- Insufficient response to empirical antibiotic treatment should prompt testing for mycoplasmas and ureaplasmas with PCR.
- Depending on extent of infection treatment either conservative or combination of interventional and conservative treatment.

Introduction

More than 50,000 hematopoietic stem cell transplantation (HSCT) and 100,800 solid organ transplants (SOT) are performed worldwide with 17,000 and 36,530, respectively performed in the United States [1–4]. In these immunocompromised patients, infectious complications are frequently seen posttransplant. *Clostridioides* (formerly *Clostridium*) *difficile* (*C. difficile*), a spore-forming, anaerobic, gram-positive bacillus, is the most common cause of hospital-acquired infectious diarrhea and the most common nosocomial infection in the United States [5, 6]. Clinical manifestations of *C. difficile* may range from a mild diarrheal illness to fulminant colitis [7]. *C. difficile* is ubiquitous in nature and may be isolated from soil, water, food, livestock, and pets.

Immunologically vulnerable ICH populations such as HSCT and SOT recipients are disproportionately affected [8–11].

Epidemiology of *C. difficile* in Transplant Recipients

The incidence and severity of CDI increased dramatically from the year 2000 to 2010 and plateaued between 2011 and 2013 at these historically high levels in the United States, while in Western Europe and England, rates have declined [10–12]. This increase was reflected in the frequency of CDI diagnoses captured in hospital discharges from 4.5 cases per 1000 discharges in 2001 to 12.1 cases in 2010 and 14.0 cases in 2014 [13]. These changes in epidemiology of CDI were associated with the emergence of the North American pulsed-field gel electrophoresis type 1 (NAP1)/restriction enzyme analysis (REA) type BI/PCR-ribotype 027 (NAP1/BI/027) strain of *C. difficile* [12]. Currently the annual burden of CDI in the United States is estimated to be nearly 500,000 cases and may be associated with 15,000–30,000 deaths per year [8]. CDI is a more frequently encountered problem in SOT recipients than in other hospitalized populations. While the incidence of CDI has been reported to be as high as 30% in SOT recipients, a meta-analysis evaluating published studies from 1991 to 2014 estimated the prevalence to be approximately 7.4% in the peri-transplant period after SOT [14]. The reported incidence of CDI associated with SOT varies depending upon the time after transplantation and the specific organ transplanted. The highest incidence is reported in lung transplant recipients (7–31%) [14–19]. The incidence of CDI is reported to be lowest in kidney recipients (2.6–16%), followed by liver recipients (2.7–19%), 0.5–7.9% in pancreas recipients, 9% in intestinal recipients, 1.8–15% in heart recipients, and 6.4–20.9% for those undergoing multiorgan transplantation This incidence in SOT recipients is higher than that seen in the general hospitalized patient populations, that typically being <1% [20, 21]. Fulminant *C. difficile*-associated colitis develops in up to 8% of immunocompetent patients with CDI while it occurs in 5.3–13% of SOT recipients [14, 22]. The incidence of CDI in SOT recipients is highest within the first 30–60 days after transplantation, probably because of more frequent antimicrobial exposure, more intense immunosuppression, and increased exposure to the healthcare setting [15, 22, 23]. Late-onset CDI occurs months to years after transplantation and is usually associated with either antimicrobial exposure or intensified immunosuppression to treat an episode of graft rejection [22]. It is not known how the NAP1/BI/027 strain has impacted the incidence and severity of CDI in SOT recipients relative to the general hospital population.

In addition to the most common risk factor for CDI, antibiotic exposure, other established factors in the general population putting individuals at risk for CDI include frequent exposures to healthcare settings, hospitalization especially if prolonged, age older than 65 years, gastrointestinal (GI) surgery or manipulation of the GI tract, uremia, and receipt of chemotherapy [10, 24]. An association between the

use of gastric acid suppressing agents, such as proton pump inhibitors and histamine-2-receptor antagonists, has been identified as a risk for CDI [25]. Both SOT and HSCT recipients share these established risk factors, in an amplified manner, but there are also risk factors specific to each of these populations (Table 1).

The enhanced incidence of CDI in HSCT recipients may be related to the use of myeloablative conditioning chemotherapy and total body irradiation, prolonged neutropenia (attributed both to resultant gut translocation of colonizing organisms and to antimicrobial prophylaxis causing microbiome disruption), mucositis, concomitant herpesvirus reactivation, and the presence of GVHD [26–28]. Individuals undergoing a cord-HSCT are at highest risk of CDI. With an incidence of 10–30% CDI is fivefold to ninefold higher in HSCT recipients when compared to the general hospitalized population [19, 28, 29]. In individuals receiving an autologous HSCT (auto-HSCT), the rates of confirmed CDI range from 5% to 15% while in those undergoing allogeneic HSCT (allo-HSCT) rates of CDI range from 12% to 34% [15, 18–20].

Among SOT recipients, hospital onset CDI has been reported to be five times more common in patients who have undergone as SOT compared to the general inpatient population. In the SOT population, the incidence of CDI ranges from 3.5% to 31% of recipients in the early posttransplant period [14, 17]. Risks for CDI specific to SOT include frequent exposures to healthcare settings, age greater than 55 years, history of CDI prior to transplantation, deceased donor organ transplant, antimicrobial exposure, graft failure/re-transplantation, and the persistent need for enhanced immunosuppression (such as pulsed steroid dosing and antithymocyte globulin for organ rejection) [30]. CDI is most likely to occur within the first 30–60 days after SOT with the risk decreasing during the 60–90 days after transplant and approximating pretransplant rates by 90 days posttransplantation [15, 23, 28]. Those individuals experiencing CDI after transplantation are at an increased risk of mortality, graft failure, and graft-versus-host disease (GVHD) [17, 31–34].

In HSCT recipients, CDI is more likely to occur in the first 100 days after transplant, with most infections occurring in the first 30 days (pre-engraftment); this increased risk of CDI continues later posttransplant as well and is highest in the post-engraftment phase in patients receiving high-risk broad-spectrum antibiotics and in those with acute GVHD [35].

Because *C. difficile* spores are ubiquitous in the environment, both ICH and non-ICH may be asymptomatically colonized [36]. Most commonly, non-toxigenic strains of *C. difficile* as well as toxigenic *C. difficile* and *C. difficile*-associated toxins are carried asymptomatically as part of a normal gut microbiome. Asymptomatic carriers of *C. difficile* have been reported to outnumber true cases of CDI 10:1; however, from an individual patient perspective, *C. difficile* colonization is a risk factor for the development of active CDI [37]. In healthy adults, 0–7% may be asymptomatic carriers of *C. difficile*, but in individuals having contact with the healthcare system, 3–26% have been found to be colonized [38–41] [42, 43]. Among individuals admitted to the hospital, a meta-analysis of 19 studies, with extractable data published between 1925 through 6/2014 that were identified

Table 1 Risk factors for CDI [27, 30, 124, 125]

All patients	Specific to SOT	Specific to HSCT
Any antibiotic therapy Highest risk antibiotics: Clindamycin Fluoroquinolones Beta-lactam and/or beta-lactamase inhibitor combination Cephalosporins Metronidazole	Immunosuppressive agents [corticosteroids > mycophenolate > azathioprine or Calcineurin inhibitors]	Male gender
Gastric ulcer prophylaxis	Male gender	Acute leukemia
Age > 65y (and especially >85y)	Gastrostomy or jejunostomy tube	Antibiotic prophylaxis
Hospitalization	Surgical procedures	Allogeneic (vs. autologous HSCT)
Intra-abdominal surgery	Antibiotic prophylaxis	Umbilical cord blood HSCT
Enteral feeding	Extended hospital stays	Total body irradiation
Chronic kidney disease	Hypogammaglobulinemia	Myeloablative conditioning
Cardiac disease/hypertension	Age > 55	Chemotherapy
Inflammatory bowel disease	History of CDI prior to SOT	Neutropenia
Chemotherapy	ATG	Mucositis
Cirrhosis	Re-transplantation	Reciprocal association with GVHD
Housing in an extended care facility	Deceased donor transplantation	CMV reactivation
Outpatient care	Organ-type affects risk Liver > heart > kidney	HSV or VZV reactivation
Emergency room/urgent care visits		Pre-colonization with toxigenic strain
Outpatient procedure/outpatient surgery center		VRE colonization
Doctor's office		Bacterial infection
Hemodialysis		Mechanical ventilation
Depression/antidepressant use		Hypogammaglobulinemia

from searches of the PUBMED and EMBASE databases, reported a pooled prevalence of toxigenic *C. difficile* colonization to be 8.1% overall and 10% in North America [37]. When hospitalized, these asymptomatic carriers are an important reservoir for transmission of *C. difficile* to previously uncolonized individuals admitted to healthcare settings [44, 45]. It is important to note that ≥50% of individuals colonized with toxigenic *C. difficile* will never develop active CDI [10, 40, 46]. Asymptomatic carriage of *C. difficile* is reported to occur in 19–84% of infants under the age of 6 months [47–50]. Colonized infants may represent a reservoir of *C. difficile* in the community. *C. difficile* has also been found to be a colonizer in community environments such as parks, stores (fresh produce and raw meat) and fast food restaurants, and in homes; all of these sites are possible reservoirs of the organism [36].

The effect of transient asymptomatic carriage of, or colonization with, toxigenic *C. difficile* on the development of CDI in SOT recipients has not been well delineated. Studies comparing the incidence of CDI in SOT recipients colonized with toxigenic *C. difficile* to those not colonized are needed.

Studies evaluating the carriage of *C. difficile* in symptomatic patients admitted to HSCT units for treatment of a hematologic malignancy or for HSCT and who on admission were screened for the presence of toxigenic *C. difficile* have reported carriage rates of 14–26% [51–54]. Those patients admitted for planned HSCT and found to be colonized with *C. difficile* have been shown to develop significantly higher rates of active CDI than those screened and found not to be colonized (56–87% active CDI in colonized individuals compared to 12–17% active CDI in those not colonized) [51, 55, 56]. There have been several studies evaluating the effect of colonization with *C. difficile* on subsequent CDI in hematologic malignancy and transplant recipients. In a large observational cohort performed at Memorial Sloan Kettering Medical Center, once weekly fecal specimens were collected on adult patients admitted for HSCT during their transplant hospitalization [57]. These specimens were tested for the presence of toxigenic *C. difficile*. Of those patients who screened positive for colonization with *C. difficile*, 17% went on to develop clinical CDI compared to 12.2% in the control population. In a prospective cohort study of patients admitted to a hematology/BMT unit for a hospital stay of more than one night, 9.3% were found to be colonized with a toxigenic strain of *C. difficile* [53]. While 3.4% of patients who were not found colonized with *C. difficile* developed CDI during their hospital stay, 13.3% of those colonized with toxigenic *C. difficile* on admission developed CDI which on multivariate analysis gave an adjusted odds ratio for development of symptomatic CDI of 11.6 (95%CI, 2.9–47.1; $P = 0.001$). Similarly, in a prospective cohort study in pediatric oncology and HSCT recipients, baseline stool samples collected within 3 days of admission found colonization with a toxigenic strain of *C. difficile* in 32.8% of patients [58]. Colonization was predictive of CDI with a clinical isolate sharing identical or closely related pulsed-field gel electrophoresis patterns to the baseline isolate (OR = 28.6%; 95% CI, 6.58–124.39; $P < 0.001$).

Hospital preventative strategies to reduce the incidence of hospital onset CDI (HO-CDI) include antimicrobial stewardship programs, contact precautions

Table 2 Strategies to prevent HO-CDI [45, 59–61]

Strategies to prevent hospital onset CDI (HO-CDI)
Antimicrobial stewardship programs
Presence and enforcement of contact precautions/isolation for infected patients
Decontamination of infected areas with sporicidal cleaners (bleach) with oversight on cleaning
Promotion of hand hygiene

(isolation and use of gowns and gloves) for infected patients, sporicidal decontamination of areas/equipment exposed to infected patients, promotion of hand hygiene (hand washing with soap and water along with mechanical drying), and identification and isolation of asymptomatic carriers [45, 59–61] (Table 2). *C. difficile* spores can remain in the hospital environment on floors, commodes, toilets, bedpans, and high-touch surfaces (call bells, over-bed tables, phones) for months or years surviving heat, desiccation, and most disinfectants [62, 63]. Daily cleaning in the rooms of CDI cases with attention to high-touch surfaces regardless of the presence of visible soiling is recommended using a hypochlorite-based disinfectant in sporicidal concentrations (at least 1000 ppm, but ideally 5000 ppm, available chlorine) after mechanical cleaning with a germicide to reduce spore colonization and organic material [10, 64].

Pathogenesis of *C. difficile*

In the environment and colon lumen, C. difficile may remain in its spore form for months. In a healthy state, the gastrointestinal microbiota provides resistance to colonization with pathogenic organisms through various mechanisms including: prevention of adherence; metabolism of primary bile acids to secondary bile acids and short chain fatty acids (SCFAs), as well as metabolism of bilirubin, heterocyclic amines, and polysaccharides; production of inhibitory substances; depletion of nutrients; and stimulation of the host's immune system [65, 66] (Fig. 1). Exposure to antimicrobials or other therapies that alter the gut microbiome (i.e., cancer chemotherapy, proton pump inhibitors, or H2 blockers) result in increased concentrations of primary bile acids along with pressure of the bacterial metabolic pathway to secondary bile acids over SCFAs in the colonic environment thereby directly leading to germination of *C. difficile* spores and overgrowth of vegetative toxin producing organisms leading to active CDI [10, 67, 68]. Any antimicrobial agent may predispose to CDI; however, third−/fourth-generation cephalosporins, fluoroquinolones, carbapenems, and clindamycin have been found to be the highest risk antibiotics and are frequently implicated in cases of active CDI.

Toxigenic strains of *C. difficil*e present in the colonic environment in the vegetative form produce one or both toxins A and B. These toxins trigger a cytotoxic response inducing host cell death, neutrophilic infiltration with profound inflammation, and cytokine release [10, 68] (Figs 2 and 3). The resulting inflammatory response leads to the development of pseudomembranes which are characteristic

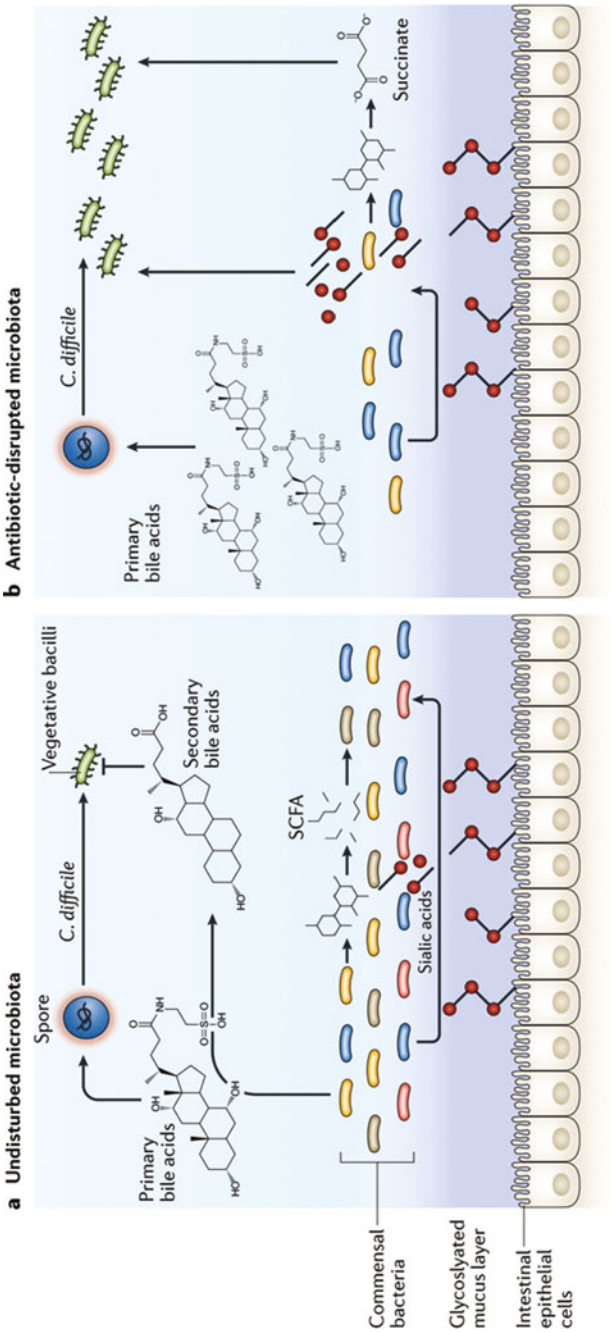

Fig. 1 Microbiota-mediated defenses against *C. difficile*: effect of antibiotics on colonic microbiome. (**a**) The intact microbiota converts primary bile acids into secondary bile acids, several derivatives of which inhibit the growth of *Clostridium difficile* through detergent-induced toxicity to vegetative bacilli. Commensal bacteria that express sialidases cleave sugars that are attached to epithelial cells and release sialic acid into the intestinal lumen. Fermenting commensal bacterial species convert carbohydrates into short-chain fatty acids (SCFAs), such as succinate. Bystander commensal bacterial populations can consume these metabolites as energy sources. (**b**)| Antibiotic-mediated disruption of the microbiota depletes primary bile acid converters, which enables *C. difficile* sporulation and growth. Antibiotics can also deplete competing sialic acid and succinate consumers, liberating an energy source for *C. difficile*. (Nat Rev. Microbiol 2016; 14: 609–620. (Copyright obtained and sent to publisher))

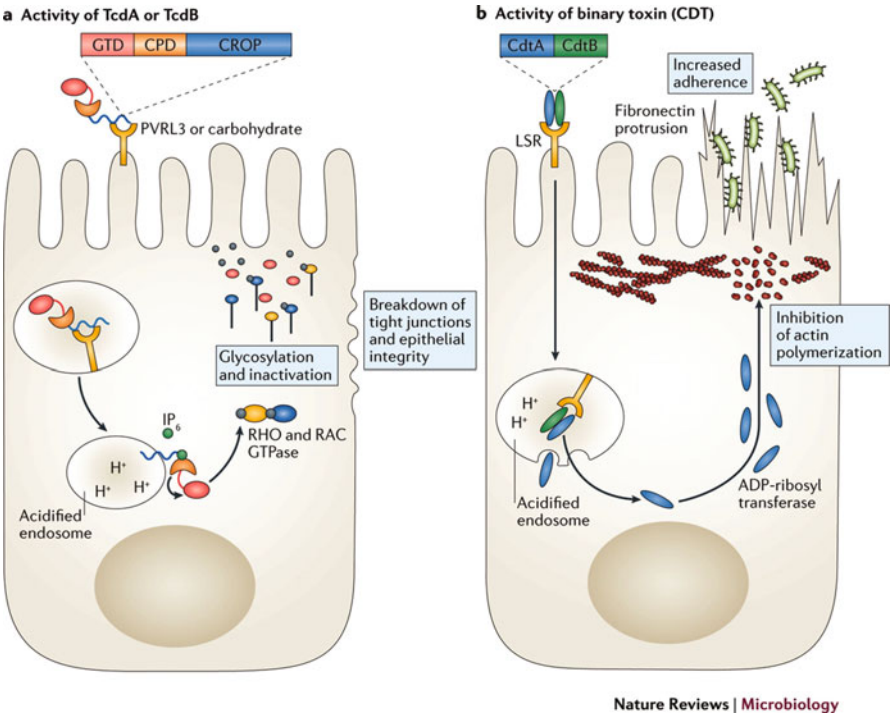

Fig. 2 Effect of *C. difficile* toxins on colonic epithelial cells. (**a**) The combined repetitive oligopeptide repeat (CROP) domain of TcdA binds to carbohydrates on the apical surface of epithelial cells, whereas TcdB binds to poliovirus receptor-like 3 (PVRL3) expressed on colonic epithelial cells. Toxin is internalized and acidification of the endosome enables the CROP domain to embed into the endosomal membrane and the subsequent transport of the cysteine protease domain (CPD) and the glucosyl transferase domain (GTD) into the cytosol. Inositol hexakisphosphate (IP_6) activates the cysteine protease to cleave and release the toxin glycotransferase. Glycosylation and thereby inactivation of RHO or RAC GTPases ultimately results in the breakdown of tight junctions and epithelial integrity. (**b**)| Binary toxin (also known as *Clostridium difficile* transferase (CDT)) binds to the lipolysis-stimulated lipoprotein receptor (LSR) and is internalized. The CdtB subunit creates pores in the acidified endosome that enable the release of the CdtA subunit into the cytosol. The ADP-ribosyl transferase activity of CdtA inhibits actin polymerization near the cell membrane, enabling fibronectin microtubules to elongate and protrude through microvilli, which increases *C. difficile* adherence to the epithelium through type IV pili. (Nat Rev. Microbiol 2016; 14: 609–620. (Needs Copyright / requested but Nat wants to charge?))

visible yellow plaques throughout the colon. Some *C. difficile* strains also produce a third toxin, binary toxin or *C. difficile* transferase (CDT), an adenosine diphosphate (ADP)-ribosyltransferase that causes actin cytoskeletal disruption and may lead to a more fulminant clinical course [68–70]. CDT is typically produced by the major, hypervirulent strains and has been associated with more severe disease, an elevated risk of recurrence, and higher mortality [71–73]. Because of blunted inflammatory responses and/or the presence of neutropenia in immunocompromised patients, the finding of pseudomembranes is less commonly seen in those being treated with

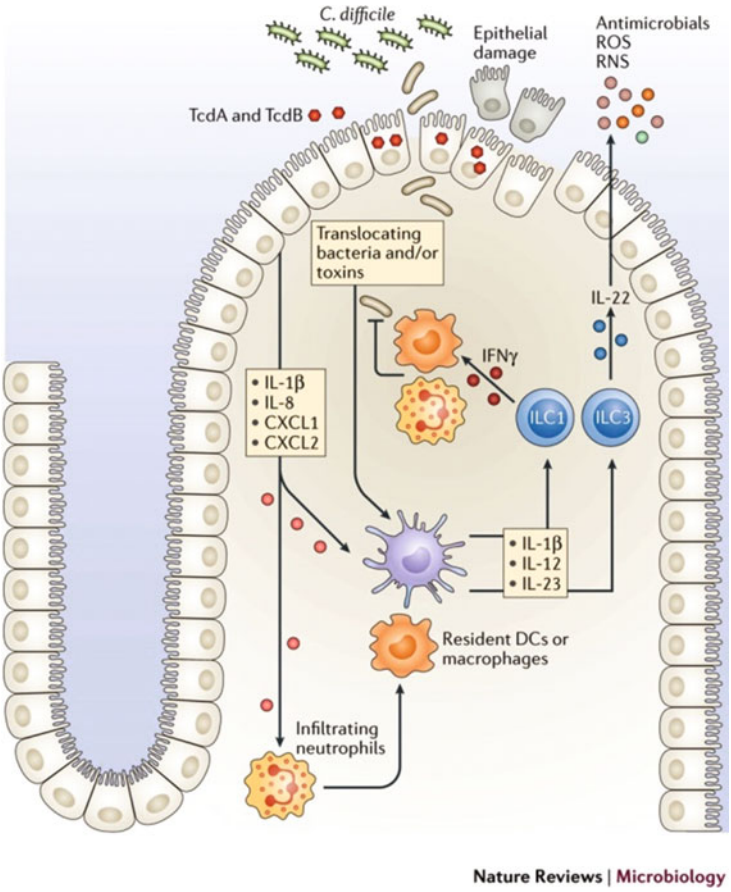

Fig. 3 Innate immune-mediated defenses against *C. difficile.* The acute host response to *Clostridium difficile* is initiated by toxin-mediated damage, loss of epithelial integrity, and the detection of translocating bacteria. Intestinal epithelial cells and resident innate immune cells secrete pro-inflammatory chemokines (such as chemokine C-X-C motif ligand 1 (CXCL1), CXCL2, and interleukin-8 (IL-8)) and pro-inflammatory cytokines (such as IL-1β, IL-12, and IL-23), which leads to the recruitment of neutrophils and the activation of innate lymphoid cells (ILCs). IL-12 signaling drives the expression of interferon-γ (IFNγ), whereas IL-1β and IL-23 signaling induces the production of IL-22. The effector cytokines IFNγ and IL-22 induce defense mechanisms such as increased phagocytic activity of macrophages and neutrophils, and the production of antimicrobial peptides and enzymes that synthesize reactive oxygen species (ROS) and reactive nitrogen species (RNS). These defense mechanisms limit bacterial dissemination, attenuate toxin activity, and repair epithelial damage. DCs, dendritic cells. (Nat Rev. Microbiol 2016; 14: 609–20. (Needs Copyright / requested but Nat wants to charge?))

immunosuppressive agents and those who previously received myeloablative regimens [74].

CDI Differential Diagnosis and Clinical Impact on Transplant Outcomes (SOT and HSCT).

As in the non-immunocompromised host population, detection of *C. difficile* or its toxins should not be assumed to be the cause of diarrhea. Etiologies of diarrhea other than *C. difficile* in transplant recipients include: drug-induced diarrhea (i.e., concomitant antibiotics, laxative use, mycophenolate) or other common etiologies of infectious diarrhea such as adenovirus, cytomegalovirus, or norovirus. In both SOT and HSCT populations, the highest rates of CDI occur within the first 30 days posttransplantation when patients have received intensive immunosuppression [28]. It should be remembered, however, that CDI in neutropenic patients may lack classic findings of inflammation such as pseudomembranes and leukocytosis [29, 33, 75].

Consequences of active CDI reported in transplant populations include dehydration, inanition, increased rates of other infections (such as cytomegalovirus (CMV) and pneumonia), longer hospital stays resulting in higher healthcare costs, organ allograft dysfunction in the SOT population, and the development of GVHD in the HSCT population [7, 17, 32, 33, 75–78]. The GVHD association may be restricted to late complications of HSCT in select hosts; two studies that included recipients of T-cell depleted grafts reported no association between CDI and GVHD, especially if CDI occurred early post-HSCT [47, 77, 79]. The pathogenesis of GI tract GVHD may result from the initiating effects of gut epithelial damage from high-intensity conditioning chemotherapy compounded by alteration of gut microflora enhancing susceptibility to infection and initiating an immune attack from graft-derived T-lymphocytes driving a destructive cascade of inflammation. The need for colectomy is relatively low in HSCT patients compared to other inpatient populations with CDI, possibly the result of reduced inflammatory responses with neutropenia and immunosuppressive therapy [33]; however, CDI-related mortality is high independent of mortality associated with relapsed malignancy [75, 78]. In the SOT population, CDI is also an independent risk factor for mortality (OR: 2.48; 2.22–2.76) with reported mortality rates between 2.3% and 8.5% [32].

Diagnosis of *C. difficile* Infection: Clinical Evaluation and Available Emerging Diagnostics

The approach and use of diagnostic testing methods to identify a patient with active CDI continues to evolve as testing methods emerge with varying sensitivities and specificities for the presence of *C. difficile* toxins or of the ability of the organism to produce toxin. After the use of expensive, complex, and time-consuming toxigenic culture (TC) and cell cytotoxicity neutralization assays (CCNAs), newer enzyme-linked fluorescent immunoassays (EIA) and nucleic acid amplification tests (NAAT) provided less cumbersome and expedient testing methods [10, 11, 80, 81]. Current guidelines recommend using these newer tests in combination, simultaneously, or in an algorithmic approach to increase the specificity of testing. Also, NAAT testing alone may be used in the diagnosis of CDI but, in an effort to increase the specificity of testing, should be reserved for use in patient specimens screened to be liquid in consistency after other common etiologies of diarrhea (e.g., laxative use) have been ruled out [10, 11]. In the future, diagnostics may include the use of fecal biomarkers,

including lactoferrin, calprotectin, and cytokines IL8 and IL1B. These modalities have been used in the diagnosis of inflammatory bowel diseases, but at the present time, there is insufficient evidence to recommend their use for CDI diagnosis in clinical practice [10].

In general, diagnostic testing for *C. difficile* has targeted the presence of the organism, the production of the toxin, or both. Toxigenic culture (TC) detects the presence of the *C. difficile* organisms in culture using selective media followed by identification using biochemical testing or MALDI-TOF (matrix-assisted laser desorption/ionization time-of-flight) and is currently considered a reference method to which other testing modalities are compared. With culture however, a separate testing modality is needed to detect the presence of toxin. The cell cytotoxicity neutralization assay (CCNA) detects toxin directly in the stool by observing for cytopathic effect on an appropriate cell line (i.e.,: human fibroblasts) after a stool filtrate has been applied to the cell culture. The filtrate is also inoculated in parallel to a second set of tissue culture cells to which *C. difficile*-specific antitoxin has been added to verify that the cytopathic effect is caused by a *C. difficile*-associated toxin and not by some other toxic component or viral infection that may be harbored in the specimen. Duplicate testing with neutralizing antibodies to *C. difficile* or cross-reactive *C. sordellii* is often performed to ensure that the cytopathic effect is due to *C. difficile* toxins. CCNA has historically been considered the gold standard in the diagnosis of active CDI; however, recently it has been questioned if this test's sensitivity of 65–90% is high enough to be appropriate for assay-comparison studies [82–86]. Further, sensitivities are approximately 75–85% when compared to TC, and the level of agreement can vary between labs [82]. These points are important to consider as these two tests are the measures to which most recently available diagnostic tests are compared. Both TC and CCNA are labor and time-intensive compared to more recent testing modalities.

Glutamate dehydrogenase (GDH) is a constitutive metabolic enzyme that converts glutamate to alpha-ketoglutarate and ammonia and is produced by both toxigenic and non-toxigenic *C. difficile* strains [80, 87]. GDH immunoassays have emerged as a screening test for the presence of *C. difficile* organisms in fecal samples obtained from individuals with a diarrheal illness. The sensitivity of GDH immunoassays are high (80–100%), and these assays have a favorable negative predictive value, a rapid turnaround time, and low cost compared to other testing modalities. These characteristics allow the GDH test be used widely as the screening step in the 2- or 3-step algorithmic approaches for the diagnosis of active CDI when it is followed by a toxin-specific test such as an enzyme-linked fluorescent immunoassay (EIA) or molecular testing.

Enzyme-linked fluorescent immunoassays (EIA) utilize monoclonal or polyclonal antibodies that are directed at *C. difficile* toxins [73, 82, 88–90]. These assays initially targeted toxin A alone but now target both toxin A and B as toxin A-negative/toxin B-positive strains have been documented. EIA testing is low cost and has a fast turnaround time. The sensitivity and specificity of EIA tests vary widely from approximately 40–100%. Heterogeneity exists between testing methods due to interlaboratory operator technical variance, geographic circulating strain

types, host antibody binding to toxin in the intestine, institutional practice, and the type of stool sample analyzed (i.e., fresh vs. frozen; cup vs. swab), as well as the gold standard used for assessment of the assay [82]. Like the GDH, EIAs are not recommended for diagnostic testing alone but may be considered to be part of an algorithmic approach [10, 11]. When compared to TC, low sensitivity of EIA immunoassays has been reported in diagnosing active CDI in immunocompromised patients who are on high-dose steroids, have leukocytopenia, and have non-severe CDI [91].

C. difficile nucleic acid amplification testing (NAAT) targets include the tcdA, tcdB, and binary toxin genes. Some assays also test for a deletion at nucleotide 117 on tcdC as surrogate markers for presumptive identification of 027/NAP1/NI strains separately or in combination. Sensitivities of NAAT testing modalities for the presence of these genes which regulate toxin production range from 77% to 100% with specificities of 87–100% depending on the individual test. Negative predictive values exceed 95%; however, positive predictive values range from 42% to 98% [82]. NAAT testing does not test for the presence of *C. difficile* toxins but for the genes responsible for the production of toxin. Because of high sensitivity, NAAT testing modalities may be overly sensitive and may identify patients with *C. difficile* carriage tested for a diarrheal illness but who do not have active CDI.

Because none of these available tests can differentiate between colonization with *C. difficile* and active infection, when considering diagnostic testing, it should be understood that active CDI is a clinical diagnosis that is supported by laboratory testing confirming the presence of toxin or toxigenic C. *difficile* bacteria in the stool of a patient with clinically significant diarrhea [10, 92]. A case of active CDI requires the presence of diarrhea or evidence of megacolon or severe ileus as well as either a positive laboratory diagnostic test result or evidence of pseudomembranes demonstrated by endoscopy or histopathology. Testing relies on submission of and should only be performed on liquid stool specimens from an individual who has had more than three unformed bowel movements within a 24-h period. It is important that other etiologies of diarrhea including other causes of infectious diarrhea, use of drugs which cause diarrhea (i.e.,: laxatives, cancer chemotherapy, or mycophenolate), the presence of inflammatory bowel disease, or use of enteral tube feedings be considered prior to submitting specimens for testing.

Encouraged by recommendations in guidelines, institutions are increasingly developing initiatives to enhance the specificity of diagnostics such as rejecting nonliquid/soft samples (those not taking the shape of the container) and screening for laxative use within the 48 h prior to submission. In a study evaluating appropriateness of testing for CDI, it was found that 19% of patients being tested for *C. difficile* had received laxatives within 48 h prior to sample submission and 36% did not have clinically significant diarrhea [92].

Repeat testing for *C. difficile* within 7 days during the same episode of diarrhea or as test-of-cure is not recommended. Repeat *C. difficile* testing in patients initially negative but having a clinical syndrome consistent with CDI and a worsening status or patients with resolution of symptoms following treatment with suspected

recurrence can be considered. In these instances, toxin-directed assays should be considered over NAAT testing as patients have been shown to continue to carry toxigenic *C. difficile* long after treatment of infection. Additionally, bowel habits may not return to normal for a long period of time after an episode of CDI, and diarrhea alone may not necessarily represent a recurrence of infection.

Approach to Patient Management Including Emerging Treatment Modalities and Options for Prophylaxis, Prevention, and Prognosis (See Fig. 4)

The most recent *C. difficile* guidelines [10, 11, 81, 93, 94] recommend oral vancomycin 125 mg administered orally at 6-h intervals for 10–14 days or fidaxomicin 200 mg by mouth twice daily for 10 days for the treatment of primary CDI. In addition to specific anti-CDI-related therapy, interventions recommended include the reduction of modifiable risk factors (avoiding unnecessary antibiotics, avoiding exposure to fluoroquinolones, clindamycin, and cephalosporins when antibiotic therapy is required) and avoidance of unnecessary proton pump inhibitors when possible.

Therapeutic guideline recommendation changes were based on the findings of clinical trials not focused on transplant recipients which compared vancomycin and metronidazole and reported an advantage to the use of oral vancomycin [10]. Zar et al. compared vancomycin and metronidazole for the treatment in *C. difficile* in a 2007 study which found that metronidazole and vancomycin were equally effective for treatment of mild CDI; however, vancomycin was superior for treating patients with severe CDAD; in this study, 17% of the patient population had underlying malignancy [95]. In a retrospective analysis, Parmer et al. reviewed the incidence and severity of *C. difficile* infection in patients with hematologic malignancies, including those undergoing HSCT and reported the response to metronidazole was 53.7%, vancomycin 50%, and in combination 38.5%, thus representing no significant difference between treatment modalities [96]. In a randomized, controlled clinical trial comparing vancomycin, metronidazole, and tolevamer for the treatment of CDI, clinical success (defined as resolution of diarrhea and absence of severe abdominal discomfort) at end of therapy in patients receiving metronidazole or vancomycin was 72.7% and 81.1%, respectively while in those who received tolevamer, it was 44.2% [89]. Clinical success in patients with severe CDI who received metronidazole was 66.3% compared to 78.5% in those who received vancomycin ($P = 0.059$). In a retrospective, propensity-matched, cohort study, Stevens et al. evaluated the risk of recurrent CDI and 30-day mortality in 10,137 veterans stratified by mild to moderate and severe CDI [97]. In this cohort, 8% received immunosuppression and 11% received chemotherapy within 30 days prior to the CDI episode. They found no difference in risk of CDI recurrence between patients treated with vancomycin versus those treated with metronidazole. However, among patients in the severe CDI cohort, those treated with vancomycin were less likely to die.

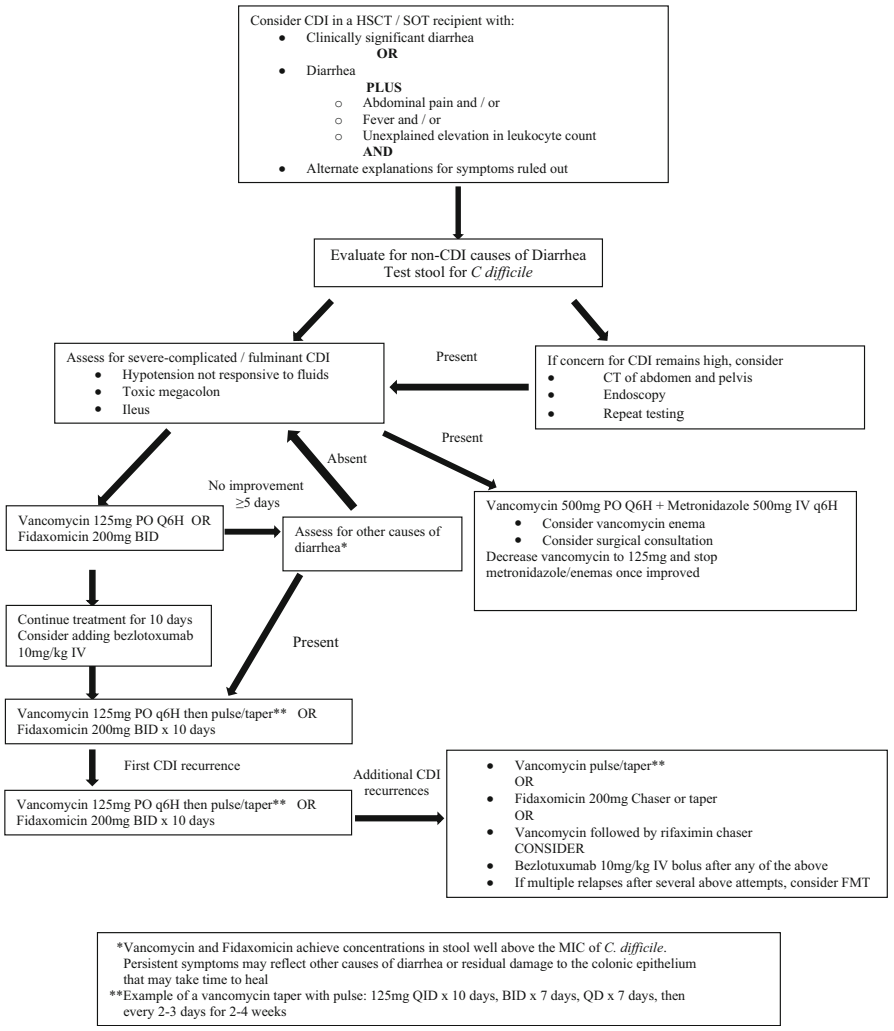

Fig. 4 Approach to diagnosis and management of C. difficile in transplant patients including emerging treatment modalities and approach to recurrences

Fidaxomicin is a macrocyclic narrow-spectrum antibiotic with activity, as is also true with vancomycin, only against vegetative (actively replicating) *C. difficile* organisms. Unlike vancomycin however, fidaxomicin also prevents new sporulation by the vegetative *C. difficile* organisms present and halts continued toxin production. Because of its narrow spectrum of antimicrobial activity, the potential advantage of fidaxomicin is sparing of healthy gut flora allowing for more rapid reconstitution of a normal gut microbiome thereby maintaining the colonization barrier to pathogenic organisms, including *C. difficile,* as well as enhancing metabolism of toxic bile salts on presentation to the colon microbiome. In two large, randomized, double-blinded

fidaxomicin registry clinical trials, fidaxomicin was found to be non-inferior in the initial clinical cure of CDI but was found to be significantly better in sustained clinical cure when compared to vancomycin [98, 99]. Additionally, in a sub-analysis, patients receiving concomitant antibiotics for other infections had a higher cure rate (90% vs. 73%, $p = 0.03$) and 12.3% lower incidence of recurrence when treated with fidaxomicin compared to those treated with vancomycin [100]. In those patients who were enrolled with the presence of a concomitant ongoing cancer, cure was more likely with fidaxomicin than vancomycin (odds ratio [OR] 2.0; $P = 0.065$), recurrence was less likely (OR = 0.37; $P = 0.018$), and sustained response more frequent (OR = 2.56; $P = 0.003$) [101]. Time to resolution of diarrhea was longer in patients with cancer treated with vancomycin compared to those who received fidaxomicin (123 vs. 74 h). No difference in clinical cure was found in a subsequent clinical trial where HSCT patients received either oral vancomycin or fidaxomicin therapy (28% vs. 27%), with no difference observed in global cure (66% vs. 67%), treatment failure, or recurrent disease (7% vs. 5%) in the first 100 days following allogeneic transplant [102]. However, patients who developed acute graft-versus-host disease had a longer mean time to onset in the fidaxomicin group when compared to the vancomycin-treated group (32 vs. 21 days; $p = 0.003$).

Lack of ability to mount an immune response to *C. difficile* toxins has been shown to be a risk factor for recurrence [103, 104]. Bezlotoxumab is a monoclonal antibody against *C. difficile* toxin B. A single infusion of 10 mg/kg bezlotoxumab administered during or at the end of therapy for an initial or first recurrence of CDI was reported to significantly lower the incidence of CDI recurrence compared with placebo (16–17% vs. 26–28%) [105]. A post-hoc analysis which evaluated the 20% of patients enrolled in the study who were immunocompromised showed a recurrence rate of 36% in patients receiving placebo versus 19% in the bezlotoxumab infusion arm [106]. Like fidaxomicin, no controlled trials have been reported comparing standard of care therapy with or without the addition of bezlotoxumab specifically in transplant patient populations.

FMT has increasing support in the literature for patients in the treatment of recurrent CDI, but concerns of safety in immunocompromised hosts, especially when donor samples are considered, exist. A recent report of two immunocompromised adults who received investigational FMT and developed invasive infections with one death due to infection with an extended-spectrum-beta-lactamase producing *Escherichia coli* highlights these concerns [107–109]. FMT has been reported as beneficial in the treatment of both acute and recurrent CDI. Available data on the use of FMT in the ICH population is limited to case reports and small series showing benefit with treatment and a decrease in recurrence with no reported adverse events, but no randomized control trials in these populations have been undertaken [110–112]. One group has reported safe use in 94 SOT patients requiring support for recurrent (78%) or severe/fulminant *C. difficile* (22%), with no FMT-associated bacteremia reported when fresh stool from a patient-directed donor or frozen stool bank samples were used [111]. Other groups have examined the utility of stool collected prior to antibiotic exposure/transplant for use as FMT post-allogeneic HSCT in an effort to restore normal gastrointestinal microbiota [113]. Taur et al.

report reconstitution of the gut microbiome of stem cell transplants through the use of auto-FMT samples collected pretransplant that when administered after engraftment increased bacterial diversity compared to patients not undergoing auto-FMT and may theoretically decrease the risk of *C. difficile* development posttransplant [113]. One small series reported use of FMT in an effort to decolonize carriage of MDR bacteria in after HSCT in an effort to restore the microbiome and potentially impact the development of GVHD [114].

Prophylaxis

There is likely a limited role for *C. difficile* prophylaxis in a general inpatient population who screen positive for *C. difficile* carriage without evidence of ongoing CDI as even exposure to vancomycin used as an agent of prophylaxis may provoke microbiome changes and result in CDI in the absence of other risk factors, including broad-spectrum antibiotic therapy. Several studies evaluating the role of prophylaxis against *C. difficile* in patients undergoing HSCT and SOT have been reported [66, 115–118].

In a large, double-blinded, randomized, placebo controlled trial comparing the use of fidaxomicin to placebo as prophylaxis against CDI in individuals undergoing autologous or allogeneic HSCT who were receiving fluoroquinolone prophylaxis for neutropenia, no difference was found between the two groups in the intention to treat analysis based on a composite outcome of "prophylaxis failure" which included confirmed CDI, receipt of CDI-effective medications (for any indication), and/or missing CDI assessment (for any reason, including death) [56, 115]. However, in the prespecified sensitivity analysis, which counted only confirmed CDI (by toxin immunoassay or nucleic acid amplification test) as failure, cases of confirmed CDAD were found to be significantly lower in those who received fidaxomicin versus the placebo recipients (4.3% vs. 10%; $p = 0.0014$). Ganetsky et al. reported no cases of CDI in patients that received vancomycin prophylaxis (0/90, 0%) compared to 11/55 (20%) who did not receive vancomycin prophylaxis during admission for allogeneic stem cell transplantation. As well, there was no association with higher risk of GVHD, relapse, or survival in these groups [119]. A decreased incidence of recurrent CDI was reported by Morrisette et al. in a retrospective cohort of adult hematologic malignancy patients, 60% of whom had undergone HSCT (of which 77% had received allogeneic HSCT) who received oral vancomycin prophylaxis after a case of primary CDI until the cessation of broad-spectrum antibiotic therapy when compared to patients who did not receive prophylaxis (5% vs. 35%; 0.016). No differences were seen in subsequent VRE infection or 60-day mortality [118].

While prophylaxis may play a role in specific circumstances such as in individuals with known CDI risk factors presenting for transplantation and found to be colonized with toxigenic *C. difficile* or in those patients with a history of recent/recurrent CDI), data are lacking. However, in individuals colonized with *C. difficile* having the expectation of neutropenia and treatment with antibiotic prophylaxis or in

ICH patients colonized with *C. difficile* and given broad-spectrum antibiotics for treatment of febrile neutropenia or other serious infections, it may be considered.

Probiotics

Approaches to support the colonization barrier that the microbiome provides to prevent *C. difficile* colonization and resultant infection have been studied in the form of probiotics, prebiotics, and FMT. The safety in immunocompromised hosts, however, has been questioned. Probiotics are "live microorganisms" which when administered in adequate amounts confer health benefit on the host [120, 121]. Timely use of probiotics in hospitalized adults has variably been shown to prevent CDI in a systematic review with meta-regression analysis [122]. Of 6,261 inpatients in 19 randomized controlled trials who received broad-spectrum antibiotics and various probiotics (*Saccharomyces boulardii*, Lactobacillus spp., Bifidobacterium spp., and Streptococcus spp., alone or in combination), a 0.42 [95% CI 0.3–0.57] relative risk of CDI was reported in the probiotic group. This review highlighted the variability in probiotics used and how cases of CDI were defined depending on study-specific diagnostic criteria.

Finally, a preparation of non-toxigenic *C. difficile* spore administered orally in an effort to compete with toxigenic *C. difficile* present in the colon was successful in reducing recurrent CDI when taken by patients with clinical cure at the end of a course of active treatment for CDI [123].

Conclusions

Clostridioides difficile infection in both SOT and HSCT patients is common and can incur high healthcare associated costs; treatment approaches are evolving. Past studies have focused on treatment of the *C. difficile* bacteria and its spores, but current studies focus on improved immune response to toxin and on the importance of restoration of healthy gut microbiota. Treatment approaches in immunocompromised hosts, including in those after HSCT or SOT, are similar to the general inpatient population for acute infection. However, depending upon the presence and type of ongoing risk factors, the use of tapering doses of antimicrobial therapy or secondary prophylaxis may need to be considered, as this group is at higher risk of developing not only primary but also recurrent CDI with worse associated outcomes when compared to immunocompetent hosts. More work is needed to develop evidence-based methods to prevent transmission and acquisition of *C. difficile* spores, to develop preventive strategies (such as the appropriate use of anti-CDI prophylaxis, bezlotoxumab, prebiotics, FMT, and non-toxigenic C. difficile spores), to prevent the development of CDI in pretransplant patients already colonized with *C. difficile*, and finally, in determining how best to reconstitute the intestinal microbiome after an expected peri-transplantation insult from broad-spectrum antibiotics, chemotherapy, and immunosuppressive agents.

Key Points

- The incidence of CDI is higher in transplant recipients than in the general hospitalized patient population and contributes to significant morbidity and mortality.
- Transplant recipients receiving more aggressive immunosuppression (hematopoietic, heart, lung, and in setting of enhanced immunosuppression due to graft failure/rejection) have a greater incidence of CDI compared to those receiving lower levels of immunosuppression (kidney and liver transplant).
- In addition to the common risk factors associated with the development of CDI, transplant recipients have additional risk factors including exposure to chemotherapy, immunosuppression, radiation therapy, and increased need for antiinfective therapy in the treatment and prevention of concomitant infections.
- Hospital-based strategies to prevent C. difficile in all patient populations, including transplant recipients, include an active antimicrobial stewardship program, use of contact precautions, effective cleaning of contaminated surfaces, and hand hygiene. Specificity of diagnostic testing may be increased through algorithmic approach or restriction programs (laboratory stewardship).
- While treatment algorithms for transplant recipients with CDI do not vary from the general population, risk of relapsing CDI is higher in immunocompromised hosts and use of prolonged courses of vancomycin and fidaxomicin, including tapers, as well as bezlotoxumab and FMT may need to be considered with initial episode or early recurrences depending on clinical context.

Disease Epidemiology

In the era before effective methods of prevention, up to 75% of organ transplant recipients developed CMV. In the modern era, that number is greatly reduced. Rates of infection after transplant depend primarily on pretransplant serology. CMV seronegative organ transplant recipients (R−) who receive an organ from seropositive donors (D+) are at highest risk for developing CMV infection after transplant. Seropositive recipients (R+) are generally at moderate risk for developing CMV infection. R+ recipients who receive organs from seropositive donors (D+)

are at higher risk for developing CMV infection compared with those who have seronegative donors, suggesting that superinfection with different CMV genotypes is clinically important [2]. Pairings where both the donor and recipient are seronegative are at very low risk for developing CMV, unless there was an error in the testing, or they were in the "window period" prior to serologic conversion, or the recipient developed CMV from transfusion of blood products at the time of transplant.

Given that the rates of CMV infection after solid organ transplant (SOT) are highest in nonimmune recipients from previously infected donors (D+/R−) and that this accounts for the majority of disease after transplant, overall rates of disease correlate with the general rates of CMV seropositivity in the community. This varies throughout the world. For example, about 50% of adults in the United States [3] and Canada are CMV seropositive, while rates are over 90% in Brazil, South Africa, India, and Italy.

In the United States, the national Scientific Registry of Transplant Recipients (SRTR) data reveal some interesting trends (Table 1) [4–9]. Among living donor adult kidney and liver transplants, there are lower rates of CMV seropositivity among both donors and recipients, which could be potentially explained by the lower average age of living kidney transplant recipients. Table 1 provides details across most organ transplants. The lower rates of CMV exposure after living donor transplantations may contribute to the generally improved outcomes after such transplants, compared with deceased donor transplantation. Furthermore, there were almost twice as many D−/R− pairs among the living donor kidney and liver transplant recipients when compared with deceased donor pairs, rendering a substantial cohort of recipients not at risk for CMV from their organ transplant. There were augmented rates of high-risk D+/R− pairs among pancreas, heart, and lung transplant recipients (25–28%) compared with deceased donor kidney and liver

Table 1 Donor-recipient cytomegalovirus serology pairs, 2016–2018. Donor serology is reported on the OPTN Donor Registration Form and recipient serology on the OPTN Transplant Recipient Registration Form. Data for intestinal recipients was not reported. Most do not add up to 100% due to lack of complete reporting or unknown status. (Data published annually in the *American Journal of Transplantation* supplement 1 (January) [5–9])

		2016–2018			
		Recipient negative		Recipient positive	
Adult	Donor type	Donor negative	Donor positive	Donor negative	Donor positive
Kidney	Deceased	13.6	17.9	25.8	41.2
	Living	25.4	17.7	21.2	32.8
Pancreas	Deceased	19.9	25.9	21.9	31.3
Liver	Deceased	14.5	22.2	22.0	39.8
	Living	32.2	14.6	25.1	26.7
Heart	Deceased	17.5	24.9	20.2	35.0
Lung >=12yo	Deceased	18.1	27.7	19.8	33.0

recipients (17–22%), which might explain some of the higher rates of CMV seen after those transplants.

Pediatric organ transplant recipients are far more likely to be naïve to CMV, and to acquire CMV at the time of transplant, especially for those undergoing organ transplants from adults. Infants may have maternal antibodies and/or passive transfer of antibodies from transfusion of blood products and require careful examination to confirm the precise risk status (i.e., to avoid interpreting maternal antibodies as a true positive, suggesting protection from infection) [10]. Nucleic acid testing for CMV from urine and oropharynx can be quite useful in confirming positive CMV status; cellular immune assays, such as CMV-specific CD4+ T cells, are sensitive and specific in children >18 months but less useful in younger children [11].

For pediatric kidney transplant recipients from deceased donors in 2016–2018, 20.3% were D+R+, 15.2% were D−R+, 39.0% were D+/R−, and 23.4% were D−/R− [6]. Similar to adult transplants, pediatric recipients and donors undergoing living donor kidney transplants were less likely to be CMV seropositive before transplantation; 19.4% were D+R+, 8.3% were D−R+, 28.9% were D+/R−, and 39.5% were D−/R− [6].

CMV infections tend to occur in settings of more intense immunosuppression. This is especially true in R+, who otherwise are at lower risk for infection after transplant given their prior immunity. Use of potent immunosuppressive agents at the time of transplant, such as antithymocyte globulin or alemtuzumab, often conveys a higher risk of CMV. At present, the majority of kidney transplants get induction at the time of transplant; almost 75% of kidney transplant recipients and just over 50% of heart and lung transplant recipients underwent immunosuppression induction with T-cell depleting agents in 2016 [12–14]. The choice of maintenance immunosuppression may impact the risk of developing CMV; for example, a reduced risk of CMV in those on sirolimus and everolimus has been seen across numerous studies [15–17]. As we are more able to effectively suppress the immune system and achieve lower rates of organ rejection with better long-term outcomes, there is often a trade-off resulting in higher rates of infection, including CMV, necessitating greater recognition of the risk and better optimization of prevention methods.

Another significant risk factor for CMV infection is low lymphocyte count, which can be a readily available marker of risk [18, 19]. There is some variation among reported risk factors for developing CMV. One recent report in a largely seropositive population of kidney transplant patients in Brazil who underwent induction with antithymocyte globulin found that reduced kidney graft function, but not acute rejection, was a risk factor for CMV infection [18].

Clinical Impact in Solid Organ Transplant

CMV infection has a significant impact on organ transplant outcomes. The "direct effects of CMV range from asymptomatic to viral syndrome to end organ disease (colitis, pneumonitis, hepatitis, retinitis). In the modern era, much CMV replication

is detected early as either asymptomatic but with a positive CMV DNA PCR test or as viral syndrome; in prior times, this was often detected late, as end organ disease. The clinical presentation of CMV infection and disease can be protean, and clinicians should think of this possibility frequently, especially within the first year after transplant, or after augmentation of immunosuppression. CMV can certainly be "the great masquerader" (akin to syphilis in internal medicine) after organ transplant. The "indirect effects" of CMV infection also have a significant impact on transplant outcomes; these include higher rates of other infections (bacterial, viral, and fungal), posttransplant lymphoproliferative disorder, cardiovascular events, new-onset diabetes mellitus after transplantation, immunosenescence, acute rejection, and mortality, as well as higher rates of transplant-specific effects including chronic allograft nephropathy and/or allograft loss after renal transplant, hepatic artery thrombosis after liver transplant, allograft vasculopathy after cardiac transplant, and bronchiolitis obliterans after lung transplant [20].

The clinical impact of CMV manifests itself in every aspect of transplant care. Prevention of CMV results in significant cost, diagnostic testing, drug toxicity (especially leukopenia, which may necessitate use of white blood cell growth factors), logistical challenges, and antiviral drug resistance. Diagnosis of CMV is straightforward the majority of the time, but can involve additional invasive studies such as endoscopy and bronchoscopy, urgent ophthalmologic examinations, and additional radiographic studies. Treatment of CMV is usually with oral therapy, although more complex cases may require intravenous antiviral therapy, hospitalization, use of CMV immunoglobulin, reduction of immunosuppression, and management of leukopenia. Ganciclovir resistant CMV infection often requires more toxic therapies such as high dose ganciclovir or foscarnet, with a greater frequency of hospitalization (sometimes for weeks) and significant cost as well as morbidity and mortality.

Obviating the risk of CMV infection after SOT through approaches such as vaccination or pathogen inactivation would revolutionize the field of SOT and would likely result in simpler clinical care, fewer diagnostics, less frequent hospitalizations, and overall better outcomes. Thus far, such approaches remain elusive.

Disease Clinical Evaluation and Diagnostics

CMV infection is primarily seen in the first year after transplant, or with subsequent intensification of immunosuppression (i.e., treatment of rejection). It generally occurs within the first three to four months either after transplant (in the setting of preemptive therapy, without prophylaxis) or after the end of prophylaxis [21, 22]. CMV infection represents a continuum of disease, ranging from asymptomatic to viral infection to end organ disease. Like other members of the human herpes virus family, CMV enters a latent phase after primary infection. Humans thus harbor the virus during their lifetime. CMV infection and disease occur during either primary infection or reactivation of latent infection. For clarity between CMV infection

and disease, the following definitions may be useful and are consistent with the American Society of Transplantation and the CMV Drug Development Forum recommendations for use in clinical trials [23, 24]. CMV infection is when there is evidence of CMV replication regardless of symptoms (differs from latent CMV), "defined as virus isolation or detection of viral proteins (antigens) or nucleic acid in any body fluid or tissue specimen" [24]. CMV disease is defined as evidence of CMV infection with attributable symptoms. CMV disease can be further categorized as a viral syndrome (i.e., fever, malaise, leukopenia, and/or thrombocytopenia), or as tissue invasive ("end organ") disease, such as with colitis, gastritis, pneumonitis, retinitis, nephritis, and other sites.

Having a low threshold to consider the diagnosis of CMV in the first year after SOT is generally prudent. Although guidelines suggest that monitoring for an infection does not need to occur while on prophylaxis [10], if there are clinical signs or symptoms of infection, it is prudent to check for CMV, which might occur with inappropriately low dosing of prophylaxis, development of antiviral resistance, excessive immunosuppression, or medication noncompliance. Initial steps include screening for symptoms of viral infection and end organ disease. Physical examination may demonstrate evidence of oral lesions, visual changes, pneumonitis, abdominal tenderness, and rarely neurologic changes. Knowledge of donor and recipient serology to better categorize the level of risk (high/moderate/low) is generally useful. CMV viral load testing of whole blood or plasma are generally readily available screening tests in most transplant centers. A chest x-ray may show findings of pneumonitis. Abdominal and or chest CT scans may be helping in demonstrating evidence of organ involvement. Clinicians should be aware that sometimes CMV viral load testing can be negative even in the setting of gastrointestinal disease, and even less commonly, with pulmonary disease after lung transplant. In that setting, clinicians may wish to pursue endoscopy or bronchoscopy for further diagnostics. Biopsy of intestine or lung may prove useful, especially with immunohistochemistry stains specific for CMV. Intestinal biopsy sent for CMV culture has been shown to enhance the diagnostic sensitivity of endoscopy [25].

Diagnostics primarily focus on the use of serology, viral load testing, CMV specific cellular immune assays, viral culture, and pathology along with immunohistochemistry. As per the CMV guidelines, the term DNAemia is preferred over viremia, to reflect the detection of CMV DNA in either blood or plasma (i.e., DNA is detected, whether actively replicating virus or not) [10]. To enhance accuracy, the phrases "viral load," "nucleic acid testing," or "quantitative nucleic acid amplification testing" are used instead of "polymerase chain reaction (PCR)."

CMV Serology

Serology for CMV is based primarily on IgG testing. IgM testing has limited diagnostic sensitivity in the setting of CMV and SOT, and its use is generally not recommended [10]. Care should be taken when using serology, as passive transfer of

antibody through transfusion of blood products could cause diagnostic confusion, especially given the high rates of seropositivity in the general population. For example, someone who was seronegative could be transiently seropositive for CMV IgG due to recent transfusion of blood products, although this would not convey significant protection against CMV infection, and they might be triaged to the wrong risk group for prophylaxis. A pretransfusion sample should be tested when feasible. Cell-mediated immunity assays may be useful in assisting in establishing true immunologic status in children and adults who may have passive antibody [26, 27]. Although CMV IgG was always perceived to be the gold standard for evidence of prior CMV exposure, levels may be diminished in the setting of hypogammaglobulinemia, immunosuppression, and other causes. Interestingly, the use of CMV specific cellular immune assays has demonstrated that some people are CMV seronegative but clearly have CMV specific cellular immune responses, suggesting that CMV IgG is less of a gold standard test than previously thought.

CMV Nucleic Acid Testing

CMV DNAemia assays are usually done by quantitative nucleic acid amplification testing. There are a variety of commercially developed and laboratory developed assays in active use. Although there has been an international standard for CMV quantitative nucleic acid amplification testing for over half a decade, which dramatically improved testing, there are still significant interassay variations noted [28, 29]. A critical analysis of both clinical specimens and international standard dilutions was disappointing; while 59% of all clinical sample results fell within $\pm$ 0.5 log10 International Units (IU)/mL of the mean viral load of each sample, the remaining 41% had more significant variation, preventing meaningful interassay result comparison. This means that comparison across different testing laboratories and diagnostic platforms should not be done, as it can be highly erroneous [10, 29]. Nuances of the assays impact results; those assays with amplicon sizes $\leq$86 base pairs had significantly higher quantitative CMV DNA results compared to tests with larger amplicon sizes ($\geq$105 base pair) ($P<0.001$) [29].

Whole blood generally has higher results by quantitative nucleic acid amplification testing when compared with plasma, sometimes by one log10 or more. While CMV DNA exists predominantly as small fragments in plasma [30], this seems to be less true for whole blood in which both intracellular and extracellular DNA are detected. Of note, persistent plasma DNAemia was demonstrated to be a better predictor of relapse at day 21 of antiviral treatment when compared with persistent whole blood DNAemia [31].

Thus, quantitative nucleic acid amplification testing provides significant and excessive interassay and interspecimen (whole blood versus plasma) variability, such that transplant programs should be prepared to pick one diagnostic type (plasma or whole blood) and testing platform for monitoring and trending an individual patient with CMV infection. Switching or alternating specimen types and diagnostics laboratories may result in clinical errors. A common example would be the suggestion that a

patient may have antiviral resistance because the viral load increased while on therapy when instead, it was a diagnostic error due to lack of comparability of the testing.

Genotyping for CMV with antiviral resistance is done at a limited number of laboratories internationally. Prior resistance testing required a positive CMV culture and phenotypic testing, which often involved months of laboratory work. Modern testing is done by genotyping and generally entails a rapid turnaround time, sometimes within a few days. The CMV population within an individual patient is often somewhat heterogeneous, and genotyping may not always reflect the extent of the genetic mutations. Knowledge of specific mutations allows for interpretation of likely antiviral resistance, facilitating changes in antiviral therapy to those agents that would be more likely to be efficacious (Table 2) [32–34].

CMV Culture and Pathology

CMV culture is performed less frequently in microbiology laboratories, but may be useful on certain specimens such as intestinal biopsies, where it may enhance diagnostic yield [25]. Sending certain specimens, such as saliva, sputum, bronchoscopy fluid, stool, urine, and others, may not allow determination between innocuous shedding of virus and infection/disease and would generally be discouraged.

Pathology may show the classic findings of CMV infection, with giant cells and "owl eyes" (used to describe the nuclei of cells infected by CMV). Characteristic findings include dark pink nuclear inclusion body surrounded by a clear halo. CMV also causes the development of cytoplasmic inclusions, seen as granules throughout the cytoplasm of the infected cells. Immunohistochemistry specifically for CMV can

Table 2 Antiviral agents with efficacy (at least *in vitro*) against CMV and other transplant related viruses. (Modified from Kotton [86])

Antiviral agent	CMV	HSV	Varicella	BK	Adenovirus	EBV
Commercially available

Maribavir	x					x

[a]acyclovir/valacyclovir/famciclovir for prophylaxis only
[b]foscarnet, cidofovir not usually used for prophylaxis

add to the diagnostic sensitivity and should be requested in settings where there is concern for CMV infection.

CMV Immune Assays

CMV specific cellular immune assays have blossomed over the past decade, initially as research assays, and now as commercially available tests. Conceptually, it would be excellent if they could predict the risk of CMV either at the time of SOT or at the end of prophylaxis, or of recurrent disease at the end of treatment. In general, they tend to be more predictive in R+, likely due to prior immunity. The more common approaches include detection of IFN-γ after stimulating whole blood or peripheral blood mononuclear cells with overlapping peptides or CMV specific antigens; other markers that have been used to correlate CMV-specific T-cell responses with the risk of CMV infection include IL-2, CD107, TNF-α, programmed death-1, and CD154. Several commercial assays are now available, usually based on interferon gamma release assays (QuantiFERON- CMV (QIAGEN), T-SPOT.CMV (Oxford Immunotec), T-Track CMV assay (Lophius Biosciences), and the CMV T Cell immunity panel (Viracor), which helps standardize the field, as much of the prior work had been with laboratory developed tests which were not necessarily reproducible across different centers.

Late CMV, which usually develops within several months after the end of prophylaxis, remains an Achilles heel of SOT. Current CMV diagnostics such as viral load and posttransplant serology do not allow accurate prediction of those at risk for infection. Focusing methods of prevention on those at higher need would likely decrease diagnostic hassles, medication related toxicities, and associated costs, as well as attenuate the associated indirect effects of CMV infection that negatively impact transplant outcomes. These CMV-specific cell mediated immunity assays may be able to help us focus on the at-risk population.

Numerous studies of CMV immunity assays exist, many of them single center; some of the more recent ones will be highlighted here. Work with D+/R+ patients who had induction with either anti-interleukin 2-receptor antibody (basilixumab) or rabbit antithymoglobulin found that those with late CMV had much lower rates of cellular mediated immunity as measured by ELISpot for the CMV antigens IE-1 and pp65 (T-spot.CMV, Oxford Immunotec) [35]. Using receiver operating characteristic curve analyses, they demonstrated that determining CMV-specific ELISpot thresholds (25 and 130 IFN-γ spots for IE-1 and pp65, respectively) allowed for classification of patients into high risk, intermediate risk, or low risk, with the antigen IE-1 being the strongest predictor. A multicenter ($n = 43$) trial was recently published, where kidney transplant recipients at the end of antiviral prophylaxis underwent CMV-specific ELISpot testing to enumerate interferon gamma (IFN-γ) binding spot-forming units after stimulation of cells with an overlapping peptide pool of CMV phosphoprotein 65 and immediate early-1 protein. The goal was to see whether the test results were predictive of subsequent CMV events. While the assay was predictive in moderate risk (R+) recipients, it

was not predictive in high risk recipients when used over the months after prophylaxis was stopped [36].

Two interventional trials using CMV immunity assays have been published recently. Kumar et al. used the Quantiferon-CMV assay to guide subsequent management at the end of treatment for CMV viremia necessitating antiviral therapy, demonstrating the efficacy of CMV-specific cellular mediated immunity testing to guide changes in CMV infection management [37]. A total of 27 patients with CMV viremia were treated until viral load negative (median initial viral load 10,900 International Units/mL). At end of treatment, a positive Quantiferon-CMV response was seen in 14/27 (51.9%), in whom antivirals were discontinued, and the remaining 13/27 (48.1%) had a negative CMV-CMI response, and were then given 2 months of secondary antiviral prophylaxis. In those with a positive Quantiferon-CMV and early discontinuation of antivirals, only a single patient experienced a low-level asymptomatic recurrence, while recurrence of infection was seen in 69.2% of Quantiferon-CMV negative patients despite more prolonged antivirals ($p = 0.001$). Although it is still not clear what to do with the Quantiferon-CMV negative patients, it would be helpful to know which population clinicians should focus their attention upon. Westall et al. did a randomized study of Quantiferon-CMV-directed versus fixed duration (5 months) valganciclovir prophylaxis to reduce late CMV after lung transplant, where those with a negative test underwent prolonged valganciclovir prophylaxis for up to 11 months after transplant [38]. The incidence of CMV infection in the lung allograft within 18 months transplant, the primary end-point, was significantly reduced in the Quantiferon-CMV directed arm compared with fixed duration (37% vs. 58%, $p = 0.03$), although CMV viral loads in blood, acute rejection, and chronic lung allograft dysfunction did not differ. Those with a positive Quantiferon-CMV had a lower incidence of CMV viral loads, as well as less severe CMV.

Management (Both Clinical Management and Preventative Care)

Prevention

Prevention of CMV is considered standard of care, as suggested by international guidelines [10, 39]. A recent survey of organ transplant programs in Europe found that almost all use prevention methods, either prophylaxis or preemptive therapy [40].

Prophylaxis involves administration of antiviral medications, often at a half of the treatment dose, for a set period of time, often 3–6 months after SOT [10]. The only readily available antiviral is ganciclovir, either in the form of the intravenous preparation ganciclovir or the oral prodrug, valganciclovir. For ease of administration, most programs use valganciclovir for prophylaxis (and treatment), unless there are concerns about malabsorption. Oral ganciclovir was the precursor to valganciclovir and is now off the market internationally; it was far less bioavailable (<10%) than valganciclovir (~60%). High dose valacyclovir has been used, although it is generally less well tolerated, and recent data suggests that when

compared with valacyclovir, valganciclovir prophylaxis was associated with a reduced risk of moderate-to-severe interstitial fibrosis and tubular atrophy in kidney transplant recipients [41]. A trial of letermovir versus valganciclovir for prophylaxis in 600 kidney transplant patients is underway (ClinicalTrials.gov NCT03443869). Maribavir was studied in the past for high risk D+/R− liver transplant recipients, but found to be inferior to oral ganciclovir [42]. Brincidofovir has not been studied in SOT for prophylaxis.

Duration of prophylaxis often ranges from 3 to 6 months, on the shorter end for those who are R+ and/or otherwise at lower risk, and 6 months for those at higher risk (D+/R−). Longer durations of prophylaxis are sometimes given to those who have undergone higher risk SOTs, such as lung, intestinal, composite tissue, and others. Some programs have even gone to lifelong prophylaxis, primarily after lung transplant, although the cost and toxicities (primarily leukopenia) are often prohibitive, and mortality remains high in those that eventually develop CMV disease [43, 44]. The Improved Protection Against Cytomegalovirus in Transplantation (IMPACT) study demonstrated a decreased risk of CMV disease in D+/R− kidney recipients given 200 days of prophylaxis (21.3%) compared to those given 100 days of prophylaxis (36.8%), $p<0.0001$ [45]. Similar large trials are lacking with other SOT types. An example of suggested prophylaxis for human herpes viruses (including CMV) appears in Table 3.

Preemptive therapy involves monitoring for a period of time during the high risk period, that is, weekly (or twice a week) monitoring for 3–4 months after transplant or during periods of more intense immunosuppression. Those SOT recipients managed with the preemptive approach should be given oral acyclovir (or similar antiherpes nucleoside analogues) to prevent disseminated varicella and herpes simplex infections [46]. While generally effective at preventing CMV disease when done rigorously, it may not prevent the "indirect effects" of CMV from occurring, and it may be less effective especially in previously nonimmune subjects (D+/R−) at preventing very rapid expansion of virus, when rapid doubling times can occur. One study demonstrated that in D+/R−, there was a median viral load doubling time of 1.54 days (range 0.55–5.5) compared with 2.67 days (range 0.27–26.7) in the D+/R+ recipients ($p<0.0001$) [21]. Monitoring patients on therapy should be done at least weekly, given the half-life of viral loads [47]. Less frequent screening (i.e., less than weekly) has been shown to result in higher rates of CMV disease and inferior long-term graft survival when compared to prophylaxis [48, 49].

Preemptive therapy is a recommended alternative to prophylaxis for most R+ SOT recipients, although it is not recommended in higher risk situations such as lung, heart, vascularized composite, pancreas, islet, and intestinal transplant, where prophylaxis may be preferable [10]. Similarly, prophylaxis may be preferable in donor and/or recipient seropositive patients at increased risk for CMV, including those on recent antilymphocyte therapy, potent immunosuppression including desensitization or ABO incompatible protocols (including those on plasmapheresis/immunoadsorption, rituximab, bortezomib, and eculizumab), and those with HIV. A comparison of prophylaxis with preemptive therapy appears in Table 4.

Table 3 Example of human herpes virus prophylaxis after kidney, liver, heart, or pancreas transplant [10]

Induction agent	Donor CMV antibody	Recipient CMV antibody	Prophylaxis	Monitoring with CMV viral load
Antithymocyte globulin, alemtuzumab	Positive	Positive	Valganciclovir × 3 months	Monitoring while on prophylaxis only if clinically indicated by symptoms; consider weekly monitoring after prophylaxis × 8–12 weeks in higher risk patients, including D+/R− and those on more potent immunosuppression
	Negative	Positive		
	Positive	Negative	Valganciclovir × 6 months (plus consider weekly monitoring afterwards × 8–12 weeks in higher risk D+/R− on more potent IS)	
	Negative	Negative	Acyclovir, famciclovir, or valacyclovir × 3 months	
Corticosteroids, basiliximab, or none	Positive	Positive	Valganciclovir × 3 months	
	Negative	Positive		
	Positive	Negative		
	Negative	Negative	Acyclovir, famciclovir, or valacyclovir × 3 months	

Notes on viral prophylaxis:
• Dosages of all antiviral agents need to be adjusted for renal function. The eGFR or creatinine clearance should be used (not simply the serum creatinine).
• For prophylaxis, the first doses may be oral valganciclovir or intravenous ganciclovir, converting IV to oral as soon as patient tolerating oral medications. There is recent data supporting the safety and efficacy of either approach in the treatment (not prophylaxis) setting [87, 88].
• While most kidney transplant recipients (given lower GFR, often 40–60) will need valganciclovir 450 mg a day (or less), some may have GFR>60 and need valganciclovir 900 mg a day. Mini-dosing not recommended [10].
• Lung, intestinal, composite tissue transplant prophylaxis would be similar, although generally with longer courses of prophylaxis, and sometimes with the use of CMV immunoglobulin.

Table 4 Comparison of prophylaxis versus preemptive therapy. (Revised from Kotton et al. [10])

	Prophylaxis	Preemptive therapy
Prevention of CMV disease	Good efficacy	Good efficacy
Late CMV (infection/ disease)	Common (usually after end of prophylaxis)	Rare
Early CMV DNAemia/ infection	Rare	Common
Ease of implementation	Relatively easy; cost/ insurance coverage can be an issue	More difficult, requires diligent testing and follow-up plus intervention if positive testing
Resistance	Uncommon	Uncommon (with weekly testing, higher with irregular testing)
Prevention of other herpes viruses	Prevents HSV, VZV Unlikely to impact EBV, HHV-6, -7, -8	Does not prevent; best if acyclovir (or similar) is given
Costs	Drug costs	Monitoring costs
Safety	Drug side effects	Less drug toxicity, unless treatment dose antiviral therapy is needed
Prevention of rejection	May prevent	Unknown
Graft survival	May improve	May improve

Developing optimal thresholds for initiation of antiviral treatment varies across different institutions, test platforms, and sample types [10]. In general, higher thresholds are acceptable for R+, as their prior immunity may be effective in containing CMV infection, whereas nonimmune subjects need a lower threshold in order to avoid significant infection. The lower levels of positive CMV viral loads, as seen with the ultrasensitive assays, can be hard to interpret with preemptive therapy. Some groups suggest that understanding viral kinetics may predict the risk of disease, which could be done by increasing the frequency of testing, perhaps to twice a week, and measuring the rate of change between samples; rapid increases suggest a need to initiate antiviral therapy at any level.

Surveillance after prophylaxis is an approach that can be considered for those SOT recipients at increased risk for postprophylaxis CMV disease, in order to capture infection in the early stages. This is a hybrid approach, combining prophylaxis followed by preemptive therapy. This may work best when used during the high risk period, done weekly for 8–12 weeks after the end of prophylaxis. Bi-weekly or monthly monitoring is considered to be insufficient for preemptive interventions, as it will likely miss the period of rapid viral expansion. Determining which individuals are at risk for CMV infection remains challenging. Serology alone is not predictive on an individual basis. Recent diagnostic developments have focused on CMV specific cellular mediated community as a marker of risk of primary infection, reactivation infection, recurrent

infection, and for optimizing duration of prophylaxis; see above for further discussion.

Vaccines

Vaccines to prevent CMV have remained elusive. In the 1970s, Dr. Stanley Plotkin and collaborators developed the live, attenuated Towne strain as the first CMV vaccine candidate, with partial but insufficient efficacy. There have been many subsequent attempts at CMV vaccine development, which would be useful for both maternal-fetal and transplant related CMV prevention. One of the more recent trials involved the DNA-based vaccine ASP0113, which had looked promising in earlier trials, but no statistically significant difference was found in D+/R− kidney transplant recipients with respect to the primary endpoint (the proportion of transplant recipients found to have CMV viremia $\geq$1000 IU/mL from Day 100 through to 1 year after the first vaccine injection) between the ASP0113 and placebo groups [50]. There are several studies of CMV vaccines for SOT recipients underway, using a variety of approaches.

Immunoglobulins

Intravenous immunoglobulins (IVIG) are immunoglobulins removed from donated human blood products and processed so as to be safe for intravenous infusion. To provide higher titer CMV IgG in intravenous immunoglobulins, donors who have high CMV IgG antibody levels are included to make "CMV immunoglobulin." There is batch-to-batch variation; generally CMV IgG levels are no more than five- and tenfold greater in CMV immunoglobulin compared with IVIG. CMV immunoglobulin was originally developed for prevention of CMV prior to the advent of directly acting antiviral therapy; this is the only indication approved by the United States Food and Drug Administration. Modern use includes prophylaxis in lung transplant and other high-risk SOT recipients (i.e., small bowel), often with concomitant antiviral prophylaxis, as well as use in settings of CMV antiviral resistance [10]. Data on lung transplant recipients suggest reduced rates of CMV disease and bronchiolitis obliterans syndrome and improved patient survival, although it is not clear if this is due to the anti-inflammatory effects of CMV immunoglobulin or the result of a reduction in CMV infection [51] or perhaps due to the immune modulation of activated CD4+ lymphocyte and of naïve B-cell subsets [52].

There tends to be heterogeneous use of CMV immunoglobulin, likely reflecting the paucity of clinical data supporting its use in the modern era. One trial in abdominal transplant recipients who were given either VGCV for 200 days versus VGCV for 100 days followed by 3 doses of monthly CMV immunoglobulin found more overall CMV infections in the CMV immunoglobulin group (45 vs. 20%), but

no statistically significant differences in overall CMV infections or late CMV disease were seen between groups [53].

Given that IVIGs are human-derived products and thus difficult to standardize, monoclonal antibodies specifically targeting key epitopes would be expected to provide an advantage in efficacy. Recent approach have included multiple monoclonal antibodies used at once, for presumed enhanced efficacy and decreased development of viral resistance. CMV is a complex virus with multiple antigens, including glycoprotein B (gB) and the gHp entameric complex; most of the naturally generated antibodies target the gB antigen, although they may not have adequate neutralizing ability to control reactivation and infection. The pentameric gH complex has been shown to be the primary target for neutralizing antiviral antibodies, so this has been a focus of recent monoclonal antibody development. For example, CSJ148 (Novartis) is a combination of two monoclonal antibodies against CMV, LJP538, which binds to the viral gB protein and LJP539, which binds to the viral gH pentameric complex. A phase 1 trial in healthy volunteers showed good safety and tolerability. Phase 2 clinical trials of CSJ148 in hematopoietic stem cell transplant (HSCT) patients have been completed (ClinicalTrials.gov NCT02268526), data not yet published. A combination of two monoclonal antibodies, RG7667 (Genentech), that bind two distinct antigens (the neutralizing epitope on CMV glycoprotein H (gH) and the neutralizing epitope on the gH/gL/UL128/UL130/UL131 complex) on the surface of CMV and inhibit its entry into relevant host cells is under development. A randomized, double-blind, placebo-controlled trial of RG7667 to prevent CMV infection in high-risk (D+/R−) kidney transplant recipients without prophylaxis demonstrated some efficacy [54]. CMV viremia occurred in 46% (27/59) of those receiving RG7667 and 61% (35 of 57) in the placebo cohort within the first 12 weeks after transplant and in 51% (30 of 59) of those receiving RG7667 and in 70% (40 of 57) on placebo within 24 weeks after transplant. The median time to CMV viremia was 139 days in the cohort on RG7667 compared with 46 days in those on placebo, and CMV disease was less common in the RG7667 (3%) than placebo (16%) groups. Thus, the monoclonal antibody RG7667 was well tolerated, significantly reduced the incidence of CMV infection within 12 and 24 weeks after transplant in high risk kidney transplant recipients (although rates were still high), delayed the onset of CMV viremia, and was associated with less CMV disease than the placebo, yet was not significantly able to prevent CMV infection. Such therapies, if developed further, may have an interesting niche in combination with other treatments (i.e., antivirals, vaccines, etc.).

Treatment of Active Infection

Once active infection has been diagnosed, treatment involves antiviral therapy, most commonly with oral valganciclovir 900 mg twice a day, renally adjusted if needed. The VICTOR trial demonstrated noninferiority of oral therapy when compared with intravenous ganciclovir [55]. Guidelines suggest that for

convenience, oral therapy is generally preferred over intravenous therapy, except when there are concerns for life or sight threatening disease, malabsorption, or economic considerations [10]. CMV viral load should be monitored at least weekly to determine the duration of therapy. Treatment is generally continued until resolution of all clinical signs of CMV disease and eradication of CMV DNAemia is achieved (defined in guidelines as below LLOQ on one highly sensitive assay (LLOQ <200 IU/ml), or lack of detection on two consecutive less sensitive assays [10]. Failure to eradicate plasma DNAemia by the end of treatment is a major predictor of virologic recurrence [55]. One the other hand, a completely undetectable viral load may not always be achievable with use of highly sensitive assays. Consideration of the net state of immunosuppression, clinical setting, time from transplant, diagnostic testing, and other factors should help determine the end of therapy in a given patient.

Appropriate antiviral dosing is crucial in the management of CMV disease. Suboptimal dosing augments the risk for clinical treatment failure and the development of resistance [56], while supratherapeutic doses increase toxicity [57]. Careful monitoring of serum creatinine and kidney function is useful. (Val)ganciclovir dosing should be adjusted as per the Cockcroft-Gault formula, which was used in the VICTOR study; other estimates of renal function, such as the Modified Diet in Renal Disease (MDRD) formula, may lead to inadequate dosing. Caution should be used with automated calculators of renal function, as they are more likely to be erroneous with malnourished, debilitated patients and patients at the extremes of size, where nuclear medicine studies or measured urine creatinine over 24 h may be useful.

Treatment outcomes associated with CMV disease are impacted by the intensity of immunosuppressive therapy [58, 59]. Numerous studies incorporate a reduction in immunosuppression as a therapeutic modality. Dual (versus triple) immunosuppressive therapy and lower blood concentrations of calcineurin inhibitors significantly correlate with eradication of CMV DNA at 21 days [58]. Unfortunately, while a reduction in immunosuppression is encouraged and seems to be effective in helping clear viral infection, there have not been formal studies regarding the relative efficacy of cessation of one agent preferentially over another. In general, clinicians are encouraged to review all immunosuppressive medications and decrease the doses of those that seem to be higher. For cases of severe or resistant CMV, where immunosuppression has been significantly reduced, clinicians may consider adding back immunosuppression after successfully gaining good control of an infection, carefully balancing the risk of rejection with the risk of worsening infection. Given the reduced risk of CMV in those on sirolimus and everolimus, some switch to these agents to diminish further CMV infections.

A significant number of patients experience leukopenia well on treatment dose (val)ganciclovir (and even on prophylaxis dose). This is often multifactorial in nature, attributable to commonly used posttransplant medications (mycophenolate mofetil, trimethoprim/sulfamethoxazole, and others) and induction therapies (antithymocyte globulin, alemtuzumab). With leukopenia, the addition of granulocyte colony stimulating factor and/or discontinuation of other myelosuppressive therapies

are recommended before changing (val)ganciclovir to another agent. Reducing the dose of (val)ganciclovir because of leukopenia is strongly discouraged, as it significantly increases the risk of antiviral resistance.

Secondary prophylaxis after treatment of infection involves administration of antiviral prophylaxis for a period of time, previously for one to 3 months. Although this was thought to likely be an effective therapy, retrospective analyses conducted in diverse transplant populations have not demonstrated a benefit to secondary prophylaxis [60–62]. While there was evidence of some delay of the onset of recurrent infection [63], most have shown no benefit. Although a good number of patients may experience recurrent DNAemia upon completion of treatment, especially in high-risk D+/R− transplant patients [64, 65], viral load replication may be slower and the subsequent peak viral load significantly lower compared with the initial episode [21], potentially due to an developing immune response. Some of these episodes of CMV DNAemia may resolve spontaneously [65]. Guidelines do not generally encourage secondary prophylaxis, although they do encourage monitoring (akin to preemptive therapy) after the end of therapy in higher risk patients [10].

Treatment Resistant and Refractory Disease

Risk factors for resistance include exposure to inadequate doses of antiviral therapy (i.e., underdosing, noncompliance), high levels of immunosuppression, prolonged prophylaxis, multiple serial transplants, and receipt of lung and intestinal transplants [66]. Multiple studies have shown significantly higher rates of morbidity and mortality with resistant CMV [66–69], although not all [70]. Rates are generally less than 5% in recent studies (range, 1% [66] to 6% (lung transplant recipients [69]) and tend to be higher in D+/R− [66], as well as lung transplant recipients and other more immunocompromised SOTs. Although there had been the perception that antiviral prophylaxis conveyed a higher risk than preemptive therapy, this has not been the case in all studies, especially when preemptive therapy is done irregularly (less than weekly blood checks) with resultant high viral loads at the time when therapy is started [71, 72].

Resistant CMV occurs infrequently, such that it is challenging to accumulate sufficient data. Unfortunately, data of this nature is not captured in national databases such as SRTR [4]. A retrospective, case-control (1:3) study of SOT recipients at University of Washington (Seattle) with genotypically confirmed ganciclovir-resistant ($n = 37$) and ganciclovir-susceptible CMV infection ($n = 109$), matched by clinical manifestation(s), donor/recipient CMV serostatus, and year and organ transplanted, found that ganciclovir resistance was associated with a longer prior of exposure to ganciclovir (median, 153 vs. 91 days, $P<0.001$) [66]. Interestingly, 3 of 17 lung transplant recipients with ganciclovir-resistant CMV had received <6 weeks of ganciclovir, while all nonlung SOT recipients had received ≥ 90 days (median, 160 days) prior to the diagnosis of ganciclovir-resistant CMV. They found that ganciclovir-resistant CMV was associated with higher mortality (11% vs. 1%, $P = 0.004$), decreased renal function (42% vs. 19%, $P = 0.008$), and fewer days

alive and nonhospitalized (73 vs. 81, $P = 0.039$) at 3 months after diagnosis. Rates of ganciclovir-resistant CMV were higher in the D+R− recipients, with rates as follows: lung (11.9%), heart (5.8%), kidney (2.4%), pancreas (7.8%), and liver (0.4%). In another series from a single institution, University of Nebraska Medical Center, those who developed antiviral resistance had higher prednisone and tacrolimus levels, had a higher rate of fungal infections, and were more likely to have undergone heart, small bowel, and mutivisceral recipients (not liver or kidney) [70]. They found no difference in duration of antiviral prophylaxis, viremia while on antiviral prophylaxis, rates of end organ CMV disease, graft loss, and overall survival. Persistent viremia and clinical disease despite antiviral therapy, perhaps due to a high degree of immunosuppression, was the most important risk factor for development of CMV resistance.

Guidelines suggest that when antiviral resistance/refractory CMV is suspected, genotypic resistance testing should be requested [10]. If there is life threatening or sight threatening disease, and the patient has been on (val)ganciclovir, a switch to foscarnet is recommended (with or without the continued use of (val)ganciclovir). If the clinical disease is only mild to moderate, high-dose ganciclovir (10 mg/kg every 12 h, renally adjusted) may be used, with the caveat that this may not overcome many resistance mutations, and is likely to cause significant leukopenia. Subsequent management should be based on genotypic resistance test results, which should help guide antiviral choices. Some clinicians may wish to use CMV immunoglobulin, especially in patients with hypogammaglobulinemia. In general, with resistance to valganciclovir, subsequent prophylaxis is very challenging, as there are no readily available oral alternatives. Some clinicians use letermovir for prophylaxis after treatment of resistant virus, although there are not yet clinical studies to support this practice. Drug availability, cost, and insurance coverage can be problematic. Recent definitions of resistant and refractory cytomegalovirus infection and disease in transplant recipients, primarily for use in clinical trials, may be helpful for clinicians diagnosing and managing infection [33].

Foscarnet is the most commonly used medication for treatment of resistant/refractory CMV infection. Although it has excellent efficacy in eradicating CMV, it does have significant potential for nephrotoxicity, as well as electrolyte wasting. In general, foscarnet is given to hospitalized patients, given the need for very careful monitoring of kidney function and electrolytes. The best descriptive review of foscarnet is in a single center study at Johns Hopkins University, in SOT and HSCT recipients over a 10-year period who were given foscarnet for treatment of resistant/refractory disease [67]. Of the 39 patients (22 SOT, 17 HSCT), 15 had documented genotypic mutations for ganciclovir resistance, and 11 (28%) of 39 had tissue-invasive CMV. Ganciclovir resistance was more common in SOT than HSCT. The median duration of foscarnet was 32 days; virologic failure occurred in 13 (33%), while relapses of viremia occurred in 31%. Mortality was noted in 12 (31%) of 39 within a year and was higher in HSCT than SOT ($P = 0.001$). Looking back, doses of ganciclovir or valganciclovir had been low in 10 (26%) of 39 at some time before converting to foscarnet. Renal dysfunction was frequent, occurring in 20 (51%) of 39 while on treatment, and was persistent in about a quarter

after 6 months. This series is helpful in framing decision making about management of resistant/refractory CMV and highlights our need for better alternative therapies.

Cidofovir is another agent that may be useful with resistant/refractory CMV, although there is some overlap between the resistance mutations for (val)ganciclovir and cidofovir, such that it may be less effective, and the nephrotoxicity and ophthalmologic toxicities of cidofovir are significant. Nonetheless, due to the long half-life, with susceptible CMV, this agent could be given as prophylaxis intravenously every two weeks, which makes it one of the few options after successful treatment of resistant/refractory CMV. Data on its use for treatment of resistant/refractory CMV is limited. A series from Innsbruck Medical University described 9 SOT recipients with complicated CMV infection or disease (0.4% of all SOTs there between 1 June 1999 and 31 December 2007), 4 of whom had undergone lung transplant, and 2 of which had undergone composite tissue transplant [68]. Most had a treatment response, yet 5 of 9 had relapse of CMV infection, and the majority had renal compromise, some of which persisted after therapy.

Maribavir is a newer agent that inhibits viral DNA assembly and inhibits egress of viral capsids from the nucleus of infected cells, with efficacy against CMV and EBV, although not against varicella and herpes. It was studied in high risk liver transplant recipients in a randomized, double-blind, multicenter controlled trial, with a primary endpoint of confirmed CMV disease within 6 months of transplantation. In a modified intent-to-treat analysis, the noninferiority of maribavir 100 mg twice a day compared to oral ganciclovir for prevention of CMV disease was not established (12% rate of CMV disease with maribavir vs. 8% with ganciclovir). There was no significant difference in graft rejection, patient survival, and non-CMV infections, and while maribavir was safe, it was not adequate for prevention of CMV disease at the dose studied [42]. More recent work with resistant/refractory CMV in a dose escalation (400, 800, and 1200 mg twice daily) phase 2 study in 120 SOT and HSCT recipients showed that 80/120 (67%) patients achieved undetectable CMV DNA within 6 weeks of treatment, with similar rates across various doses. Recurrent CMV infections while on treatment occurred in 25 patients; of those, 13 had developed mutations that conferred maribavir resistance [73]. Further phase 3 studies are underway to assess the efficacy and safety of maribavir treatment compared to standard, investigator-assigned treatment in transplant recipients with refractory or resistant CMV infections (ClinicalTrials.gov NCT02931539).

Letermovir is a CMV-specific antiviral agent that inhibits CMV replication by binding to components of the terminase complex (UL51, UL56, or both), resulting in the formation of concatemers of CMV. It has been shown in a phase 3 trial to be effective in preventing CMV infections when given through 14 weeks after HSCT when compared with placebo, with decreased rates of CMV infection at 24 weeks (38%) versus placebo (61%), and less mortality, with all-cause mortality at week 48 after transplantation 20.9% in letermovir recipients and 25.5% among placebo recipients [74]. Studies are underway for letermovir in SOT (ClinicalTrials.gov NCT03443869). Letermovir is not likely to be useful for

treatment of active infection and will probably be reserved for prophylaxis, as it has a low barrier to resistance [75].

Brincidofovir is a prodrug of cidofovir, conjugated to a lipid. It releases cidofovir intracellularly, allowing for higher intracellular and lower plasma concentrations of cidofovir, effectively increasing antiviral activity while minimizing toxicity. A randomized, double-blind, placebo-controlled phase 3 trial of oral brincidofovir for CMV prophylaxis in allogeneic HSCT recipients demonstrated that although it had good anti-CMV activity, it did not decrease clinically significant CMV infection (CMV disease or CMV DNAemia requiring preemptive therapy) through week 24 compared with placebo, likely confounded by the fact that it was associated with increased gastrointestinal toxicity which could not be differentiated from acute gastrointestinal graft versus host disease and which resulted in a much higher rate of steroid use in the arm with brincidofovir [76]. At present, it is not being developed as an oral drug for CMV prophylaxis or treatment because of this gastrointestinal toxicity, although an intravenous preparation might possibly alleviate this problem.

Adoptive CMV-specific T-cell therapy may be useful in cases of resistant/refractory CMV infection in organ transplant recipients [77–81]. CMV-specific T-cells undergo in vitro expansion with either viral lysate or CMV synthetic peptides, and then they are infused into the recipient to enhance viral immunity, lessen CMV viral loads, and/or promote resolution of CMV disease. The source of the cells can be "off the shelf" T-cells using HLA-matched third party banked cells, or cells obtained from the transplant recipient (autologous), although the process of generating effector cells can take several weeks. There is more experience in the HSCT field using CMV-specific T cells, with varying degrees of efficacy and no evidence of association with graft versus host disease [82, 83]. Commercialization of HLA-matched third party banked CMV-specific T-cells may allow increased use for resistant/refractory CMV in SOT recipients [84, 85]. As there are only case reports at present, significant efficacy and safety studies will be needed.

Key Points, Research Needs, and Future Trends

The past decade has brought marked improvements in CMV management, in both molecular and cellular diagnostics, novel therapeutics including innovative antiviral and cellular therapies, better prevention, and optimized management of resistant/refractory CMV infection. Nonetheless, many needs and gaps remain, including as outlined here:

- Effective, affordable antiviral therapies for prophylaxis and treatment with limited toxicities, resistance, and drug interactions; the current options are limited by leukopenia, cost, and some development of resistance.
- Vaccines that are able to induce long term immunity and protection, optimally in both previously immune and nonimmune organ transplant recipients; this could

abrogate the need for other methods of prevention, additional diagnostics, etc., and could truly alter the SOT field.

- Molecular diagnostics with better comparability across different testing platforms and perhaps even across different specimen types. Trending test results is crucial, and we are currently quite limited when comparing values from different test centers.
- Cellular mediated immunity assays that are predictive of the risk of infection after transplant, and of risk of recurrent infection after treatment of infection would allow us to focus on those at higher risk for infection, which would enhance care while saving on drugs, diagnostics, and follow-up care.
- Better understanding of the optimal choices of immunosuppression and adjunctive therapies for an individual SOT recipient and how to tailor them to abrogate the risk of CMV infection.
- Optimizing the management of resistant/refractory CMV infection after SOT, including better knowledge of novel antiviral therapies and their use in combination, will be critical in the subset of patients who develop this challenging and morbid infection.

The Virus

Human CMV is the prototypic member of the β herpesvirus subfamily, which also includes human herpesviruses 6 and 7. CMV genome is the largest among known human viruses (~230 kb), containing 200 genes encoding proteins [1, 5]. CMV is

able to infect several cell types, such as endothelial cells, epithelial cells (including retinal cells), smooth muscle cells, fibroblasts, leukocytes, and dendritic cells. Like other herpesviruses, CMV becomes clinically quiescent after the primary infection is brought under control by the host immune response [4, 10].

Epidemiology and Risk Factors

A recent analysis revealed an overall 50% seroprevalence among adults in the United States [11], but rates in some populations are even higher. Approximately 90% of Mexican-Americans in the United States are seropositive by age 50, as are 88% of HSCT patients in Italy and 96% of individuals in southern Brazil [11–14]. Transplant centers with high volume of international patients can have rates of CMV-seropositive recipients >85% [8].

CMV remains one of the most important complications after HSCT. The overall incidence of CMV reactivation at any level of viremia by day 100 (early CMV reactivation) after allogeneic HSCT in large cohort studies is in the range of 63–69% [8, 9], with reported median time from HSCT to first detectable (>137 IU/mL) CMV viremia of 17 days (IQR, 7–30 days) [8]. In a study that used a cutoff of ≥273 IU/mL, the median time from transplantation to CMV DNAemia was 48 (35–62) days [15]. Of note, in the era of preemptive antiviral therapy, most of the episodes of CMV reactivation correspond to low-grade viremias with less than 40% of patients achieving a plasma viral load of more than 150 IU/mL, and only 12% of patients achieving a viral load of more than 1000 IU/mL [9].

The rate of CMV infection after autologous HSCT is significantly lower in comparison with that in CMV-seropositive patients after allogeneic HSCT [16]. In autologous HSCT, CMV reactivation is reported to occur in up to 41% of CMV-seropositive patients when a prospective monitoring of antigenemia and/or viremia by polymerase chain reaction is adopted. However, more contained frequencies, up to 12%, have been reported when the monitoring criteria were based on a clinically driven diagnostic strategy. The most relevant risk factors appear to be CD34+ selected autografts, total body irradiation, and prior treatment with alemtuzumab, fludarabine, or bortezomib [16–18].

Among allogeneic HSCT recipients, the most important pretransplant risk factor for CMV disease is the serological status of the donor (D) and recipient (R). The risk is highest among seropositive HSCT recipients (i.e., those who were infected prior to transplant) who receive grafts from seronegative donors (i.e., lacking immunity against CMV) and almost null in seronegative recipients from seronegative donors (D− /R+ > D+ /R+ > D+ /R− > D− /R−) [4]. Namely, CMV reactivation occurs in 60–80% of seropositive (R+) individuals, 20–30% among D+/R−, and <5% of cases in D−/R− where infection is typically transfusion-related [1, 6–9]. Thus, strict use of CMV seronegative or leukoreduced blood products is highly recommended in CMV D−/R− recipients. The risk of transfusion-related CMV is higher with filtered

red blood cell products than with leukocyte-reduced platelets (4%) and lowest with use of CMV seronegative products (<2%) [19].

In addition to D/R serostatus, other well-established risk factors for early CMV reactivation include high-dose corticosteroids (in most studies >1 mg/kg/day of prednisone or equivalent is considered high dose); ex vivo or in vivo T-cell depletion (anti-thymocyte globulin (ATG), alemtuzumab, CD34 selection) [3, 20]; acute graft-versus-host disease (GVHD) grades II–IV, especially GVHD requiring systemic steroids; and the use of mismatched or unrelated donors [6]. T-cell depletion by CD34+ selection effectively reduces rates of GVHD, but it is also associated with delayed immune recovery and higher rates of CMV infection compared with those of unmodified HSCT [20]. Acute GVHD and receipt of a graft from a CMV-negative donor by a CMV-positive patient are the most significant clinical risk factors for CMV disease [21].

In 928 HSCT patients who received cyclosporine/methotrexate/ATG GVHD prophylaxis, D− /R+ patients had a substantially lower survival than D+ /R+ patients [22]. Survival rates were also lower for D− /R+ HLA-matched sibling recipients compared with D+ /R+ HLA-matched unrelated donor transplant recipients, demonstrating the significance of donor serostatus.

Among graft sources, umbilical cord blood (UCB) transplantation is associated with delayed immune reconstitution [23] and the highest cumulative incidence of CMV infection, whereas peripheral blood stem cell (PBSC) HSCT is associated with the lowest incidence [24]. Indeed, among CMV-seropositive UCB transplantation recipients, CMV reactivation occurs in up to 100% of patients within 100 days after transplantation [25–27]. HLA-haploidentical (i.e., 5/10 HLA-mismatched related donor) HSCT with conditioning regimens using posttransplant cyclophosphamide (PTCy) are associated with CMV reactivation and disease in 55–74% and 12–15% cases, respectively [28, 29]. By allowing faster recovery of CD4+ T cells, the use of PTCy seems to result in a lower risk of CMV reactivation compared to patients receiving ATG-based conditioning for HLA-haploidentical transplantation [30].

Underlying lymphoma is also a risk factor for CMV infection and progression to clinically significant CMV [8], especially among those with active and stage III/IV lymphoma [31]. CMV reactivation and disease are more common among patients with non-Hodgkin's lymphoma than among those with Hodgkin's disease [31]. Dasatinib use after HSCT to prevent or preemptively treat molecular relapse of Philadelphia chromosome-positive hematological malignancies significantly increased the risk of CMV reactivation in the first year after transplant in CMV-seropositive recipients, independent of acute GVHD [32]. Similarly, CMV tissue-invasive disease can occur after administration of ruxolitinib, a Janus kinase 1/2 inhibitor used for prevention and treatment of steroid-refractory GVHD [33, 34].

In a study of 269 consecutive allogeneic HSCT, the overall incidence of late (occurring beyond day +100) CMV reactivation was 31% [35]. In this study, the

primary determinant of late CMV reactivation was antecedent early reactivation (45% of those who experienced early CMV reactivation experienced late reactivation versus 16% late reactivation rate in those without early reactivation). Other clinical factors associated with the occurrence of late CMV viremia were GVHD, donor-type (mismatched or unrelated donors) and CMV serostatus (CMV-seronegative graft), and type of malignancy (higher risk in those with lymphoid malignancy). Lymphopenia at day +100 and UCB transplantation are additional risk factors for late CMV reactivation.

Even in the absence of antiviral prophylaxis, not all the individuals with the abovementioned risk factors will develop CMV. Indeed more than half of the patients in the placebo arm of the pivotal letermovir prophylaxis trial (NCT02137772) did not develop clinically significant CMV infection by week 24 [36]. This suggests that there are host factors unique to each individual that influence the risk of uncontrolled viremia. It is generally accepted that reconstitution of CMV-specific immunity is the most important factor in controlling the reactivation of the virus and in establishing long-term protection [37–40]; in recent years, assessment of IFNγ production [41–43] or virus-specific CD8+ T-cell functional signatures has been found predictive of risk of CMV following HSCT [44].

Immune Reconstitution

Following infection, CMV remains latent and reactivation controlled primarily by virus-specific CD4+ and CD8+ cytotoxic T lymphocytes (CTL) via coordinated cytokine production and degranulation. The dominant sites of CMV latency or persistence in humans remain unclear, although the risk of transfusion-associated CMV infection from asymptomatic donors implicates mononuclear cells [1]. In seropositive humans, a strikingly high fraction (10–40%) of circulating T lymphocytes target CMV [45], and this proportion of circulating CMV-specific T cells increases with age.

CMV reactivation risk following HSCT is highly dependent on the extent of CMV-specific immune reconstitution. Reconstitution of CD8+ T cells is faster than that of CD4+ T cells after HSCT, which usually occurs around day +100 or later and is indicated by the inversion of the CD4+/CD8+ T-cell ratio. For this reason, the risk of DNA virus reactivation including CMV is highest in the first 100 days post-HSCT. In ATG-treated patients, CD8 recovery might take up to 6 months, and CD4 recovery might not occur after 12 months [46]; complete reconstitution of CD4+ T cells can take up to 2 years after allogenic HSCT [47]. CMV-specific T-cell reconstitution is delayed significantly in recipients of seronegative donors and in marrow recipients [47]. Timing of recovery of CMV-specific CTL responses is also influenced by the type of donor, being severely delayed in recipients of matched unrelated donors (mean 200 ± 117 days) compared with recipients of sibling donors (58 ± 23 days) [43].

In one study that included 148 HSCT recipients [47], among patients with CMV reactivation, the number of CD8+ T cells recovered to and above normal levels within 6 (866×10^6 cells/l) and 12 months (1203×10^6 cells/l), whereas counts in patients with absent CMV reactivation remained within the lower normal range (221 and 300×10^6 cells/l after 6 and 12 months, respectively). Although it seems paradoxical that patients with higher CD8+ T-cell counts were the ones who experienced CMV reactivation, this observation may be attributed to clonal expansion of T cells driven by antigenic exposure to CMV. Higher frequencies of CMV-specific CD4+ and CD8+ T-cell responses are present in subjects experiencing CMV viremia [39]. Absolute lymphocyte count (ALC) and number of virus-specific CD8+ lymphocytes do not discriminate well between HSCT patients with different CMV outcomes [44], whereas functional signatures within the CMV-specific CD8+ T-cell compartment are highly predictive of CMV outcomes, independent of steroid use or donor type. Altogether, these observations indicate that the inability to control CMV reactivation following allogeneic HSCT is due to the impaired function of antigen-specific CD8+ T cells rather than an inability to recover sufficient numbers of CMV-specific T cells.

The polyfunctionality (e.g., the ability to produce 2 or more cytokines) of virus-specific T cells is an important correlate of protective immunity against chronic viral infections. It is estimated that more than half of CD8+ T cells responding to common viruses such as CMV, Epstein–Barr virus, and influenza virus exhibit up to four or five functions [48]. In 118 pediatric HSCT recipients, dual IFN-γ/IL-2-producing $CD8^+$ T cells were present in patients who spontaneously controlled CMV reactivation but were absent from those who required antivirals [40]. Lilleri et al. found that 90% of HSCT adult patients who spontaneously controlled CMV infection had IFN-γ/IL-2-producing CMV-specific T cells [49]. The presence of polyfunctional virus-specific CD8+ T cells is also associated with lower levels of CMV replication and higher frequency of self-resolved episodes. Reduced number of polyfunctional CMV-specific CD8+ T cells measured on day +30 posttransplant can predict risk of clinically significant CMV reactivation in allogeneic HSCT recipients [44]. Robust CMV-specific CTL responses are also characteristic of patients who eradicate viremia in <14 days in response to ganciclovir treatment [50].

Clinical Manifestations

Definitions

The CMV Drug Development Forum published definitions of CMV infection and disease in transplant patients [51]. Although such definitions were developed for the purpose of facilitating consistent reporting of CMV outcomes in clinical trials, they have some applicability in clinical setting.

CMV Syndrome

The definition of probable CMV syndrome requires detection of CMV in blood by viral isolation, rapid culture, antigenemia, or nucleic acid testing (NAT) together with at least two of the following: fever $\geq$38 °C for at least 2 days, new or increased malaise/fatigue, leukopenia or neutropenia, thrombocytopenia, >5% atypical lymphocytes, and elevation of hepatic aminotransferases to 2 times the upper limit of normal.

Pneumonia

Proven CMV pneumonia is defined as the presence of compatible clinical symptoms and/or signs along with documentation of CMV in lung tissue by histopathology, virus isolation, rapid culture, immunohistochemistry, or DNA hybridization. Probable CMV pneumonia is defined as the detection of CMV in BAL fluid (e.g., by PCR or culture) combined with clinical symptoms and/or signs of pneumonia. It should be noted that detection of CMV in BAL is common and results should be interpreted with caution (see "Diagnosis" section). A definite cutoff for CMV DNA load in BAL has not been established.

Gastrointestinal (GI) Disease

Proven GI disease (e.g., esophagitis, colitis) requires symptoms and evidence of macroscopic mucosal lesions plus CMV detection in tissue. In the absence of macroscopic mucosal lesions, GI disease is considered as probable. Proven liver disease requires abnormal liver function tests plus CMV documented in tissue by histopathology, immunohistochemistry, virus isolation, rapid culture, or DNA hybridization techniques and the absence of other documented cause of hepatitis. Probable disease is not a recommended category for CMV hepatitis due to the risk for other confounders such GVHD in allogeneic HSCT recipients, as well as the common occurrence of drug-associated liver dysfunction.

Retinitis

Proven disease requires typical ophthalmological signs judged by an ophthalmologist experienced with the diagnosis of CMV retinitis. Alternatively, the diagnosis might be supported by CMV documented in vitreous fluid by PCR.

Encephalitis

Proven disease requires central nervous system (CNS) symptoms plus detection of CMV in CNS tissue by virus isolation, rapid culture, immunohistochemical analysis, in situ hybridization, or preferably quantitative PCR. In patients with symptoms plus abnormal imaging results or evidence of encephalitis on electroencephalography but in whom CNS tissue is not available, detection of CMV in CSF without visible contamination of blood ("bloody tap") supports the diagnosis and is defined as probable encephalitis.

GU Disease

The detection of CMV in urine by PCR or culture, in the absence of detection of CMV in tissue, is not sufficient for the diagnosis of CMV nephritis or cystitis as asymptomatic viral shedding in urine is common.

Other End-Organ Disease Categories

CMV can also cause disease in other organs (e.g., myocarditis, pancreatitis), and the definitions of these additional disease categories include the presence of compatible symptoms and signs and documentation of CMV in tissue biopsy by virus isolation, rapid culture, immunohistochemistry, or DNA hybridization.

Clinical Manifestations of CMV

Although CMV reactivation can result in tissue-invasive disease, including pneumonia, hepatitis, colitis, retinitis, and encephalitis [1, 2, 6, 37, 38] with high mortality rates, asymptomatic viremia is the most common (>85%) clinical presentation of CMV reactivation in the current preemptive therapy era [8, 9, 15]. Symptomatic patients typically present with CMV syndrome (≈10%) defined as fever, malaise, cytopenias, or transaminitis in patients with concurrent CMV viremia and less commonly (<5%) with tissue-invasive disease [2, 8, 24, 36]. The incidence of CMV disease is higher in allogeneic than autologous HSCT recipients [52].

In the report by Green et al., the cumulative incidence of CMV disease in the first year after transplantation was 11% [9]. Among those with tissue-invasive CMV disease, 62% patients had gastrointestinal tract disease, whereas pneumonia and retinitis were less common, occurring in 35% and 3% patients, respectively. CMV viremia is associated with an increased risk of CMV disease in patients not receiving preemptive therapy [9]; and those with symptomatic CMV reactivation experience higher viremias with a stepwise increase in the median peak viremia for patients with asymptomatic viremia (724 IU/mL; IQR, 181–2049 IU/mL) and CMV syndrome (3075 IU/mL; IQR, 774–35,519 IU/mL) and those with tissue-invasive disease (7393 IU/mL; IQR, 5900–2,185,018 IU/mL) in one study that included 106 HSCT recipients with CMV viremia [8]. Similarly, Ljungman et al. showed that the peak viral load was significantly higher in patients who developed CMV disease than in patients without CMV disease [21].

CMV pneumonia is a potentially fatal disease. Mortality in HSCT recipients with CMV pneumonia can be as high as 60% [37, 38], and outcomes have only modestly improved over the past 25 years [53]. Patients might present with fever, shortness of breath, cough, and hypoxia that can rapidly progress to respiratory failure. Specific risk factors for severe CMV pneumonia include lymphocytopenia, male sex, and severe acute GVHD [54]. Imaging in most patients with CMV pneumonia typically reveals bilateral, diffuse ground-glass opacities. Other common findings are small, consolidated centrilobular (nodule-like) opacities, reticular opacities, and pleural effusions [52]. The gold standard for diagnosis of CMV pneumonia is (1) demonstration of either CMV within cells or atypical

intranuclear inclusions and/or (2) detection of CMV using immunohistochemical staining or in situ hybridization in lung biopsy specimens. CMV can also be detected in BAL specimens using the shell vial culture method. Determination of CMV viral load via PCR in BAL fluid has been used; however this method has not been standardized, and detection of CMV in BAL by PCR needs to be interpreted with caution.

GI disease is the most common type of CMV end-organ disease. A cumulative incidence rate for GI CMV disease of 2% at 2 years after HSCT, with a median time to onset of 88 days and a wide range of 17–1099 days [55]. GI CMV disease is an erosive and/or an ulcerative condition that can occur at any location in the GI tract, from the mouth to rectum. Patients with esophagitis may present with odynophagia and substernal pain secondary to painful ulcerations. Small bowel CMV infection ranges from asymptomatic to upper GI bleeding or obstruction due to severe ulcerations and mucosal inflammation. Patients with CMV colitis may have diarrhea, hematochezia, urgency, tenesmus, and abdominal pain. However, none of these symptoms is pathognomonic. Although CMV colitis can be diagnosed on sigmoidoscopy, total colon examination up to the terminal ileum is preferred [55]. The distinction between GI CMV disease and GVHD is crucial. Histologic distinction between CMV infection and GVHD in the colon relies heavily on identification of viral inclusions and positive CMV-specific immunostains, as the morphologic features (inflammatory changes and ulcerations) of these two entities may be similar [52]. Detection of CMV DNA by PCR in tissue biopsy alone is not sufficient for diagnosis of GI disease in the absence of compatible histological and clinical findings, especially among those with concurrent viremia since blood contamination can occur at the time of biopsy.

CMV CNS disease after allogeneic HSCT usually manifests as ventriculoencephalitis with rapid progression of cognitive dysfunction and occurs as a late-onset disease, with median time to onset ranging from 155 to 285 days after HSCT [56–58]. Incidence of CMV encephalitis has not been established, but it is very rare. As a reference, the incidence of viral encephalitis in a study that included more than 2500 HSCT recipients was only 1.2%, with highest risk among those undergoing T-cell depletion. In that report, HHV-6, HSV, EBV, and JC were more common etiologies of viral encephalitis post-HSCT than CMV [59].

CMV retinitis is also infrequently reported in HSCT recipients, with an estimated prevalence rate of 1–3% [9, 60]. Symptoms include blurring or loss of central vision, scotomata, floaters, or photopsia depending on the anatomic site of retinal destruction and whether retinal detachment has occurred. CMV retinitis is characterized by full-thickness retinal necrosis and edema that is subsequently replaced with scar tissue which can lead to retinal detachment. Bilateral involvement is not uncommon. The diagnosis of retinitis is based on ophthalmologic examination; similar to GI or CNS disease, CMV DNAemia can be absent in cases of CMV retinitis. Diagnosis can be confirmed through PCR analysis of the aqueous humor or vitreous body specimens for the presence of CMV. Treatment includes intravitreal injections of ganciclovir or foscarnet which can be used as an adjunct to systemic therapy. Administration of systemic antivirals to patients with unilateral CMV

retinitis is essential, even among those receiving intravitreal injections, in order to prevent extension of CMV sight-threatening disease into the contralateral eye or other tissues.

In addition to CMV syndrome and end-organ disease, CMV infection has been linked to indirect effects in HSCT recipients. Namely, CMV infection is associated with an increased risk of secondary bacterial and fungal infections following allogeneic HSCT [61, 62] as well as a potentially increased risk of GVHD [63, 64] and increased non-relapse mortality (NRM) [8, 35, 65–67]. CMV disease is an independent risk factor for invasive aspergillosis (adjusted hazard ratio 7.0) [61, 68, 69] and candidemia (adjusted relative risk 16.4) [70]. In addition, >40% of HSCT recipients receiving ganciclovir for CMV reactivation develop neutropenia at a mean of 35 days after starting treatment [8, 71], and ganciclovir use is associated with a 13-fold increased risk of invasive aspergillosis (each week of ganciclovir treatment increases the risk by a factor of 1.4), a much higher risk than that seen with the use of corticosteroids [69]. Nichols et al. reported higher mortality due to bacteremia or invasive fungal infection among CMV D+/R− (18.3%) than D−/R− (9.7%) patients ($P < 0.001$) [62].

Several large cohort studies have shown that CMV reactivation or seropositivity is associated with increased risk of NRM [8, 35, 65–67]. In a recent report by the Center for International Blood and Marrow Transplant Research that included data from 9,469 HSCT recipients who underwent transplantation between 2003 and 2010, CMV reactivation was associated with higher NRM (regardless of the underlying hematologic disease) [67], confirming that CMV remains a serious problem in the current era. At least two contemporary studies have reported an association between a CMV viral load ≥250 IU/mL and increased risk of mortality in the posttransplantation period [9]. In the study by Green et al., CMV DNA levels >500 IU/ml were associated with a 20-fold increase in the risk of death by day 60 [9]. In a recent study, allogeneic HSCT recipients with refractory CMV reactivation (defined as CMV DNAemia lasting for >2 weeks despite administration of a full dose of antiviral drug therapy) within 100 days of transplantation had a higher incidence of CMV disease and non-relapse mortality (11.9% and 17.1%, respectively) than did those without refractory CMV (0.8% and 8.3%, respectively) [72]. At our center, we observed very high probability of NRM among patients who failed to eradicate CMV viremia, whereas early eradication of viremia conferred a survival benefit [8]. Specifically, the probability of NRM was significantly higher among patients who failed to eradicate CMV viremia by treatment day 35 compared with those who cleared CMV viremia within 35 days in response to antiviral therapy (23%, 32%, and 42% vs. 3%, 6%, and 15% at 100, 200, and 365 days post-HSCT; $P = 0.02$, 0.01, and 0.01, respectively). One-year NRM was significantly higher among patients with therapeutic failure compared with those who cleared CMV viremia in response to antiviral therapy (91% vs. 15%; $P < 0.0001$) [8]. Failure to achieve clearance of CMV viremia in response to antiviral therapy is associated with >25-fold increase in 1-year NRM (adjusted HR, 25.9; 95% CI, 7.7–87; $P < 0.0001$) [8]. Most of these deaths were attributed to bacterial and fungal sepsis, confirming the established relationship between CMV and other opportunistic infections.

Diagnosis

The diagnosis of CMV replication and disease in HSCT recipients can be made using different laboratory methods, including histology, pp65 antigenemia, or CMV DNA by quantitative NAT (QNAT) utilizing polymerase chain reaction (PCR) DNA amplification.

Serology. All donors and transplant candidates should be tested for baseline CMV immune status using CMV-IgG serology. CMV-IgM is not routinely recommended due to potential for false positivity. In the rare event there is an indeterminate serology results, the assignment of baseline serologic status should consider the "highest-risk" scenario for CMV prevention purposes. For example, if the HSCT recipient CMV-IgG is borderline or indeterminate, test should be repeated prior to transplant, and if repeat test is not available, it should be considered as positive. If the donor is CMV-IgG indeterminate, it should be considered as positive for CMV seronegative recipients and as negative for CMV-seropositive recipients. Serological testing is not indicated posttransplant as false-negative results can occur in patients receiving immunosuppression, and more importantly, serological testing is unlikely to change management or be useful since it cannot differentiate between previous exposure and active infection.

Histopathology. CMV-infected cells are cytomegalic cells, typically two- to fourfold larger than normal, containing basophilic intranuclear inclusion bodies ("Cowdry bodies") surrounded by a clear halo, giving the appearance of an "owl's eye." Cells show a thickened nuclear membrane and smaller granular intracytoplasmic inclusions. Many of these infected cells can be seen surrounding blood vessels, as the most commonly infected cells are endothelial cells and mesenchymal cells [73]. Although histological appearance is somewhat specific for CMV, it has a low sensitivity. Immunohistochemistry (IHC) or hematoxylin and eosin (H&E) staining can be used to improve sensitivity [74]. The sensitivity has been reported as 82.6% on H&E and 95.7% with IHC [73]. Unfortunately, the most sensitive test for CMV, CMV biopsy PCR, does not seem to have sufficient specificity to be used alone to make a diagnosis of CMV colitis. CMV viral cell culture is also sensitive but labor-intensive and has, therefore, been replaced by nucleic acid detection. Up to 25% of patients with CMV colitis have normal colonic mucosa on endoscopy but histologic evidence of CMV on biopsy. Thus, random multiple biopsies should be performed throughout the colon regardless of the macroscopic appearance on colonoscopy.

Viral culture. Viral culture has a sensitivity of 45% to 78% and a very high specificity (89–100%) [75]. However, results take days to weeks to complete.

Antigenemia. The CMV antigenemia assay consists of the detection of the CMV phosphoprotein 65 (pp65) antigen in neutrophils, which correlates semiquantitatively with viral replication [52]. This assay is relatively easy to perform and does not require expensive equipment, although it is limited by a lack of standardization, including subjective interpretation of results and the need for an adequate neutrophil count (>1000/ml) [52]. CMV PCR is more sensitive than pp65 antigenemia [76, 77], and it has largely replaced other methods for screening and diagnosis of CMV

infection [78]. Primer optimization and improved DNA extraction techniques resulted in high sensitivity (>80%) and specificity (>90%) of CMV PCR in HSCT recipients [77].

Quantitative Nucleic Acid Testing

PCR in blood. The quantification of CMV viral load by quantitative PCR can give important prognostic information, and this technique is now widely available [3], largely replacing the now obsolete detection of antigen (pp65; antigenemia assay). The CMV PCR test has become the standard of care for screening and diagnosis of CMV in HSCT. Molecular quantitative DNA assays in general afford earlier detection of CMV viremia compared to pp65 antigenemia tests [27]. In a study that included more than 700 specimens from HSCT patients, the FDA-approved Cobas AmpliPrep/Cobas TaqMan CMV test had sensitivity and specificity of 85% and 98% when performed in whole blood and 100% and 91% when performed in plasma, respectively [79].

The main disadvantage of CMV PCR testing is the significant inter-assay quantification variability. The variability of viral load tests is greatest near the lower and upper levels of quantitation. Viral load values in most patients are about 10–100-fold higher in whole blood compared with plasma [80]. A number of studies have shown a low correlation between the viral loads determined using different specimen types and molecular platforms [79]. Different primers to amplify CMV DNA by PCR lead to different size amplicons (52–340 base pairs) and, consequently, different viral loads [81]; namely, larger amplicons can lead to under quantitation in some samples and vice versa. However, when the same PCR assay is used, the test performs consistently across laboratories [82].

Despite the development of the World Health Organization (WHO) international standard for CMV DNA (so that quantitative PCR results could be reported in international units (IU) per mL instead of copies per mL), clinical studies in CMV remain difficult to interpret due to testing variability. Caliendo et al. [81] tested 40 genotyped CMV DNA-positive pooled clinical plasma samples in 6 laboratories using 10 quantitative PCR assays calibrated to the WHO international standard. Strikingly, they observed a median variance of 1.50 $\log_{10}$ IU/mL (range, 1.22–2.82 $\log_{10}$ IU/mL), with <60% of the results falling within ± 0.5 $\log_{10}$ IU/mL of the mean viral load of each sample. Because of pre-analytical and other analytical variables, the calibration of assays using the WHO standards alone is not enough to correct the variability across different assays [79, 81]. Transplant clinicians should be aware of this constraint of quantitative assays and always use a single laboratory for viral load testing when assessing viral kinetics and response to therapy so that results can be accurately interpreted.

Another drawback of CMV PCR monitoring is that low viral load values are common and their clinical significance can be difficult to assess. The increased sensitivity of molecular tests results in the prolonged detection of low-level viremia [79] (e.g., 25–200 IU/mL range) which can be difficult to interpret to

the clinician and can result in prolonged therapy and increased toxicity. As outlined above, many patients with low-grade viremia (typically <150 IU/mL) experience spontaneous clearance [8, 44]. On the other hand, sustained viremias >150 IU/mL are associated with significantly reduced probability of spontaneous clearance [8, 83].

It should be noted that due to compartmentalization of CMV in the CNS and GI tract, lack of CMV viremia does not rule out end-organ disease particularly CMV encephalitis, retinitis, or colitis. The opposite is also true; although detection of CMV nucleic acid in any body fluid or tissue specimen reflects CMV infection [51], it is not always indicative of disease.

PCR in BAL. In an elegant study conducted at the Fred Hutchinson Cancer Research Center using archived BAL aliquots from 132 HSCT patients with CMV pneumonia, 99%, 96%, 80%, 29%, and 6% of the patients had CMV detected by PCR, shell vial assay, culture, DFA, and cytology in BAL fluid, respectively. Patients with CMV pneumonia had higher median viral loads (3.9 $\log_{10}$ IU/mL; IQR, 2.6–6.0 $\log_{10}$ IU/mL) than controls: 0 $\log_{10}$ IU/mL, IQR, 0–1.6 $\log_{10}$ IU/mL for patients with non-CMV pneumonia; 0 $\log_{10}$ IU/mL, IQR, 0–1.6 $\log_{10}$ IU/mL for patients with idiopathic pneumonia syndrome; and 1.63 $\log_{10}$ IU/mL, IQR, 0–2.5 $\log_{10}$ IU/mL for patients who were asymptomatic; $P < 0.001$ for all comparisons to patients with CMV pneumonia. Thus, the likelihood for CMV pneumonia increases with increasing DNA viral load in BAL. The authors concluded that CMV DNA levels of >500 IU/mL in BAL can be used to differentiate CMV pneumonia from asymptomatic pulmonary shedding in HSCT recipients. However, considering the high variability in CMV DNA levels between different PCR methods [79, 81], this specific cutoff cannot be easily extrapolated to other centers where different primers and PCR platforms are used to quantify CMV. For example, in a study of CMV pneumonia in immunocompromised patients (including allogeneic HSCT and hematological malignancy) using the Cobas AmpliPrep/Cobas TaqMan CMV test calibrated to the WHO International Standard for CMV DNA, a BAL CMV viral load threshold of 34,800, IU/mL had 91.7% sensitivity and 100% specificity for diagnosis of CMV pneumonia in transplant patients; however, sample size was small, and patient population was heterogeneous [84]. In addition, the viral load cutoff can vary according to how the BAL procedure and processing are performed. Furthermore, CMV DNA levels may vary considerably between patients with varying degrees of severity of CMV pneumonia, which may impact the predictive values of any cutoff. Indeed, CMV shedding in the lower respiratory tract is common, and a low CMV DNA load might well represent asymptomatic infection. Thus, to date, a definite cutoff for CMV DNA load in BAL has not been established [51]. It is important to note that a negative CMV DNA test in the BAL fluid has a negative predictive value close to 100% and therefore excludes the possibility of CMV pneumonia [85].

PCR in tissue. High viral DNA levels detected with PCR in tissue from the relevant organ likely represent CMV disease, especially when blood sampled at the same time does not contain CMV DNA. CMV retinitis is the only condition where the symptoms and/or signs are sufficiently characteristic to allow a diagnosis of proven end-organ disease, even without testing for CMV in a tissue

sample. CMV documented by PCR from tissue biopsies is not sufficient for the diagnosis of CMV GI disease, especially in the absence of macroscopic mucosal lesion or histopathological findings (e.g., viral cytopathic effects). Interpretation of a positive CMV PCR in this setting can be even more difficult in cases of concurrent viremia, where contamination with circulating CMV at the time of tissue sampling could have occurred. Similarly, detection of CMV by PCR in CSF is less relevant in cases of visible contamination of blood ("bloody tap") [51].

Preventive Strategies

Currently, two main strategies are available for prevention of CMV disease following HSCT (Table 1): antiviral prophylaxis and CMV DNA level monitoring followed by preemptive therapy. In the 1990s, even though it had a significant reduction in the rates of CMV infection and disease, ganciclovir (GCV) prophylaxis was discontinued in many centers due to myelotoxicity [86]. Moreover, delayed CMV-immune reconstitution and late-onset CMV disease were observed in GCV preemptive and prophylaxis regimens [37, 87]. Recently, the Food and Drug Administration (FDA) approved letermovir, a non-myelotoxic drug, for CMV prophylaxis in CMV-seropositive HSCT recipients. Studies are now being conducted to establish the optimal duration of letermovir prophylaxis and the occurrence of delayed immune reconstitution or late-onset CMV disease.

It is important to emphasize that not all CMV-seropositive HSCT recipients develop CMV reactivation, even those with risk factors and not receiving prophylaxis. More than half of the patients in the placebo arm of the phase 3 letermovir trial (NCT02137772) did not develop clinically significant CMV infection by week 24 [36]. We have previously reported that 28% of allogeneic HSCT patients who develop detectable CMV DNAemia experience spontaneous clearance [8]. Thus, a significant proportion of CMV-seropositive HSCT recipients might not develop DNAemia or might experience self-resolved episodes. Such individuals are not likely to benefit from prophylaxis or preemptive antiviral therapy, respectively. A recent study showed that deep immune phenotyping of virus-specific CD8+ T-cell functional signatures can facilitate identification of patients at risk for clinically significant CMV infection [44], emerging as a clinical tool to assist in CMV risk stratification and management in HSCT recipients.

Preemptive Therapy

Unlike the case with other DNA viruses such as BK and HHV-6 for which the role of preemptive therapy remains largely unexplored and expectant management of asymptomatic viremia with close monitoring of viral load is almost always adequate, preemptive therapy is generally administered for detection of CMV in blood,

Table 1 Preventive strategies for CMV infection in allogeneic HCT recipients

D−/R− Low risk (<5%)
Leukoreduced blood products
CMV seronegative products
D+/R- Moderate risk (20–30%)
Preemptive therapy (see below) is favored
D+/R+ or D−/R+ High risk (60–80%)
Letermovir prophylaxis
Only indicated in CMV-seropositive
Consider PCR monitoring at least weekly since prophylaxis failure can occur
Requires concurrent administration of acyclovir for HSV/VZV prophylaxis
Preemptive therapy
Consider CMV PCR once or twice weekly until day 100 and then on clinic visits until day 200 and longer monitoring in those with ongoing immunosuppression (e.g., GvHD)
Optimal cutoff for initiation of therapy is unknown but viral loads >150 IU/mL[a] during the first 100 days often fail to resolve without antiviral therapy, particularly among high-risk patients[b].
Transplant centers should derive specific viral load thresholds depending on the CMV PCR assay they use and the population at risk
Valganciclovir is the agent of choice. In cases of severe thrombocytopenia or leukopenia, foscarnet may be preferred
While on therapy, CMV PCR should be monitored weekly. Viral load might not decrease after 2–3 weeks of therapy. If viral load increases (>1 $\log_{10}$) after 2 weeks of adequate therapy, antiviral resistance genetic testing should be ordered
Treat until clearance of viremia with at least one PCR result negative or below level of quantitation
Maintenance therapy does not effectively prevent recurrent viremia
CMV PCR monitoring should continue for at least 4–8 weeks after completion of therapy as recurrent CMV viremia occurs in >50% cases
Immune monitoring
In both prophylactic and preemptive strategies, assessment of CMV immunity may facilitate identification of individuals at risk for clinically significant CMV and guide duration of therapy.

[a]Cobas AmpliPrep/Cobas TaqMan CMV test
[b]T-cell depletion, mismatched donors, haploidentical, umbilical cord blood, GvHD, steroids >1 mg/kg

especially in cases with rising viral load on repeat testing or persistent viremia (>7 days; i.e., no blip).

Preventive preemptive strategies have dramatically decreased the incidence of early CMV disease from 25–30% to <5% according to the latest randomized trials [1, 2, 36]. In the preemptive strategy, antiviral therapy is initiated before the onset of CMV disease when viral load measurements reach a given threshold. One caveat to this approach is that, as noted earlier in this chapter, even low levels of CMV viremia early after allogeneic HSCT have been associated with increased NRM. Another limitation is that the frequency of monitoring (typically once or twice weekly) and the viremia cutoffs for initiation of CMV therapy vary widely across centers [3, 25, 35, 64–67, 88–93]. The recommended monitoring frequency is at least once weekly,

and the duration is at least 100–200 days after HSCT. The prevalence of CMV disease increases with screening intervals >14 days [15]. Even among patients who undergo weekly screening, the incidence of CMV disease can be above 10%. Thus, twice weekly screening, when feasible, might be a better approach during the first 100 days.

Once initiated, preemptive antiviral therapy is continued until virologic clearance (i.e., the virus is no longer detectable by CMV QNAT or has reached levels below a pre-defined viral load threshold). In a recent study in HSCT patients who received preemptive therapy, the median time to treatment-induced clearance was 28 days (IQR, 18–41 days), with a median duration of viremia of 42 days (IQR, 31–54 days) [8]. Delayed initiation of therapy results in prolonged duration of viremia and more protracted antiviral therapy.

Avoidance of marrow suppression is the major rationale for the preferred use of preemptive strategies in allogeneic HSCT in the pre-engraftment period. Disadvantages of the preemptive antiviral strategy include risk of disease prior to treatment initiation in individuals with rapid CMV replication (viral load doubling time can be as short as 2–3 days in high-risk patients [93, 94]), indirect effects of CMV replication, and laboratory costs due to more frequent viral load monitoring [82].

When to start therapy? Perhaps the major drawback of the preemptive approach is the lack of established quantitative cutoffs that are predictive of CMV disease in HSCT recipients due to the lack of standardized quantification assays that perform comparably across laboratories. Many centers in North America have implemented CMV viremia thresholds ranging from 25 to 300 IU/mL for initiation of therapy in high-risk patients [25, 88, 91], whereas some centers in Europe delay initiation of anti-CMV therapy until viremia reaches ≥1500 to 2500 IU/mL [92, 93]. CMV viremia thresholds should be interpreted with caution because CMV DNA levels vary considerably across studies depending on the type of specimen (i.e., higher CMV viral loads in whole blood compared with plasma) and the specific CMV PCR platform [80, 81].

Initiation of preemptive therapy at low CMV levels is associated with shorter episodes of viremia and shorter courses of antiviral therapy [8, 25, 91]. Recently, Boeckh et al. [9] reported an association between CMV viral load ≥250 IU/mL and increased risk of mortality in the early (days 0–60) posttransplantation period, suggesting that preemptive strategies should be aimed at keeping CMV viremia below this threshold. In a large HSCT cohort, a lower treatment threshold (≥25 IU/mL) in patients at greater risk of rapid CMV replication (e.g., T-depleted or steroid-treated recipients) improved preemptive treatment success [88]. The use of the 25 copies/mL viral load threshold for initiation of therapy as part of an intensive strategy significantly reduced the incidence of CMV disease among umbilical cord recipients [25]. In a study that included 213 T cell depleted by CD34+ selection, CMV viremia occurred in >70% of seropositive patients at a median time of 27 days post-HSCT. The risk of persistent viremia in this study increased by 9% for each day of delayed antiviral therapy [20]. Recently, Tan et al. reported significantly shorter median time to resolution of viremia when treatment was initiated at lower viral loads: 15 days for

135–440 IU/mL, 18 days for 441–1000 IU/mL, and 21 days at >1000 IU/mL ($P < 0.001$) [91]; the authors suggested that that preemptive therapy should be started with low-level viremia (135 IU/mL) but also acknowledged that this may unnecessarily treat viremia that might resolve spontaneously. This poses a therapeutic dilemma, because the salutatory effects of early antiviral therapy must be balanced against the risk of drug-related toxicity due to overtreatment, in addition to the financial burden.

Transplant centers are encouraged to derive specific viral load thresholds depending on the CMV QNAT assay they use and the population at risk. In a study of 174 HSCT recipients transplanted at our center, the proportion of patients who experienced spontaneous clearance decreased in a stepwise manner with increasing peak viremia thresholds: 25%, 14%, 4%, 3%, 1%, and 0% for CMV peak viremias of >100, >150, >200, >350, >500, and >1000 IU/mL, respectively [8]. Among patients with a CMV peak viremia <150 IU/mL, 89% achieved spontaneous clearance, compared with only 14% with a peak viremia level ≥150 IU/mL ($P = 0.0001$) [8]. A CMV peak viremia ≥150 IU/mL was strongly associated with a >80% reduced probability of spontaneous clearance independent of other factors including CMV donor serostatus, administration of ATG, and underlying lymphoid malignancy [8]. Among the subgroup of patients who received antiviral therapy, those who started treatment with a preceding CMV value ≥350 IU/mL exhibited more protracted viremia that in many cases required an antiviral course >35 days, beyond which point the risk of therapeutic failure and NRM increased substantially [8]. These data suggest that when using the Cobas AmpliPrep/Cobas TaqMan CMV test, initiation of preemptive therapy should not be delayed until viral load levels >350 IU/mL, and preferably antiviral therapy should be started in those with viremia >150 IU/mL, especially in high-risk allogeneic patients. We did not observe an increased incidence of (val)ganciclovir-related myelotoxicity among patients who received preemptive therapy at lower viral loads (<350 IU/mL) [8]. This suggests that early initiation of antiviral therapy is not only beneficial (i.e., shorter duration of viremia) but also well-tolerated.

In the letermovir trial [36], using thresholds for the preemptive treatment of CMV viremia of >150 copies/mL (equivalent to 137 IU/mL) for high-risk patients and >300 copies/mL for low-risk patients, CMV disease was uncommon (occurring in 1.5% of the patients in the letermovir group and 1.8% of those in the placebo group) and involved the gastrointestinal tract in all cases.

Viral kinetics are more useful than a single viral load [80, 94–96], and therefore preemptive strategies guided by the viral doubling time have been proposed recently [97]. In a cohort that included solid organ ($n = 74$) or HSCT ($n = 119$) recipients, the median doubling time (dt) of CMV DNA plasma levels was 4.3 days (IQR 2.5–7.8) [98], but it may be as short as 2 to 3 days in high-risk allogeneic HSCT recipients such as those receiving ATG or corticosteroids [93, 94]. Some groups have used the CMV dt to initiate preemptive therapy in those with evidence of rapid CMV replication (dt ⩽ 2 days) [93, 97, 99]. This strategy resulted in earlier initiation of therapy and shorter course of antivirals, but larger studies are needed [97].

Who to treat? Among asymptomatic HSCT patients undergoing regular monitoring with CMV PCR, three clinical phenotypes have been recently described [44]: (1) *elite controllers*, CMV-seropositive recipients who despite being at risk do not have evidence of CMV DNAemia on surveillance testing; (2) *spontaneous controllers*, CMV-seropositive recipients who spontaneously resolve low-grade CMV DNAemia (e.g., CMV DNA level <200 IU/ml) without antiviral therapy; and (3) *non-controllers*, CMV-seropositive recipients who experience clinically significant CMV defined as CMV disease [51] or CMV DNAemia leading to preemptive treatment. Non-controllers typically experience high-grade CMV DNAemia (peak >1,000 IU/mL) lasting more than 7 days. In a report that included 149 CMV-seropositive allogeneic HSCT recipients, 29% exhibited features of elite controllers; 20% were spontaneous controllers; and 51% were non-controllers. Since not all individuals at risk develop viremia and among those with CMV viremia only some (non-controllers) require preemptive antiviral therapy, research efforts have recently focused on the use immune monitoring to identify patients at risk of clinically significant CMV.

Interferon gamma (IFN-γ) is the dominant cytokine produced by T cells in response to CMV. QuantiFERON-CMV assay has predictive value for risk of late onset CMV disease in high-risk solid organ transplant (SOT) recipients [100]. Similarly, assessment of CMV cell-mediated immunity determined by production of IFN-γ using an enzyme-linked immunospot (ELISPOT) [41] or the QuantiFERON-CMV assay [42, 101] has been proposed as a method of immune monitoring to predict CMV outcomes following HSCT. A novel strategy that consisted of interrupting anti-CMV therapy upon CMV DNAemia clearance (first undetectable CMV DNA PCR result) and concurrent detection of virus-specific IFN-γ-producing CD8+ T cells at levels of >1 cell/μL was associated with reduced incidence of recurrent CMV DNAemia and shorter duration of therapy [102]. Chemaly and colleagues reported a strong association between low CMV-ELISPOT response and risk of CMV reactivation and progression to clinically significant CMV viremia [103]. However, factors such as the occurrence of GVHD and the use of systemic corticosteroids favored the development of CMV reactivation, regardless of the ELISPOT CMV assay result. In addition, IFN-γ production alone assessed by flow cytometry was not predictive of CMV clinical phenotypes in a recent study [44]. Thus, the clinical utility of IFN-γ-based immune monitoring methods for assessment of risk of CMV following HSCT requires further study.

Deep immunophenotyping of CMV(pp65)-specific CD8+ T cells using IFN-γ, MIP-1β, TNF-α, and IL-2 permits assessment of two donor-derived functional signatures that are highly predictive of CMV outcomes [44]. The first of them, the *non-protective signature* (IL2-IFNγ + TNFα-MIP1 β+), was found at increased levels among patients who experienced early CMV reactivation. Increased skewing toward this signature was highly predictive for CMV reactivation (any DNAemia) and the risk of progression to clinical significant CMV infection [44]. The second signature associated with risk of CMV was the *protective signature* (IL2 + IFNγ + TNFα+MIP1β+); patients whose CD8+ T-cell responses contained a lower relative proportion of cells with this signature had an increased risk of

clinically significant CMV [44]. If prospectively validated in large cohort studies, assessment of these functional signatures – using a readily available technique across transplant centers – could standardize CMV immune monitoring and guide clinical decisions such as initiation and duration of prophylactic and preemptive antiviral therapy [104].

What to start? (Val)ganciclovir is the agent of choice for preemptive therapy (typically 900 mg p.o. every 12 h of valganciclovir or 5 mg/kg i.v. every 12 h of ganciclovir; Table 2). In patients with neutropenia (e.g., <1000/μl) or severe thrombocytopenia (e.g., platelet count <20,000/μl), foscarnet (typically 90 mg/kg i.v. every 12 h) is the preferred agent. Both agents are effective at halting viral replication and preventing CMV disease. In a randomized multicenter trial of foscarnet ($n = 110$) versus ganciclovir ($n = 103$) for preemptive therapy of CMV, the occurrence of CMV disease or death from any cause within 180 days after HSCT was similar in the two treatment groups. Severe neutropenia ($< 0.5 \times 10(9)/L$) occurred in 11% patients on ganciclovir versus 4% patients on foscarnet ($P = 0.04$), and impaired renal function was observed in 5% patients on foscarnet versus 2% patients on ganciclovir ($P = 0.4$) [105].

When to stop? Antiviral preemptive therapy is typically continued for a minimum of 2 weeks and until there is resolution of viremia. With the advent of CMV PCR, one common approach is to discontinue therapy once CMV DNA is no longer detected in blood by PCR or detected but below level of quantitation on two separate specimens drawn a few days or a week apart. Once viremia resolves, many HSCT providers traditionally continue antiviral therapy at reduced dose (e.g., valganciclovir 900 mg daily) for a minimum of 2–4 weeks as maintenance therapy or secondary prophylaxis. The theoretical rationale for maintenance therapy is the high rate of recurrent viremia. In a recent report of 66 allogeneic HSCT recipients, 71% had a second episode of CMV viremia after documented treatment-induced clearance of viremia [106]. The median time to the first recurrence of CMV viremia was 38 days (IQR, 26–72 days).

However, recent data suggests that cessation of antiviral treatment at detection of the first negative CMV DNA load is as safe as doing so upon documentation of two consecutive PCR results and that secondary prophylaxis does not reduce incidence of recurrent viremia. Solano et al. discontinued antiviral therapy at the first negative (undetectable) PCR result (<20 copies/mL or 31 IU/mL), in 38 allogeneic HSCT recipients with preemptively treated CMV viremia, irrespective of the number of days the patient had received antiviral therapy [99]. Interestingly, the cumulative incidence of recurrent viremia was similar to a group of historical controls ($n = 40$) in whom antiviral therapy was discontinued after two consecutive negative PCR results after a minimum of 2 weeks treatment. In an open-labelled study that included SOT and HSCT recipients, Griffiths et al. found no significant difference in the incidence of recurrent viremia (35 vs. 45%) among patients in whom antiviral treatment was interrupted after two consecutive negative PCR results (CMV DNA load <168 IU/mL) and those in whom the threshold used to prompt the inception of antivirals (CMV DNA load <2520 IU/mL) was used to guide discontinuation of therapy, respectively [107]. Similarly, our group recently reported that among

Table 2 Antiviral agents for prophylaxis and treatment of CMV infection

Brand name	Dose	Mechanism of action	FDA approval	Major toxicity	Resistance	Primary indication	Comments
Ganciclovir	Prophylaxis 5 mg/kg IV daily Treatment 5 mg/kg IV every12h	Inhibition of DNA polymerase (pUL54)	1989	Myelosuppression	UL97, UL54	Treatment (and secondary prophylaxis/ maintenance therapy)	Drug of choice to treat CMV infections Myelotoxicity precludes its use for primary prophylaxis Activity dependent on phosphorylation by pUL97 kinase Renal dosing required
Valganciclovir	Prophylaxis 900 mg PO daily Treatment 900 mg PO every 12 h		2001				
Foscarnet	Prophylaxis 90 mg/kg IV daily Treatment 90 mg/kg IV every 12 h	Inhibition of DNA polymerase (pUL54)	1991	Nephrotoxicity, electrolyte imbalances, myelosuppression, penile/vulvar ulceration	UL54	Treatment (and secondary prophylaxis/ maintenance therapy)	Drug of choice for patients who are intolerant or fail to respond to (val) ganciclovir Renal dosing required using calculation of

(continued)

Table 2 (continued)

Brand name	Dose	Mechanism of action	FDA approval	Major toxicity	Resistance	Primary indication	Comments
							creatinine clearance (mL/min/kg)
Cidofovir	5 mg/kg IV weekly or 1 mg/kg IV three times a week	Inhibition of DNA polymerase (pUL54)	1996	Nephrotoxicity, myelosuppression	UL54	Treatment	
Maribavir	400, 800, or 1200 mg PO every 12 h	Competes with ATP for binding to pUL97, thereby inhibiting CMV DNA replication, maturation, encapsidation, and nuclear egress of viral capsids	Drug has been granted fast track status by US FDA	Dysgeusia (>60%)	UL97	Treatment of resistant or refractory CMV. 70% efficacy rate reported in phase 2 trial (**NCT01611974**) Two confirmatory phase 3 studies are underway for resistant or refractory CMV (NCT02931539) and preemptive therapy (NCT02927067)	After successful phase 1 and 2 trials, maribavir, at a potentially suboptimal selected dosage (100 mg BID), failed to show efficacy in the prevention of CMV disease in a phase 3 trial CMV isolates that are UL97 resistant to maribavir remain susceptible to ganciclovir (and vice versa)

Brincidofovir (CMX001)	100 mg PO twice a week	Inhibition of DNA polymerase (pUL54)	No longer under investigation in the United States	Diarrhea (>10%)	UL54	Treatment of resistant or refractory CMV (and mixed dsDNA infections)	Oral lipid conjugate of cidofovir with broad antiviral activity in vitro against dsDNA viruses including herpesviruses, polyomaviruses, adenoviruses, papillomaviruses, and variola virus High oral bioavailability and long half-life, allowing twice weekly oral dosing. No nephrotoxicity or myelosuppression In the phase 3 trial, brincidofovir failed to prevent clinically significant CMV infection through week 24 after HCT

Table 2 (continued)

Brand name	Dose	Mechanism of action	FDA approval	Major toxicity	Resistance	Primary indication	Comments
Letermovir	480 mg IV/PO daily beginning between day 0 and 28 (typically before day +10) until day +100 240 mg daily if co-administered with cyclosporine	Inhibits CMV DNA synthesis at a late step by targeting the pUL56 subunit of the terminase enzyme complex	2017	Well-tolerated	UL56	Primary prophylaxis (until day +100) Treatment of resistant or refractory CMV Studies ongoing for use of letermovir for extended primary prophylaxis (until day 200) and for secondary prophylaxis	Most potent in vitro anti-CMV agent to date Superior to placebo in phase 3 trial (NCT02137772) Needs co-administration of acyclovir for HSV/VZV prophylaxis CMV PCR monitoring indicated to screen for breakthrough infections Not recommended for patients with severe hepatic impairment (Child-Pugh class C). Renal dosage adjustments for creatinine clearance (CrCl) of less than 10 mL/min, though serum creatinine should be monitored when administered to patients with a CrCl of less than 50 mL/min.

patients with an initial episode of early CMV reactivation who achieved viral clearance in response to preemptive therapy ($n = 66$) recurrence occurred at a similar rate in patients who received maintenance therapy (72%) and those who did not (79%) [106]. Altogether, these studies indicate that earlier discontinuation of preemptive therapy does not result in increased risk of recurrence viremia. While further studies are needed, assessment of virus-specific cell-mediated immunity might be useful to guide duration of therapy [104]. The efficacy of this approach has been recently demonstrated in SOT recipients [108].

Prophylaxis

Prior to November 2017, preemptive strategy was the most commonly used approach due to the prohibitive toxicity of the until then approved antivirals with CMV activity. With the advent of letermovir, CMV prophylaxis is now feasible for high-risk CMV-seropositive HSCT patients. The main advantage of prophylaxis is prevention of replication in the early posttransplant period potentially reducing the indirect effects of CMV such as predisposition to opportunistic infections and increased NRM. Another theoretical advantage is the elimination of the need for viral load monitoring during prophylaxis, although in the phase 3 letermovir trial patients underwent CMV viral load monitoring while taking the drug, and considering that prophylaxis failure (i.e., breakthrough CMV infection) can occur in up to 18% [36], it is prudent to continue to monitor CMV viral load in patients receiving letermovir prophylaxis.

In a meta-analysis that included 4173 patients enrolled in 19 clinical trials (1981–2017), 14 trials that compared antiviral prophylaxis (acyclovir, valacyclovir, ganciclovir, maribavir, brincidofovir, and letermovir) with placebo demonstrated overall effectiveness in reducing incidence of CMV early infection (odds ratio [OR], 0.49; 95% confidence interval [CI], 0.42–0.58), CMV disease (OR, 0.56; 95% CI, 0.40–0.80), and the use of preemptive therapy (OR, 0.51; 95% CI, 0.42–0.62; 6 trials); however, none demonstrated reduction in all-cause mortality (OR, 0.96; 95% CI, 0.78–1.18) except the phase 3 trial of letermovir (week 24 OR, 0.59; 95% CI, 0.38–0.98) [109].

(Val)ganciclovir. Administration of ganciclovir to allogeneic HSCT recipients from engraftment to day 100 results in low rates of CMV disease (2.7%), but it is associated with increased risk of early invasive fungal infections and late CMV disease [87]. In a recent randomized, double-blind, multicenter trial that included 184 HSCT recipients at high risk for late CMV disease, 6-month valganciclovir prophylaxis was compared with a strategy of CMV PCR-guided preemptive therapy. Although the incidence of a CMV DNAemia level of 1000 copies/mL or greater or a fivefold increase over baseline was reduced in the valganciclovir group (11% vs. 36%; $P < 0.001$), there were no differences between these two strategies in the composite primary end point of death, CMV disease, or other invasive infections by 270 days after HSCT [110]. In a randomized clinical trial of ganciclovir versus acyclovir for prevention of CMV, patients received i.v. ganciclovir 5 mg/kg every

12 h days −7 to −2, followed by i.v. acyclovir 10 mg/kg every 8 h from day −1 until neutrophil engraftment and then randomly assigned to either ganciclovir 5 mg/kg 5 days a week ($n = 45$) or acyclovir 800 mg p.o. five times a day ($n = 46$) until day 100 posttransplant. There were no differences in the cumulative incidence of CMV antigenemia or disease [111]. However, bacterial infections (12.4 per 1000 patient-days) and secondary neutropenia (71%) occurred more frequently in the ganciclovir group.

Five randomized trials suggested that ganciclovir (administered for a median of 101 days) was effective in reducing incidence of CMV infection and CMV disease after allogeneic HSCT but was not associated with a reduction in all-cause mortality, likely secondary to drug discontinuation related to clinically significant myelosuppression [109]. The reported incidence of neutropenia (absolute neutrophil count, ANC <1000 cells/mm^3) in patients receiving valganciclovir prophylaxis is 43% [110]; the incidence of neutropenia with ANC < 500 in the late CMV prevention trial was 7% although in the study protocol growth factors were prescribed for neutropenia <1000 cells/mm^3) [112]. In another randomized trial, neutropenia requiring treatment interruption occurred in 58% of the patients receiving i.v. ganciclovir for prevention of early CMV [113]. In a retrospective study among 72 patients who received preemptive therapy (treatment dose is twice that of prophylaxis dose) with valganciclovir, the occurrence of treatment-associated cytopenia (defined as neutropenia with an ANC <500 cells/mm^3 or requiring administration of growth factors or platelet transfusion while receiving antiviral therapy) was >50%, especially among those patients in whom therapy was started at viral loads >350 IU/mL [8].

(Val)acyclovir. Compared to historical controls, high-dose acyclovir (500 mg/m^2 i.v. every 8 h, or 800 mg p.o. four times a day) from day 7 for 3 months post-transplant in conjunction with weekly CMV pp65 antigenemia monitoring and preemptive treatment was associated with reduced incidence of CMV disease [114]. However, in a recent meta-analysis, acyclovir showed nonsignificant efficacy in preventing CMV infection or disease [109]. In a study that included more than 700 allogeneic HSCT recipients, administration of oral valacyclovir 2 g p.o. four times a day until week 18 after transplantation was more effective than acyclovir 800 mg p. o. four times a day in preventing CMV reactivation and showed a similar safety profile. GI symptoms such as nausea, abdominal pain, or diarrhea were the most common adverse events (reported in approximately 20%) [115]. A retrospective study in which valacyclovir at a dose of 1 g p.o. three times a day was used as primary ($n = 12$) or secondary prophylaxis ($n = 19$) demonstrated significantly lower incidence of CMV reactivation (25 vs. 77%) or recurrence (26 vs. 67%) compared to a control group ($n = 31$) that received acyclovir 400 mg p.o. twice a day for varicella-zoster virus prophylaxis [116]. Milano et al. [25] demonstrated a lower rate of CMV reactivation and disease among seropositive umbilical cord blood transplantation recipients receiving an "intensive" prophylaxis strategy consisting of ganciclovir on days −8 to −2 pretransplantation, high-dose valacyclovir post-transplantation (2 g of valacyclovir p.o. every 8 h or 500 mg/m^2 acyclovir i.v. every 8 h until tolerating oral medications), and twice-weekly serum CMV polymerase

chain reaction testing. Preemptive therapy in this intensive strategy was initiated at viral loads ≥25 copies/mL. CMV disease in the first 100 days was 4.6% in the intensive approach versus 27.6% with the standard strategy, consisting of acyclovir 800 mg p.o. or valacyclovir 500 mg p.o. twice daily for VZV/HSV prophylaxis and initiation of anti-CMV therapy if patients developed ≥500 copies/mL (or ≥100 copies/mL if receiving steroids) on weekly testing. In a follow-up study, the authors showed that a "modified intensive" approach without pretransplant ganciclovir resulted in similar rates of CMV reactivation and CMV disease in umbilical cord transplant recipients compared with those receiving an intensive strategy [117].

Maribavir. A dose-escalation phase 2 trial had demonstrated antiviral activity (reduced CMV infection and need for preemptive therapy) at doses ranging from 100 to 400 mg p.o. twice daily [118]. However, the results of the phase 3 trial demonstrated that maribavir at 100 mg twice daily started after engraftment had no significant effect on incidence of CMV disease, CMV reactivation, or preemptive therapy for CMV after allogeneic HSCT compared with placebo by HSCT week 24 and had no statistically significant effect on mortality [109, 119, 120]. Taste disturbance occurred in up to a third of the patients (18–31%) in the maribavir arm.

Brincidofovir. Similar to maribavir, brincidofovir (CMX001) showed antiviral activity in the phase 2 trial but was not superior to placebo in the phase 3 trial. The phase 2 dose-ranging trial demonstrated significantly lower CMV events with brincidofovir at a dose of 100 mg p.o. twice weekly when started after engraftment through week 13 post-HSCT [121]. Yet, the same dose of brincidofovir did not improve CMV-related outcomes in the phase 3 (SUPPRESS) trial that evaluated treatment against placebo beginning a median of 15 days post-HSCT [122]. Furthermore, brincidofovir was associated with increased rates of diarrhea (61%), acute GVHD with gastrointestinal involvement (57%), other gastrointestinal adverse events, and a nonsignificant increased risk of death when compared with placebo [121, 122]. Whether the development of an intravenous formulation of brincidofovir that does not result in gastrointestinal accumulation but retains the drug's spectrum, antiviral activity, and lack of nephrotoxicity or myelotoxicity could provide a more effective and safer prevention of CMV remains to be studied [122].

Letermovir. In the phase 3 trial that included 495 adult seropositive HSCT patients with undetectable CMV DNA at randomization, fewer patients in the letermovir group (letermovir started at a median of 9 days posttransplantation) than in the placebo group had clinically significant CMV infection (defined as CMV disease or CMV viremia leading to preemptive treatment) or were imputed as having a primary end point event by week 24 after transplantation (122 of 325 patients [37.5%] vs. 103 of 170 [60.6%], $P < 0.001$). Clinically significant CMV occurred in 18 versus 42% of patients in the letermovir and placebo groups, respectively. Administration of letermovir through week 14 (approximately 100 days) after HSCT was also associated with reduced all-cause mortality at week 24. However, this survival benefit was not statistically significant at week 48. The rates of myelotoxic and nephrotoxic events were similar in the letermovir

group and the placebo group. Gastrointestinal disorders are common with administration of letermovir (52–76%); peripheral edema, cough, headache, and fatigue occur at a rate >10% in letermovir-treated patients. In the phase 3 trial, atrial fibrillation or flutter occurred in 4.6% and 1.0% of letermovir and placebo-treated patients, respectively. Drug-drug interactions are another important consideration as letermovir is a weak-to-moderate inhibitor of cytochrome P-450 3A (CYP3A) and a weak-to-moderate inducer of CYP2C9 and CYP2C19 enzymes [36]. Letermovir increases levels of cyclosporine, and it is administered at a dose 240 mg per day in patients taking cyclosporine. For patients with tacrolimus or sirolimus levels >8 ng/mL, empirical reductions of 50% and monitoring of immunosuppressant drug levels are advisable [109]. The dose of statins should also be reduced if co-administered with letermovir [109]. Letermovir reduces the levels of voriconazole, and an alternative agent for anti-mold prophylaxis such as posaconazole should be considered.

Lin et al. reported 15 patients who received letermovir as secondary prophylaxis for a median duration of 127 days (18–270) with no reactivation (TCT 2019, abstract #128). However, other small case series have shown a breakthrough CMV infection rate of 30% in 6 HSCT patients receiving letermovir for this indication (TCT 2019, abstracts #406 and #416). Thus, there are currently insufficient data to recommend the use of letermovir for secondary prophylaxis. However, in a recent French study that included 80 HSCT recipients with at least one prior episode of CMV (infection or disease), letermovir was found to be effective for secondary prophylaxis with <6% of the patients developing breakthrough infections [123].

It should be noted that concurrent administration of acyclovir or equivalent for HSV/VZV prophylaxis is indicated in patients receiving letermovir prophylaxis as this agent only has anti-CMV activity. Also, CMV PCR monitoring is highly recommended in patients receiving letermovir prophylaxis as breakthrough infections can occur [124, 125]. Recently, breakthrough CMV pneumonia was reported in a haploidentical cord blood transplant recipient receiving letermovir prophylaxis. Resistance in this case was conferred by a UL56 C325F mutation [124].

Other considerations. Simultaneous reactivation of DNA viruses is a common phenomenon following allogeneic HSCT [126]. In the experience of the author, breakthrough CMV DNAemia can occur in patients receiving cidofovir for other indications such as BK hemorrhagic cystitis or adenovirus infections. Thus, in patients with mixed viral DNA infection who have not cleared CMV DNAemia prior to initiation of cidofovir, CMV preemptive or maintenance therapy might need to be continued while on cidofovir. Brincidofovir, an oral lipid conjugate of cidofovir, has more potent activity than cidofovir against CMV and has been shown to be useful for the treatment of mixed DNA viral infection [127].

In a large cohort study, Marty et al. showed that sirolimus-containing GVHD prophylaxis regimens are associated with a significant reduction in the incidence of CMV reactivation [128]. This concept was confirmed in recent studies where risk for CMV DNAemia increased with increasing tacrolimus concentrations and decreased with increasing sirolimus concentrations among HSCT recipients receiving GVHD prophylaxis [129, 130].

A Cochrane systematic review of polyvalent immunoglobulins or hyperimmune CMV-IVIG prophylaxis that included 6 trials including CMV infections in 986 hematological malignancy and HSCT participants showed no difference in the occurrence of CMV infection or all-cause mortality, compared to control subjects [131].

Treatment

Antivirals

Four antiviral drugs are approved by the US Food and Drug Administration for treatment of CMV (Table 2): ganciclovir (1989), foscarnet (1991), cidofovir (1996), and the prodrug valganciclovir (2001). Intravenous ganciclovir is the recommended initial treatment for severe or life-threatening CMV disease. Because of the risk of nephrotoxicity, foscarnet and cidofovir are considered second and third line drugs, respectively, for HSCT recipients unable to tolerate valganciclovir or ganciclovir. Although letermovir can be considered in selected cases for salvage therapy in patients with highly resistant UL97/UL54 mutation CMV [132, 133], currently there is insufficient data to support its use for secondary prophylaxis or treatment.

CMV DNA levels should be measured weekly while on treatment. More frequent assessments are not recommended as they do not provide useful information and might make the clinical picture confusing due to variability of the PCR testing. Importantly, the CMV levels often continue to rise during the first week or two of therapy [52], and this should not be interpreted as failure to therapy nor lead to concerns about resistance. Also, in order to be able to accurately assess response to therapy, it is important to send baseline CMV DNA levels on the day of initiation of therapy, especially if the PCR results triggering initiation of therapy were obtained >2–3 days prior to first dose of antiviral.

A minimum of 2–3 weeks of antiviral therapy should be administered to patients with CMV reactivation. Duration of therapy should be guided by resolution of signs/symptoms in cases of CMV disease and by resolution of viremia in cases of asymptomatic reactivation.

Resistance

CMV resistance has been increasingly recognized and may be caused by mutations targeting the UL54 DNA polymerase and the UL97 kinase. Antiviral drug resistance should be suspected when CMV viremia (DNAemia or antigenemia) fails to improve (i.e., >1 $\log_{10}$ increase in CMV DNA levels in blood or serum) after 2 weeks of appropriately dosed and delivered antiviral therapy. Antiviral drug resistance should also be suspected when CMV end-organ disease occurs during prolonged antiviral therapy (>6 weeks of antiviral drug exposure, including 2 weeks of full-dose

therapy) in the presence of risk factors [5]. In adult drug-naive patients, it is unusual for resistance to develop during the first 6 weeks of therapy.

Refractory CMV infection is defined as CMV viremia that increases (i.e., >1 $\log_{10}$ increase in CMV DNA levels in blood or serum between peak viral load within the first week and the peak viral load at ≥ 2 weeks as measured in the same laboratory with the same assay) after at least 2 weeks of appropriately dosed antiviral therapy [134]; this is similar to resistance, except that known genetic mutations conferring resistance are not detected (clinical resistance). A modest quantitative increase in viral loads during the first 2 weeks of anti-CMV therapy may occur; this is not an indication of drug resistance and may not necessitate a change of therapy [5].

Risk factors for CMV resistance in HSCT recipients [5, 134] include:

i) Host factors: prolonged antiviral CMV drug exposure (>3 months); previous antiviral CMV drug exposure; recurrent CMV infection; inadequate antiviral CMV drug absorption and bioavailability; inadequate antiviral CMV oral prodrug conversion; variation in antiviral CMV drug clearance; subtherapeutic antiviral CMV drug level; poor patient compliance with antiviral drug regimen; T-cell depletion; haploidentical, allogeneic, or cord blood HSCT; delayed immune reconstitution; CMV-seropositive recipient and CMV-seronegative donor; treatment with ATG; active GVHD; young age;
congenital immunodeficiency syndromes
ii) Viral factors: CMV viral load rise while receiving treatment (after >2 weeks of adequate dosing); failure of CMV viral load to fall despite appropriate treatment; rise in CMV viral load after initial decline while receiving appropriate treatment; intermittent low-level CMV viremia; and high CMV viral loads

CMV resistance has been reported in the range 0% to 10% [135–139]. At our center CMV resistance was observed in 3% of allogeneic HSCT recipients [8]. Among high-risk patients, such as haploidentical transplants, the incidence of CMV resistance has been reported to be as high as 14.5% [140].

Genotypic testing is commonly done on the same plasma or whole-blood specimens used for viral load assays. DNA sequencing is currently the standard for detection of drug resistance, and the analysis is more reliable if the CMV viral load is at least 1000 IU/mL [5]. The accuracy of detection of variant CMV subpopulations is reduced with insufficient CMV DNA present in the sample (e.g., <500 IU/mL). False negatives can occur if mutant strains comprising 20% to 30% of the viral population are not reported [5]. Detection of emerging drug-resistant mutant CMV subpopulations can be improved by deep sequencing, but this technology is not widely available [141, 142]. In some cases where drug-resistant viral genomes and disease have become localized to a particular body site without significant viremia, a tissue-specific sample (i.e., vitreal fluid, cerebrospinal fluid, or biopsy) may be more informative.

In order to understand antiviral resistance mechanisms, it is important to understand key proteins encoded in the 236 kb CMV genome [5]:

- *UL54* (pol) encodes the highly conserved CMV DNA polymerase pUL54.
- pUL97, a protein kinase, is the product of the *UL97* and phosphorylates some CMV viral and cellular proteins and controls the phosphorylation of ganciclovir in CMV-infected cells.
- pUL56, which is encoded by *UL56*, is one of two proteins forming the CMV terminase complex responsible for the process of replication, cleavage, and packaging of new virions.

(Val)ganciclovir, (brin)cidofovir, and foscarnet all target and inhibit CMV DNA polymerase pUL54 preventing viral DNA synthesis. In order to become active, ganciclovir must undergo activation to ganciclovir-triphosphate upon phosphorylation by pUL97 and cellular kinases in the CMV-infected cell. Maribavir competes with ATP for binding to pUL97, and it does not require intracellular phosphorylation and is independent of pUL54. Since maribavir inhibits UL97, it impairs phosphorylation of ganciclovir, and these two drugs should not be co-administered [143]. Letermovir has a unique mechanism of action as it is the only antiviral that targets the pUL56 subunit of the CMV terminase complex.

CMV resistance to (val)ganciclovir can result from modification of pUL97, whereas foscarnet and (brin)cidofovir activity is independent of pUL97 and is therefore unaffected by *UL97* mutations. *UL54* mutations induce various patterns of cross-resistance among all these drugs. Although ganciclovir and valganciclovir are affected by both UL97 and UL54 mutations, in the clinical setting, *UL97* mutations are much more likely to emerge first. CMV isolates that are resistant to maribavir may remain susceptible to ganciclovir (and vice versa) [5]. Due to its mechanism of action, letermovir can overcome any *UL97/UL54* mutations, but antiviral activity can be affected by *UL56* mutations.

A comprehensive review of the specific CMV codon mutations conferring different degrees of antiviral resistance is beyond the scope of this chapter, and excellent reviews are available on this topic [5, 144–149]. For ganciclovir, the most common *UL97* mutations confer a three- to tenfold increase in the EC_{50} (drug concentration required to reduce viral growth in cell culture by 50%), but combinations of UL97 and UL54 mutations result in higher levels of resistance [5]. Seven viral UL97 kinase mutations (amino acid substitutions M460 V/I, H520Q, C592G, A594V, L595S, and C603W) are established as the genetic basis of ganciclovir resistance in most cases [5, 148]. Namely, M460 V/I, H520Q, A594V, L595S, L595F, and C603W confer 5–15-fold increase in the EC_{50}, whereas C592G confers two- to fivefold increase. Viral *UL54* DNA polymerase gene mutations can confer resistance to any or all of the traditional CMV polymerase inhibitors ganciclovir, foscarnet, and cidofovir. Unlike UL97, there is no compact list of canonical resistance mutations [148] conferring resistance to maribavir. Maribavir-resistant mutations map to the *UL97* and the *UL27* genes [149]. Amino acid substitutions conferring resistance to letermovir selected in vitro map primarily to the pUL56 and rarely to the pUL89 and pUL51 subunits of the CMV terminase complex [149]. *UL56* mutations in the codon range 231–369 can confer impressive levels of resistance to letermovir [148, 150]. Breakthrough CMV viremia during letermovir

treatment can occur in the presence of the *UL56* V236M mutation [36]. The *UL56* mutation C325Y, which confers high-level resistance to letermovir, has been described in both SOT and HSCT recipients [36, 124, 132, 151, 152]. Critical letermovir binding residues are not critical to the biological function of the terminase complex [148]. Considering that letermovir was approved in 2017 and it has been mostly used for primary prophylaxis, the fact that UL56 have already been identified in letermovir-treated patients [36, 124, 132, 151] suggests low genetic barrier to resistance [124, 132, 148, 150–153].

When refractory or resistant CMV is suspected during (val)ganciclovir therapy, genotypic analysis for drug resistance should be obtained immediately, and empiric switch of antiviral therapy to foscarnet should be considered while awaiting genotypic analysis results, especially in symptomatic patients or those considered high risk for CMV disease (e.g., T-cell depletion, unrelated donors, GVHD on high-dose steroids) and those with the risk factors for CMV resistance outlined above. Foscarnet therapy should be continued in patients with CMV end-organ disease (regardless of the *UL97* mutation) and those with documented high-grade *UL97*-resistant mutations (e.g., M460V, A594V, H520Q, L595S, L595F, C603W). In the absence of CMV end-organ disease, dose escalation of ganciclovir (i.e., 7.5–10 mg/kg every 12 h) can be considered to overcome *UL97* mutations conferring low-grade resistance such as C592G [5, 144, 148]. Hematologic toxicity occurs in most patients receiving high-dose ganciclovir for more than 4 weeks. If there are additional *UL54* mutations increasing the overall level of resistance, combination therapy (e.g., ganciclovir plus foscarnet) should be strongly considered and tailored to the specific resistance pattern [5, 148]. For ganciclovir-foscarnet-cidofovir-resistant strains, investigational agents alone or in combination with standard therapies, as well as adoptive T-cell therapy [154–161], can be considered.

The full potential of novel therapies such as maribavir, brincidofovir, and letermovir for the treatment of CMV in HSCT remains to be established. In a recent randomized trial that included 47 allogeneic HSCT recipients, maribavir (doses from 400–1200 mg twice a day) was effective for treatment of refractory or resistant CMV infection, with 70% of patients achieving undetectable CMV DNA within 6 weeks of treatment [162]. Dysgeusia occurred in two thirds of the maribavir-treated patients but only led to discontinuation in one patient [162]. Brincidofovir can be used for ganciclovir-resistant CMV infection, unless resistance is acquired through a *UL54* mutation [5, 127, 163]. Letermovir might have a role in the treatment of *UL97* or *UL54* mutants [132, 164]. However, current evidence for the use of brincidofovir or letermovir in the treatment of refractory or resistant CMV infection is only anecdotal.

As it is the case with any serious infection in immunocompromised hosts, tapering of immunosuppression, in particular steroids, is a critical step in the management of resistant/refractory CMV infection. Adjunctive therapies such as CMV-Ig (or IVIG) and adaptive infusions of CMV-specific T cells may improve antiviral host defenses [154–161, 165–167]. There is in vitro and case report level of evidence for other agents such as leflunomide [168–174], artesunate [175–178], and mTOR inhibitors [128, 179]. However, the clinical efficacy of such therapies remains questionable. In patients who require ongoing immunosuppression for

GVHD prophylaxis or treatment, switching immunosuppressive therapy to an mTOR inhibitor may be reasonable [128, 179].

Adoptive CMV-Specific T-Cell Therapy

Administration of CMV-specific T cells obtained from the patient (autologous) [160, 161], the stem cell donor [155, 156, 158], or a third-party donor [154, 155, 159] has been shown to be safe and effective in the treatment and prevention of CMV infection in transplant recipients. The infusion of in vitro expanded autologous CMV(IE-1/pp65)-specific T cells was successfully used for the treatment of a lung transplant recipient with respiratory failure due to a ganciclovir-foscarnet resistant strain of CMV [160]. Cells exhibited a late effector/memory (CCR7- CD45 RA-) T-cell phenotype. In a recent open-label phase 1 clinical trial of 22 SOT patients with recurrent or ganciclovir-resistant CMV infection, the use of 1–6 infusions of in vitro-expanded autologous CMV-specific T cells led to improvement in symptoms, including complete resolution or reduction in DNAemia and CMV-associated end-organ disease and/or the cessation or reduced use of antiviral drugs, in 11 (84%) of the 13 treated patients [161]. Adoptive T-cell therapy was associated with no therapy-related serious adverse events. In vitro-expanded cells were predominantly $CD3^{+}CD8^{+}$ T cells with polyfunctional capacity (i.e., capable of expressing IFN-γ, TNF, and CD107a).

Administration of CMV-specific T-cell lines generated by short-term culture from the blood of transplant donors to 16 allogeneic HSCT recipients with early CMV infection resulted in no need for antiviral therapy in half of the cases and low rates (13%) of recurrent CMV [180]. In a follow-up study, none of the seven patients who were treated prophylactically with T-cell therapy required CMV antiviral therapy within the next 6 months [181]. In another study, among seven allogeneic HSCT recipients with persistent CMV viremia after 4 weeks of antiviral therapy and/or lacking CMV-specific T-cell proliferation who underwent adoptive transfer of donor-derived CMV-specific T cells, complete response was observed in five (71%) and partial response (transient reduction in viremia) in two [166]. In a phase 2 trial, a single dose of adoptively transferred donor-derived CMV-specific CD8+ T lymphocytes administered after day 28 posttransplant to 50 allogeneic HSCT recipients did not reduce the overall rate of CMV reactivation but did reduce the need for preemptive therapy and shortened the duration of antiviral therapy [167], without increasing the rates of GVHD. There were no serious, immediate infusion-related toxicities. Adoptive transfer of virus-specific T cells (VSTs; specific for EBV, CMV, AdV, HHV-6, and BKV), generated from allogeneic stem cell transplant donors, administered to 11 HSCT recipients, was shown to be safe in all subjects and produced an overall 94% virological and clinical response rate that was sustained long term [158]. In another study of 17 patients treated with transplant donor ($n = 16$) or third-party ($n = 1$) CMV(pp65)-specific CD8+ T cells, 15 (88%) cleared viremia, including 3 of 5 with overt disease. In responding patients, the infused CMV(pp65)-specific CD8+ T cells could be detected for a period of 120 days to up to 2 years after infusion [155].

Despite this compelling evidence, the use of cellular therapy in the clinical setting has been limited by logistical difficulties. Namely, the use of autologous or donor-derived CMV-specific T cells is problematic due to the cost and complexity of individualized product manufacture, the time needed for custom manufacturing (typically several weeks), which may preclude the immediate availability of T cells for urgent medical need, and the requirement for seropositive donors [154] (although recent data demonstrate that CMV-specific T cells that recognize atypical epitopes of CMV pp65 can be derived from naïve T cells taken from CMV-seronegative people and might be protective in vivo) [182]. In recent years, there have been efforts to generate HLA-matched VST lines from healthy seropositive donors, which can be available for immediate use as an "off-the-shelf" product. In a multicenter study of banked third-party VSTs (specific for EBV, CMV, and AdV) that included 23 allogeneic HSCT recipients with severe or refractory CMV infection, complete or partial responses at 6 weeks post-infusion were documented in 74% of the cases, with no immediate infusion-related adverse events or de novo (grades 2–4) GVHD [157]. In a phase 2 trial, a total of 23 allogeneic HSCT recipients received 1–3 infusions of off-the-shelf third-party polyclonal VSTs (T-cell lines specific for 12 viral antigens from EBV, CMV(IE-1/pp65), AdV, HHV-6, and BKV), including a total of 17 patients who received VSTs for persistent CMV, 8 of them with antiviral-resistant CMV; the response rate (complete and partial) was 94% [154]. Importantly, the in vivo persistence of VSTs from the infused line for up to 12 weeks was documented in 69% of the patients. Infusions were well-tolerated without serious immediate toxicities and no cases of de novo grades 2–4 GVHD or cytokine release syndrome. Of note, the authors could identify a suitable VST line for 54 (96%) of the 56 patients screened for study participation [154] suggesting that off-the-shelf products could be easily available to patients in urgent need for therapy. A recent study that included 28 allogeneic HSCT patients with persistent or recurrent CMV treated with infusions of partially HLA-matched, third-party, ex vivo-expanded VSTs showed that at 12 months, the cumulative incidence of overall response was 93% [159]. Acute GVHD occurred in only two patients, despite a median HLA match between VSTs and the recipient of two of six antigens. This data support the long-term safety and durability of off-the-shelf therapy.

Altogether these data support the applicability of CMV-specific T-cell therapy for the management of CMV infection in allogeneic HSCT recipients.

Vaccines

An effective CMV vaccine would have potential benefits not only for women of childbearing age (to prevent congenital CMV infection) but also for SOT and HSCT patients. In HSCT recipients, protection from CMV viremia is critically dependent upon the reconstitution and expansion of CMV-specific T-cell subsets, such as pp65 tegument (UL83) and the immediate early 1 (IE1, UL123) T cells [183]. Thus, there is significant interest in the development of immunization strategies that enhance CMV-specific immunity and prevent CMV viremia by triggering robust, functional,

and durable CMV-specific T-cell responses. A comprehensive review of the literature on prophylactic and therapeutic CMV vaccine development is out of the scope of this chapter, and excellent reviews are available on this topic [184–187]. To the date, only few CMV vaccines have been evaluated in randomized clinical trials in HSCT population [188, 189].

In a phase 2 trial of a CMV therapeutic DNA vaccine (TransVax) [188] that contains plasmids encoding CMV glycoprotein B and phosphoprotein pp65 formulated with poloxamer CRL1005 and benzalkonium chloride, 19 (48%) of 40 vaccine recipients required CMV-specific antiviral therapy, compared with 21 (62%) of 34 controls ($p = 0.145$). Although the rates of clinically significant viremia did not differ from those noted for placebo, vaccine significantly reduced the occurrence and recurrence of CMV viremia and improved the time-to-event for viremia episodes compared with placebo. The vaccine was well-tolerated. A phase 3 clinical trial is ongoing (NCT01877655).

CMVPepVax is a chimeric peptide composed of a cytotoxic CD8 T-cell epitope from CMV pp65 and a tetanus T-helper epitope. It is formulated with the adjuvant PF03512676, a Toll-like receptor 9 agonist, which augments cellular immunity. CMVPepVax, administered subcutaneously on days 28 and 56, was shown to be safe in allogeneic HSCT recipients, with no secondary graft failures or cases of GVHD in vaccinated subjects [189]. The vaccine was immunogenic providing proof of concept that HSCT recipients are able to mount vaccine-driven CMV-specific T-cell response within 6 weeks post-HSCT, when they are at the highest risk for CMV reactivation. However, CMVPepVax includes an HLA A∗0201 restricted CD8 T-cell peptide epitope of the pp65 protein, and consequently, its use is restricted to patients who are HLA A∗0201 positive. A phase 2 clinical trial is ongoing (NCT02396134).

CMV-MVA Triplex is a newer CMV vaccine developed by constructing a recombinant attenuated poxvirus-modified vaccinia Ankara encoding 3 immunodominant CMV antigens: UL83 (pp65), UL123 (IE1-exon4), and UL122 (IE2-exon5). In healthy subjects, Triplex vaccinations induced significant expansion of pp65-specific IFNγ+ CD8+ T cells, indicating that vaccine was able to expand a functional subset of CMV-specific T cells, even in the absence of CMV viremia. Expansion of durable CMV-specific T cells was observed in both CMV-seropositive and CMV-seronegative participants. This high immunogenicity of Triplex is in contrast to previously reported responses in CMV-seropositive healthy adults that were either low or detectable only after in vitro stimulation for both CMVPepVax peptide vaccine [190] and the TransVax CMV DNA vaccine [191]. Phase 2 trial with CMV-MVA Triplex is ongoing (NCT02506933).

Concluding Remarks

In conclusion, despite enormous advancements on molecular diagnostics and therapeutics over the last two decades, CMV remains a serious complication of HSCT associated with significant morbidity and mortality. However, a number of emerging

developments in the fields of CMV prophylaxis, treatment, and precision medicine have transformed the panorama by promising to improve outcomes of HSCT patients and facilitate clinical decision-making of HSCT providers, including:

1. The recent advent of effective and well-tolerated agents, such as letermovir, for prevention of CMV reactivation in seropositive HSCT recipients
2. The promising efficacy of investigational antiviral agents, such as maribavir, for the treatment of refractory or resistant CMV infection in transplant recipients
3. The revolutionary use of immune monitoring, based on deep immune phenotyping of virus-specific CD8+ T cells, emerging as a bench-to-bedside clinical tool to assist in CMV risk stratification and management of HSCT recipients
4. The remarkable development of highly effective off-the-shelf virus-specific T-cell therapies for treatment of CMV infection
5. CMV remains a serious complication of HSCT associated with significant morbidity and mortality
6. Effective and well-tolerated agents, such as letermovir, for prevention of CMV reactivation in seropositive HSCT recipients are now available
7. Investigational antiviral agents, such as maribavir, might have a role for the treatment of refractory or resistant CMV infection in transplant recipients
8. Immune monitoring, based on deep immune phenotyping of virus-specific CD8+ T cells, has emerged as a bench-to-bedside clinical tool to assist in CMV risk stratification and management of HSCT recipients
9. Highly effective off-the-shelf virus-specific T-cell therapies for treatment of CMV infection seem promising for the treatment of refractory or resistant CMV infection

Introduction

HSV-1, -2, and VZV are the only three α-herpesviruses to infect humans. They are characterized by rapid replication, the ability to infect multiple tissues, and to establish latency in neurons. Humans have been infected with herpes viruses since we evolved from our primate ancestors. The herpes simplex viruses (HSV-1 and HSV-2) evolved from a common primate virus, but now only infect humans. The evolutionary origin of varicella zoster virus is not as clear, but likely also co-evolved with primates and humans in a similar fashion many millions of years ago [1]. It is difficult to out-smart millions of years of evolution, so despite significant advances in medicine we have still not been able to eradicate these pathogens from our population. Herpes viruses are challenging in part due to the fact that they integrate into the DNA of human cells and use our cellular mechanisms to reproduce and to evade eradication. Despite this, we have lived with these viruses with a minimum of morbidity to the population; however, as we perturb normal human systems, as in the setting of transplantation, we agitate this delicate balance. Thus, we see increased incidence of serious and potentially life-threatening manifestations from herpes viruses in the setting of transplant and immune compromise. In fact, even in the era of modern antiviral prophylaxis, herpesviruses (HSV/VZV) remain the most common viral infections in solid organ recipients, accounting for 51% of viral infections diagnosed in the first year after transplant [2].

Disease Epidemiology

Herpes Simplex

While genetically very similar, HSV-1 and HSV-2 have historically had different epidemiology, risks, and clinical manifestations. HSV-1 is the classic oropharyngeal virus and is acquired early in life, while HSV-2 has been associated mostly with genital infections and is usually acquired after sexual debut. However, the epidemiology of HSV is changing. The prevalence of both HSV 1 and 2 is decreasing in the US (Fig. 1) [3]. Additionally, an increasing number of persons are infected with HSV-1 genitally. The WHO estimates that "140 million people aged 15–49 years are infected with genital HSV-1 infection, primarily in the Americas, Europe, and Western Pacific. Fewer people in high-income countries are becoming infected with HSV-1 as children, likely due to better hygiene and living conditions, and are instead at risk of contracting it genitally through oral sex after they become sexually active." [4] In fact, they estimate that half a billion people 15–49 are infected with HSV-1 or -2 genitally. Few data exist on the seroprevalence of HSV in transplant recipients, but it is felt to be similar to that in the general population, varying by age and other usual risk factors.

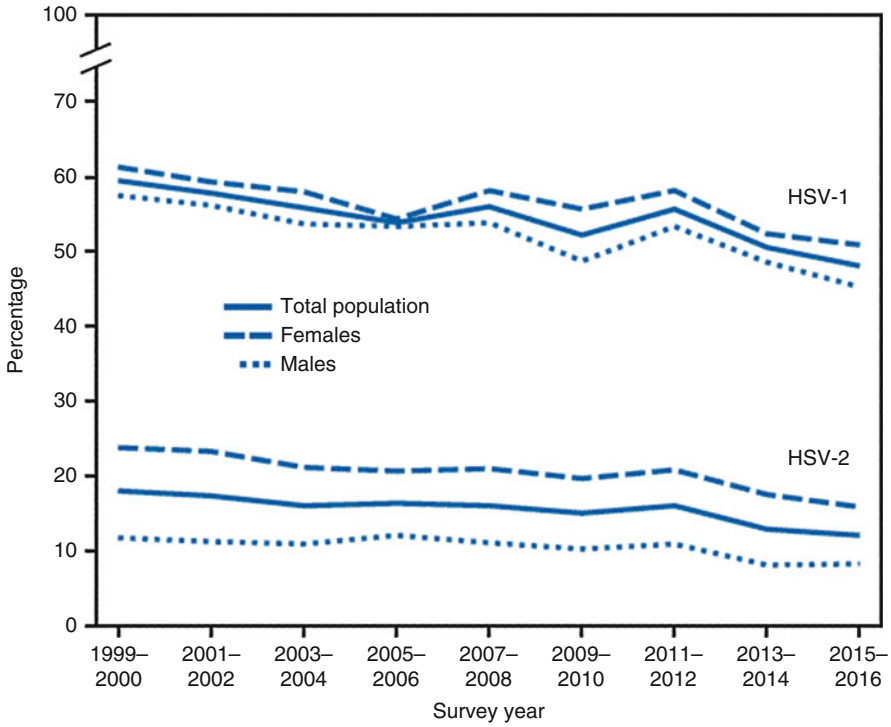

Fig. 1 Age-adjusted trends in the prevalence of Herpes Simplex Virus Type 1 (HSV-1) and Herpes Simplex Virus Type 2 (HSV-2) among adolescents and adults aged 14–49 years – United States, 1999–2000 Through 2015–2016 [3]

These statistics have important implications for transplant patients and their clinicians. While lower rates of seropositivity in a population may predict lower rates of clinically evident HSV reactivation after transplant, they could potentially create a larger pool of seronegative transplant recipients at risk for acute primary infection, which may be more severe and potentially life-threatening in immunocompromised patients. Transplant volumes continue to increase, and more transplant recipients will have risk for HSV acquisition, so clinicians will need to adapt to this changing epidemiology. Acquisition of HSV from a transplant donor is very rare, so the majority of primary HSV will be via acquisition from sexual or other close contacts.

The incidence of clinically apparent HSV disease in seropositive transplant patients not receiving prophylaxis ranges from 35 to >80% [5, 6]. In the era of modern antiviral prophylaxis, the incidence of HSV reactivation is low. Figure 2 shows the probability of HSV reactivation after solid organ transplantation (SOT) depending on the antiviral prophylaxis regimen [7]. Patients on universal prophylaxis for CMV with antivirals that have activity against HSV have very low rates of HSV reactivation. A similar phenomenon is also evident in hematopoietic stem

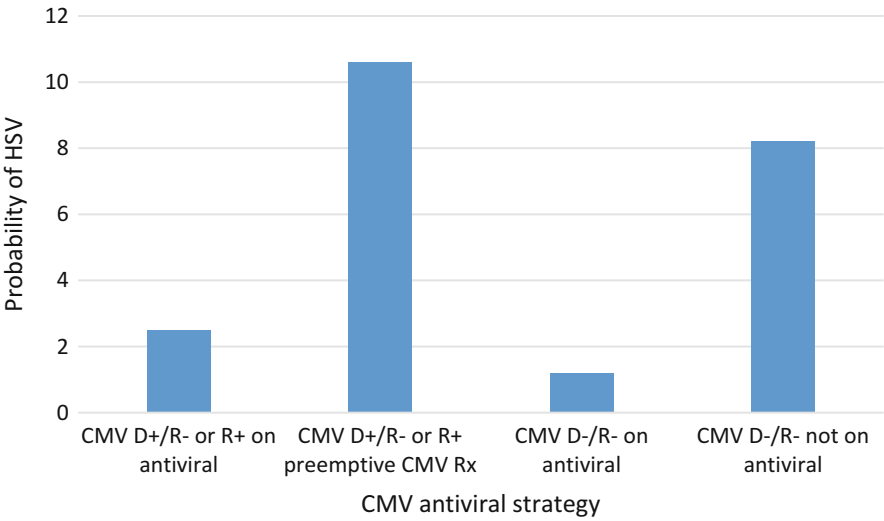

Fig. 2 Probability of HSV infection after organ transplantation according to the CMV serostatus and antiviral preventive strategy. (Probability of HSV infection at one year depending on antiviral therapy. Regardless of CMV prevention strategy, shows the effectiveness of antiviral prophylaxis on HSV reactivation (p <0.001 comparison of antiviral versus not). HSV, herpes simplex virus; CMV, cytomegalovirus, D, donor; R, recipient; + seropositive; − seronegative [7])

cell transplant (HSCT) recipients, where routine extended antiviral prophylaxis for VZV also prevents symptomatic HSV reactivation. Moving forward, an increasing number of transplant recipients may be on anti-CMV medications that do not have activity against HSV (i.e., letermovir and maribavir), and some organ recipients may be on a preemptive preventive strategy, so HSV reactivation epidemiology will need to be monitored.

Most HSV reactivation in SOT and HSCT occurs in the immediate post-transplant period when immunosuppression is most profound. In SOT, without antiviral prophylaxis, 8–10% of patients will reactivate HSV in the first year, whereas with antiviral prophylaxis, that rate drops to <2.5% (Fig. 2) [7]. Historically, agents associated with compromised cell-mediated immunity have been associated with increased risk of HSV reactivation after transplantation. In HSCT, risk increases similarly with compromised cell-mediated immunity in the setting of anti-GvHD therapy, but in fact, HSV reactivation is most common earlier during the profound neutropenia associated with conditioning therapy, particularly in association with mucositis [8].

Acquisition of HSV in a seronegative recipient can occur at any time after transplant. Despite this, the clinical severity of primary disease may be related to the relative immune status of the at-risk individual, which is greatest soon after transplant and also during treatment of rejection or graft versus host disease. Few studies have assessed the incidence of HSV reactivation with various immune suppression regimens, but a recent review in SOT did not suggest any particular agents to be associated with higher risk [7].

Clinical Pearls

- HSV seroincidence is declining, but genital HSV-1 is increasing.
- There is expectation of a growing pool of seronegative transplant recipients at risk of acute primary HSV infection.
- As antiviral prophylaxis guidelines change for CMV with more narrow spectrum antiviral agents, HSV prevention will need to be revisited.

Varicella

Varicella is a highly contagious virus, so is extraordinarily common throughout the world. The incidence and prevalence of clinical manifestations and complications of varicella is correlated with the strength of local and regional vaccination campaigns. For example, in the United States, where >90% of children have been vaccinated since the vaccine was introduced in 1995, morbidity, and deaths from varicella have declined by >90% [9]. In fact, it is estimated that more than 3.5 million cases of varicella, 9,000 hospitalizations, and 100 deaths are prevented yearly by varicella vaccination in the United States.

VZV seroprevalence in the USA varies by age, with approximately 98% of persons seropositive by age 19–40 [10]. Children are eligible for VZV vaccination at 1 year old, so in the current era, the majority transplant patients are likely to have some immunity to VZV. Approximately 3% of adult SOT recipients are seronegative for VZV and therefore susceptible to primary infection [11]. In seropositive recipients, without extended prophylaxis, about 2.5% of organ transplant patients will have an episode of HZ reactivation in the first year after transplant; however, the incidence of HZ remains relatively constant for years after transplant, such that about 5% of patients will have a HZ reactivation within 3 years and about 9% by 6 years [12]. The low rate in organ transplant patients is likely in part related to the fact that they receive less intense immunosuppression and historically have been on universal CMV prophylaxis during the period of most intense immune suppression. This is in contrast to HSCT, with more intense immunosuppression, where over 20% of patients will reactivate varicella [13]. With shorter course prophylaxis in HSCT, reactivation rates may approach 40–50% after stopping prophylaxis [14]. A recent review of 1000 consecutive autologous HSCT patients showed that even with a year of prophylaxis, 21% of patients had reactivation disease within 5 years, 82% after stopping antiviral prophylaxis (Fig. 3) [13]. Additionally, 16% of those who did reactivate had a second episode. Nevertheless, within a year of stopping prophylaxis, cumulative HSCT VZV reactivation incidence stabilizes, whereas in SOT, cases continue to present at a steady rate for many years. In solid organ recipients, lung recipients appear to be at highest risk (55.1 cases per 1000 person-years of follow-up) for zoster reactivation as compared with heart (40.0), kidney (24.4), and liver (18.3), which is significantly higher than the incidence of 3.6 per 1000 person years in the general population [12].

Persons who receive the varicella vaccination as their primary exposure to varicella still can get reactivation disease, but the risk of reactivation is ~79%

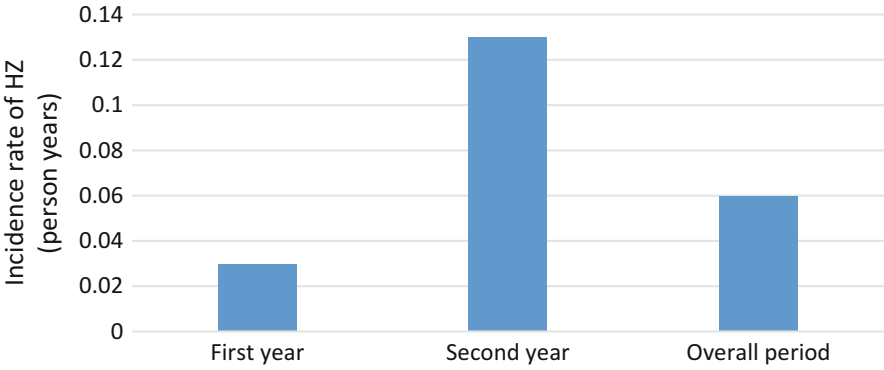

Fig. 3 Incidence of HZ after autologous HSCT. Shows the high rate of HZ reactivation in 194 patients who received approximately 1 year of antiviral prophylaxis. Overall 21% of patients had HZ reactivation in the 5 years of follow-up [13].

lower and the clinical manifestations are usually less severe when reactivation occurs [15]. Interestingly, half of zoster reactivation in vaccines was with wild-type virus suggesting the possibility of breakthrough infection. Eventually, in locations with high vaccination rates, the population will age to a point where the majority of transplant recipients will have been vaccinated as their sole exposure to varicella. This will likely reduce the population incidence and severity of clinical manifestations. More importantly, with the availability of the new adjuvanted varicella vaccination to boost cell-mediated immunity and prevent reactivation (Shingrix®, GlaxoSmithKline), varicella reactivation could eventually become rare in transplant recipients through appropriately directed vaccination strategies. More research will be necessary to evaluate these options in organ and marrow recipients and donors. Regardless, without more aggressive vaccination efforts throughout the world, we will surely continue to see persons developing wild-type disease and its manifestations.

The primary risk factor for VZV reactivation after transplant is loss of cell-mediated immunity. This is more profound early after transplant (after conditioning or induction therapy), and in the setting of treatment of rejection or graft versus host disease. Transplant patients, and in particular those undergoing HSCT, may have significant enough immune compromise to make them susceptible to acute acquisition even if they are seropositive for VZV, though this is rare. Importantly, even though risk of reactivation is higher with decreased CMI, the risk of primary VZV acquisition is associated with lack of antibody to varicella. This is why serostatus prior to transplant is important and also why varicella-specific antibody works to prevent VZV acquisition. As with HSV, acute primary varicella is more likely to be severe if acquired during periods of more significant immune compromise. Acquisition of vaccine strain from a recently immunized individual is extraordinarily rare, with only 11 confirmed cases to date, and all index cases had a rash [16].

Clinical Pearls

- Most patients going into transplant will be seropositive for VZV.
- VZV immunization has decreased the incidence of serious and nonserious clinical disease significantly.
- Even with prophylaxis, many transplant recipients will still develop VZV reactivation disease.
- Transmission of vaccine strain is very rare.

Clinical Impact in Transplant

HSV

Reactivation HSV: The majority of HSV disease in transplant recipients is reactivation disease, which appears as painful vesicular or ulcerative lesions, the majority of which is oropharyngeal. Asymptomatic HSV reactivation is very common, with HSV being found in the oropharynx in >70% of renal transplant and leukemia patients [17]. Genital herpes reactivation is less common, in part likely reflecting lower seroprevalence of HSV-2 [18]. HSV reactivation in transplant recipients can be more severe and prolonged than in immunocompetent patients. Most symptomatic HSV disease occurs early after transplantation and in the setting of intensified immunosuppressive therapy, such as treatment of organ rejection or graft versus host disease [19, 20]. HSV seropositive recipients are at risk of clinical reactivation post-transplant in the absence of antiviral prophylaxis even if they have not had prior clinical HSV disease. Clinically evident HSV recurrences are characterized by lesions that are similar to primary infection but may also present in an atypical fashion (ulcers, plaques, and hemorrhagic lesions) (Table 1) [21, 22].

The majority of HSV reactivation in HSCT recipients is oropharyngeal and/or gingivostomatitis. There is an association between mucositis and HSV reactivation in HSCT recipients, such that all HSCT recipients usually receive antivirals to prevent HSV-associated mucositis. HSV-associated mucositis has a more severe and prolonged course than non-HSV-associated mucositis [8, 23]. In patients receiving cytotoxic chemotherapy or conditioning chemotherapy, HSV should be considered in the setting of complex mucositis that does not improve as expected or is associated with vesicles. Patients often have vesicles or painful ulcers, but classic HSV lesions may not be present. Often patients develop bleeding ulcers and scabbing on the lips. Even with appropriate prophylaxis, up to 25% of marrow recipients may still shed HSV [24]. Oropharyngeal HSV reactivation may descend into the lower respiratory tract in critically ill and intubated patients and rarely can cause pneumonia [25]. In addition to oropharyngeal reactivation, HSV may occur in genital, peri-anal, and other mucocutaneous locations. Rarely, post-transplant patients may have a more disseminated or fulminant clinical course of HSV reactivation, including esophagitis, pneumonitis, enteritis, hepatitis, and disseminated disease [26].

Table 1 Clinical Issues and Risk factors for VZV and HSV infections in transplant patients

	Clinical issues	Risk factors
VZV		
Primary	Disseminated pruritic rash, >98% symptomatic Starts on face and spreads to trunk, spares hands and feet Lesions in various stages More severe in immunocompromised Rarely causes end-organ damage (liver, CNS, lung, and visceral)	Seronegative Inhalation or direct contact Transmission by donor very rare (SOT only)
Reactivated	Localized Shingles: ≤2 unilateral dermatomes Disseminated: >2 dermatomes or 2 noncontiguous May be atypical or severe/disseminated in transplant patients Cranial nerve/ophthalmic involvement, vasculopathy as a complication PHN or superinfection as complications	Decreased VZV-CMI Older age More immunosuppression No shingles vaccine (possible)
HSV		
Primary	Vesicular and/or ulcerative lesions may extend locally in the orolabial, genital, or perianal regions More severe and prolonged in transplant Dissemination rare (skin, liver, and CNS)	Seronegative Contact with symptomatic or asymptomatic Transmission from donor rare (SOT only)
Reactivated	Asymptomatic reactivation common Lesions similar to primary infection HSV-associated mucositis in HSCT more severe Disseminated disease rare	More immunosuppression Neutropenia, mucositis (HSCT) HSV seronegative donor in allo-HSCT

Modified from Zuckerman and Limaye [35]. See text for references
HSV, herpes simplex virus; VZV, varicella zoster virus; SOT, solid organ transplant; PHN, post-herpetic neuralgia; CMI, cell mediated immunity; CNS, central nervous system

Primary HSV: Since asymptomatic viral shedding is frequent, HSV is most often acquired from persons without clinical lesions. HSV seronegative transplant recipients may acquire primary HSV from intimate contacts, with a usual incubation period of 3–7 days. HSV usually appears as classic vesicular and/or ulcerative lesions and may extend locally in the orolabial, genital, or perianal regions. Rarely, primary HSV infection can be associated with more severe and disseminated disease, including skin, liver, CNS, and other organs. Primary infection from an organ allograft is rare, but if it occurs is fulminant and has a poor outcome [27]. Transmission of HSV from stem cell products has not been described.

HSV should be considered in the differential diagnosis of clinically appropriate syndromes regardless of serostatus prior to transplant. In all transplant recipients (organ and marrow), visceral or disseminated disease can occur, including disseminated cutaneous disease, esophagitis, hepatitis, CNS disease, and pneumonitis. Fever, leukopenia, and hepatitis are common presenting signs of disseminated disease.

Clinical Pearls
- HSV can present with atypical lesions and manifestations in transplant patents.
- HSV-associated mucositis can be more severe and prolonged.
- Transplant patients may acquire HSV after transplant.

VZV

Reactivation VZV: VZV remains latent lifelong in trigeminal and dorsal root ganglia, and is generally symptomatic when reactivation occurs. VZV reactivation usually presents as cutaneous herpes zoster (HZ) or "shingles" (Table 1). HZ typically presents as a painful vesicular rash that involves ≤2 adjacent unilateral dermatomes. Recurrence is rare, but does occur, typically in a different dermatome from the prior episode. The rash can be similar to HSV (vesicles, scabs) but can often be differentiated based on location as VZV rash does not cross the midline and VZV usually does not recur in the same location like HSV. Because there is a spectrum of immune control in transplant recipients, patients may have atypical lesions (plaques, nodules) and varying rates of progression of lesions, including a more prolonged onset and slower rate of crusting and scabbing. It is not uncommon for patients to develop new lesions for many days to a week after onset. Recurrent HZ (>2 episodes), particularly in the same dermatome, should prompt evaluation for another cause, most commonly HSV. Viral testing is recommended for recurrent lesions in this setting.

Secondary complications are common with HZ. The incidence of post-herpetic neuralgia (PHN, chronic neuropathic pain at the site of the skin lesions) is higher in transplant patients (20–40%) than in the general population (18%) [28, 29]. With open skin lesions, patients are at risk for bacterial superinfection.

Transplant recipients have a greater chance of multidermatomal and disseminated disease than immunocompetent persons [30]. Disseminated VZV is defined by a distribution of greater than 2 dermatomes, or involvement of 2 noncontiguous dermatomes. Rarely, patients may develop invasive complications (CNS, visceral) without skin manifestations (zoster sine herpete). Immunocompromised children may present with hemorrhagic lesions [31]. VZV reactivation may also present with ophthalmologic findings, with or without rash. Herpes zoster ophthalmicus (HZO) and progressive outer retinal necrosis (PORN) are sight-threatening emergencies that require prompt ophthalmologic evaluation and treatment (see ▶ Chap. 64, "Ophthalmic Infections in Transplant"). The nasociliary nerve innervates the tip of the nose and the globe, so a vesicular rash on the nose (Hutchinson sign) should prompt consideration of ophthalmic involvement.

In addition to direct nerve involvement of VZV causing inflammatory neuritis, patients with VZV reactivation are at risk for VZV vasculopathy, which may lead to neurovascular complications such as ischemic or hemorrhagic stroke and granulomatous small and large vessel disease. VZV vasculopathy is more common in immune-compromised individuals, including HIV and renal transplant, and can present weeks to months after HZ, or even without prior clinically evident HZ

disease [32]. The course is often complicated and chronic, with poor response to therapy and is associated with significant morbidity.

Primary VZV: Varicella zoster virus is highly infectious to seronegative persons and is primarily transmitted through respiratory droplets but can also be spread through direct contact with active skin lesions. Rarely, virus may be aerosolized from patients with active skin lesions and transmitted to mucosal surfaces. Only one organ donor transmitted infection has been reported; there have been no reports of stem cell transmission [33]. The incubation period for varicella is 10–21 days after exposure to the rash, but may be shorted in immunocompromised patients. Patients are infectious from 1–2 days prior to lesion formation until all lesions are crusted.

Clinically, primary varicella presents as a disseminated pruritic rash that often starts on the face and spreads down the trunk, with relative sparing of the hands and soles of the feet; mucosal involvement can occur. Lesions begin as papules then progress to vesicles, followed by crusting and scabbing. New lesions continue to appear for several days such that patients have lesions of various stages (papules, vesicles, and crusted lesions) at the same time. Clinical manifestations may depend on the immune status of the patient and can be atypical in transplant patients [34]. Highly immunosuppressed patients may have more severe primary infection with rapid progression and multiorgan involvement, including pneumonia or CNS disease.

Clinical Pearls

- Transplant recipients may have HZ lesions develop for many days with reactivation.
- Patients with primary VZV are infectious prior to lesions developing and until lesions are crusted.
- Recurrent HZ, particularly multiple episodes in the same dermatome, should prompt evaluation for HSV infection.
- VZV vasculopathy can be a devastating neurologic complication of reactivation.

Disease Diagnostics and Clinical Evaluation

Pretransplant

All pretransplant recipients should have IgG serologic testing for HSV and VZV. Serum IgG level and not IgM level is recommended given the potential for isolated false-positive IgM levels which have no clinical value outside of the diagnosis of acute herpesvirus infection in the appropriate clinical setting [36]. The majority of patients even without a history of clinical VZV infection will be seropositive; nevertheless, negative serology prior to transplant is an important part of identifying prevention (vaccine, immunoprophylaxis) efforts prior to and after transplant. If IVIG administration is anticipated, patients should have serologic testing prior to the IVIG as this can give falsely positive results.

Type-specific testing for HSV (HSV-1, HSV-2) is recommended for risk stratification of potential for oral and/or genital reactivation or acquisition after transplant. Many patients may not be aware of their serostatus and thus may need counseling regarding the meaning of a positive test. The CDC has good information for practitioners regarding the significance of a positive test (https://www.cdc.gov/std/herpes/screening.htm). Given the potentially sensitive nature of a positive serologic test for HSV-2, practitioners should counsel patients prior to and after testing.

Patients with a history of pretransplant, clinical HSV reactivation should be counseled on the possibility of an increase in frequency and/or severity after prophylaxis is stopped. Seronegative recipients should be made aware of their serostatus to provide counseling regarding the potential for HSV acquisition after transplant.

Donor serologic testing for HSV and VZV is not routinely done as it has not been an important part of posttransplant care. In organ transplant, donor serology does not predict the rare case of allograft transmission of HSV and donor Immunity is not transferred to the recipient. In allogeneic stem cell transplant, having a seropositive donor may decrease the incidence of HSV reactivation after transplant, but knowledge of donor serology has not been used to alter care after transplant [37]. In allo-HSCT, it is not known if donor VZV serostatus has any bearing on post-transplant VZV reactivation or acquisition. However, given that most donors will be seropositive, donor serostatus is not routinely checked.

Posttransplant

HSV

Most patients present with typical orolabial and genital lesions and can be diagnosed clinically. However, HSV in an immunocompromised host may present atypically so laboratory confirmation may be necessary. To sample for HSV, the lesion should be unroofed, scraped, and sent for Direct Fluorescent Antibody (DFA) testing, viral culture, or polymerase chain reaction (PCR). Earlier sampling of HSV lesions improves the diagnostic yield. Direct Fluorescent Antibody (DFA) testing of mucocutaneous lesions, bronchoalveolar lavage (BAL), and other clinical samples can provide rapid results; however, the sample needs to include enough cells for staining. Compared with tissue culture, the sensitivity is between 60% and 75% and specificity is 85–99% [38]. PCR for HSV DNA is fourfold more sensitive than tissue culture for diagnosing mucocutaneous HSV and has largely replaced culture and DFA for HSV diagnosis in most body sites (Table 2) [39]. HSV PCR testing availability has increased dramatically and is available at most medical centers though may be performed at an outside reference laboratory. Turnaround time may vary depending on availability, so alternative on-site laboratory tests (DFA, culture, Tzanck, and histopathology) may be useful. Cerebrospinal fluid PCR is the gold standard for diagnosing HSV meningitis or meningo-encephalitis with a sensitivity of 98% and specificity of 100% [40]. FDA-

approved rapid multiplex nucleic acid amplification testing (NAAT) on CSF is becoming the standard of care at many medical centers, making CNS infections more easily identified quickly. It should be noted that HSV PCR testing may be negative in the CSF very early in the disease, so in patients with a compatible clinical syndrome and other diagnostic testing (EEG showing temporal lobe findings, MRI with temporal lobe encephalitis), a repeat LP may be necessary [41]. The significance of HSV DNA detected in other secretions (e.g., BAL) should be evaluated in the context of the patients' clinical disease as HSV shedding may occur outside of clinically significant reactivation. Histopathologic evaluation for confirmation is recommended and can be done on BAL-acquired cells. HSV DNA can also be detected in the blood of patients without clinically evident disease [42]. However, the clinical significance of finding HSV DNA in the blood outside of patients with clinical syndromes consistent with disseminated disease has not been well established [43].

HSV culture should be done when other testing is not readily available or when drug resistant HSV disease is suspected. Genotypic testing for HSV resistance testing is available, but not often used for clinical care because the database for clinical resistance is not complete. Tissue or cell-block histopathology can be helpful with immunocytochemistry for HSV and is recommended to confirm a diagnosis where PCR or other tests may represent contamination (e.g., BAL contaminated from oropharynx). Serologic testing is rarely useful for diagnosing acute infection as increased IgM levels in HSV may occur with reactivation and not a new acquisition [44]. Novel diagnostic tests are being evaluated for clinical use, including Next-Generation Sequencing (NGS) and functional immunologic assays (T-cells), but these are not in wide clinical use.

Diagnosis of HSV keratitis remains primarily a clinical diagnosis based on characteristic features of the corneal lesion on slit lamp microscopy. Patients with ocular disease should be referred to an ophthalmologist for appropriate diagnosis and treatment.

VZV

As with HSV, the majority of primary and reactivation VZV can be diagnosed based on clinical presentation [45]. However, as discussed previously, VZV can present with atypical lesions due to altered immune status and can also present in deep sites (CNS, visceral) necessitating the use of diagnostic tests. VZV diagnostics are similar as for HSV, with a few minor differences (Table 2). When available, PCR is the most sensitive and specific rapid diagnostic test to perform on scrapings, vesicle fluid, serum, spinal fluid, and other tissues. However, PCR may not always be available in real-time on all sample types at most medical centers. As with HSV, PCR of CSF is the gold standard for CNS disease. PCR testing may be positive only early in the setting of VZV vasculopathy, but in immunocompetent patients, CSF VZV IgG has been proposed to be more sensitive [46]. This has not been evaluated in transplant patients. PCR of saliva has been found to be more sensitive than serum PCR in patients with HZ skin lesions, but is not commonly used clinically [47]. In the rare circumstance where there is concern for vaccine strain associated

Table 2 Laboratory Methods for Diagnosis of HSV and VZV

Test	Advantage	Disadvantage
Direct Fluorescent Antibody (DFA)	Rapidly available Virus-specific Good specificity, 85–99%	Lower sensitivity (40–90%) than PCR Limited sample types (needs cells to stain; e.g., not CSF) Time/labor intensive
PCR	Most sensitive (98%) Done on most sample types	Not available at all centers High cost Positive result other than in CSF requires interpretation
Culture (standard tissue based)[a]	Identify type-specific HSV Able to isolate virus for drug susceptibility testing	Turn-around time Labor intensive Sensitivity affected by storage and transport (30–90%)
Culture (shell vial)[a]	Faster turnaround than tissue culture (24–48 h) Similar sensitivity to tissue culture	Labor intensive Does not grow virus for phenotypic sensitivity testing
Tzanck Smear	Rapid Direct visualization	Fresh lesion needed Requires experience Nonspecific to HSV or VZV
Histopathology with immunohistochemistry	Can prove tissue-invasive disease Specific to HSV or VZV	Samples more difficult to acquire Long turn-around time
Serology (IgG, IgM)	Useful to guide pre-transplant risk stratification and prevention Can be used to document response to primary VZV vaccine series[a] CSF VZV IgG can be used for CNS vasculopathy	Insensitive marker for acute infection False-positive IgM
Drug resistance phenotypic assay (plaque reduction assay)[b]	Clinically reliable Can test multiple medications	Need positive culture (see above re: sensitivity) Turn around time
Drug resistance genotypic assay	Rapid	Available for research use, commercial assays not readily available Resistance mutations not completely characterized
Virus-specific immune responses (e.g., CD4/CD8 cell-mediated immunity)[b]	Can show functional immune responses Potential to help guide prevention	Expensive, complex Not validated

(continued)

Table 2 (continued)

Test	Advantage	Disadvantage
Next-generation sequencing (NGS)[c]	Sensitive and specific Can detect specific pathogens and resistance genes Many sample types	Investigational Not widely available Expensive Not validated

Modified from Lee and Zuckerman [53]. See text for references

[a]Culture and phenotypic resistance testing are not commonly used in clinical practice for VZV (see text); however culture may assist in confirming HSV vs. VZV infection if other tests are unavailable. Culture (standard tissue based), Culture (Shell vial), Drug resistance phenotypic assay (plaque reduction assay)

[b]Practitioners should be aware of sensitivity of their laboratory assay for vaccine-induced antibody as some assays have reduced sensitivity. Can be used to document response to primary VZV vaccine series

[c]Purely investigational/hypothetical. Virus-specific immune responses (e.g.....), Next-generation sequencing (NGS)

disease, CDC has PCR testing available for the OKA (vaccine) strain. DFA, though cumbersome, may be more readily available in some centers for rapid identification of VZV skin and mucosal lesions. Viral culture is rarely used clinically for the diagnosis of VZV infections given its low sensitivity (48%) [48]. For HSV, culture is often done to evaluate for antiviral resistance, but given the low sensitivity of culture for VZV, susceptibility testing, if done, has been via PCR for thymidine kinase and polymerase mutations which may confer resistance, but have been poorly described in clinically significant resistance [49]. Given the presumed low likelihood of clinically significant antiviral resistance in VZV infections, routine testing is not recommended. Nevertheless, for patients with a high clinical suspicion, PCR testing may be available on an experimental basis. Nonresponse to acyclovir may be a function of the higher IC50 of VZV for acyclovir than in HSV, so failure is usually due to inadequate dosing or duration of antivirals [50].

Commercially available serologic testing for VZV detects both natural infection and vaccine-induced antibody. However, care should be taken with interpretation of negative results as some commercial assays have been reported to have reduced sensitivity for detection of vaccine-induced immunity [51]. Nevertheless, test characteristics have been improving so clinicians should be aware of which assay is used in their institution [52].

Clinical Pearls

- Serology is only useful to document pretransplant status and response to VZV primary vaccine series, though some assays have reduced sensitivity for vaccine-induced immunity.
- PCR is the most sensitive and specific diagnostic test in most samples.
- HSV resistance testing takes time, so treatment may need to be changed prior to results.

Management

Clinical Disease

HSV

HSV treatment in the immunocompromised host depends on the serostatus of the patient, degree of immune compromise, and clinical manifestations. Acute primary HSV in an immunocompromised patient may spread rapidly so early initiation of therapy is recommended, including starting with IV therapy if there is any clinical concern for progression or dissemination. In seropositive patients, the majority of mucocutaneous disease can be treated with oral therapy (acyclovir, valacyclovir, or famciclovir) (Table 3). It is important to remember that by the time clinical HSV symptoms arise, there has been significant viral production in deep nerve and epithelial cells. As terminators of viral production, nucleoside analogues (acyclovir and derivatives) are effective at diminishing new virions from being produced, but do not stop the ongoing damage from the many virions already in the tissues by the time symptoms are present. Therefore, early administration of antivirals has a greater chance of altering disease trajectory. In immunocompromised patients, viral production is less likely to be controlled by the innate and adaptive immune system and lesions have a tendency to persist for longer and take longer to crust or resolve; therefore, it is reasonable to initiate therapy when the diagnosis is made later than the usually recommended 72 h window for herpes infections. Once crusting of all lesions occurs, initiation of antiviral therapy is unlikely to alter the outcome. Therapy should be continued until complete healing of the lesions and a minimum of 5–7 days [53].

In the immunocompromised patient, intravenous acyclovir should be used for more extensive mucocutaneous disease and when there is disseminated, visceral, or CNS involvement. It goes without saying that early initiation of therapy is associated with improved outcomes in patients with more severe disease. Therapy in severe disease should be continued for a minimum of 14 days. If identified and treated early, HSV-infected organs (not known at the time of transplant) have been used successfully for transplantation and retransplantation [54]. Liver transplantation can be performed in cases of fulminant HSV hepatitis without recurrence in the new organ; however, recurrence has been reported in a patient due to acyclovir-resistant HSV [55].

Children clear acyclovir more rapidly than adults and need higher doses. Dosing guidelines are extrapolated from studies in other pediatric populations and appear in Table 3. Epidemiologically, children are more likely to be seronegative for HSV, so at risk for primary infection after transplant.

Ocular HSV manifestations are treated with various topical and/or systemic therapies and should be done in coordination with an ophthalmologist. Transplant clinicians should be aware that there are risks of epithelial toxicity with various topical agents, so oral therapies may be used as either an adjunct or as primary therapy of ocular HSV infections such as keratitis and endotheliitis [56]. Treatments may need to be continued for an extended period of time depending on the extent of

Table 3 Recommendations for HSV treatment in transplant patients [53]

	Agents	Comments
Limited mucocutaneous disease		
Adult	Acyclovir 400 mg three times a day Valacyclovir 1000 mg twice a day Famciclovir 500 mg twice a day Acyclovir 5 mg/kg IV every 8 h (if unable to take PO or more extensive disease)	Therapy should be started based on clinical diagnosis, pending laboratory confirmation Therapy should be continued until complete healing of all lesions or at least 5–7 days, some give longer courses for more extensive disease
Pediatric	Acyclovir 10 mg/kg IV every 8 h Acyclovir 80 mg/kg divided qid (not to exceed 800 mg/dose)	
Severe, visceral/ disseminated/ CNS disease		
Adult	Acyclovir IV 10 mg/kg every 8 h	Intravenous therapy should be continued until resolution of disease, or 14 days, and then oral medication may be given. For CNS infection may consider 21 days of IV therapy. Continue for 21 days for disseminated or CNS infection
Pediatric	Acyclovir IV 45–60 mg/kg/day in three divided doses	
Acyclovir-resistant HSV		
	Foscarnet 80–120 mg/kg/day IV in two or three divided doses Cidofovir IV 5 mg/kg IV q wk. given with provenecid Topical cidofovir or foscarnet Topical trifluridine	Resistance should be laboratory-confirmed, although empiric therapy can be started Reduce immunosuppression, if possible
Chronic Suppression		
	Valacyclovir 500 mg po BID (preferred over 1 g daily) Famciclovir 250 mg po BID Acyclovir 400 mg po BID	Patients with recurrences (≥2) after cessation of antiviral prophylaxis Can be continued long-term

Modified from Lee and Zuckerman [53]. See text for references
Dosages are for GFR≥50, adjustment is necessary for renal insufficiency
HSV, herpes simplex virus; PO, orally; IV, intravenously

infection, viral integration into the corneal layers, and the risk of relapse following cessation of treatment.

Chronic Suppression

Acyclovir and valacyclovir are well tolerated for chronic suppression of HSV, and associated with minimal risk and toxicity at the doses required for suppression. Therefore, patients entering transplant on chronic suppression and those with bothersome recurrences (≥2) after cessation of antiviral prophylaxis may be candidates for suppressive therapy. Some patients may prefer to remain on this therapy for years or indefinitely, but it is reasonable to consider attempting to stop suppressive therapy in some individuals when immune suppressive therapy is tapered, particularly in those patients not requiring suppressive therapy prior to transplant.

Suppressive therapy can be safely continued for many years and is associated with less frequent acyclovir-resistant HSV than episodic therapy in immunocompromised patients [57]. It is important to give appropriately recommended doses of antiviral therapy to avoid increased risk of clinical breakthrough or resistance. Clinicians must consider the toxicities, costs, risks of transmission, adherence, and psychosocial issues when discussing chronic suppression with patients.

Acyclovir Resistance

Acyclovir resistance can occur in up to 10.9% of immunocompromised hosts and is more common in HSCT than in SOT patients [24]. Patients typically present with lesions that do not respond to high-doses of antiviral therapy. Often, they have had prior acyclovir exposure and/or recurrent disease. HSV resistance to nucleoside analogues is usually due to diminished or absent thymidine kinase (TK) activity (e.g., UL23 gene) or altered DNA polymerase. Drugs that utilize TK (acyclovir, famciclovir, valacyclovir, ganciclovir) are all affected by TK mutations. Evaluation should include laboratory confirmation of HSV disease, including a viral culture as testing for acyclovir resistance generally relies on phenotypic assays. This is most commonly a plaque reduction assay which gives an IC50, the concentration of a drug that is required for 50% inhibition in vitro. Given that testing relies on growth of the virus, results may be delayed for weeks or even months. Genotypic testing may be performed more rapidly than phenotypic testing but is not routinely available for clinical use and requires cautious interpretation. NGS may be a future option for rapid detection of HSV resistance [58].

Foscarnet is the usual first-line therapy medication for acyclovir-resistant HSV infections, but may be limited by toxicity. Renal function and electrolytes need to be followed closely and some patients may develop genital ulcerations that may be mistaken for herpes lesions [59]. Cidofovir is an option, but due to its long half-life, toxicity is difficult to attenuate once it manifests. Probenecid is used with cidofovir to protect against renal toxicity. Cidofovir and foscarnet can also be compounded for topical use, if necessary. Brincidofovir and helicase-primase inhibitors (e.g., amenamevir and pritelivir) are currently in later stages of development and may be available in the near future. Recurrent acyclovir-resistant HSV disease may require repeated courses of therapy. However, subsequent recurrences may be susceptible to acyclovir therapy [60].

Clinical Pearls

- Nucleoside analogues (acyclovir, etc.) are effective in preventing new virions from being produced, but do not prevent damage from the significant amount of virus present by the time patients have symptoms.
- For limited mucocutaneous lesions, oral therapy can be used.
- Suppressive therapy is associated with less frequent acyclovir-resistant HSV than episodic therapy in immunocompromised patients.

VZV

Primary Varicella

Aggressive pretransplant screening/vaccination and posttransplant, postexposure prophylaxis should lead to very few patients developing primary varicella disease. In those at risk, primary varicella can be highly morbid in the posttransplant setting so should be treated rapidly with IV therapy, preferably within 24 h of onset of symptoms or rash (Table 4). Additional supportive measures may include IV hydration (to avoid nephrotoxicity), lesion care to prevent super-infection and pain control. Some patients with severe disease (e.g., pneumonitis, CNS disease) may require ICU-level care. IVIG and VZV-specific immune globulin have been used in some cases of severe disease, but the efficacy of this treatment has not been confirmed [61]. After crusting of all lesions or when patients have improved clinically and no new lesions are forming, most patients can be safely transitioned to oral therapy. It is important to remember that the doses of acyclovir (both IV and oral) required to treat varicella are higher than for HSV due to the higher IC50 of varicella.

Reactivation Disease

Patients with disseminated, CNS or other, visceral varicella should be treated initially with IV acyclovir and supportive care similarly to those with acute primary

Table 4 Recommendations for VZV treatment in transplant patients

	Agents	Comments
Localized HZ, uncomplicated		
Adult	Acyclovir 800 mg 5× a day Valacyclovir 1000 mg 3× a day Famciclovir 500 mg 3× a day	Therapy should be started based on clinical diagnosis Therapy should be continued until complete crusting of all lesions or at least 7 days, longer courses may be necessary for lesions slow to resolve
Pediatric	Valacyclovir 20 mg/kg tid (2–18 years old) Acyclovir 800 mg po 5× a day (≥12 years old) Acyclovir 10 mg/kg IV every 8 h (<2 years old or unable to take PO)	
Acute primary or Severe (visceral/ disseminated/ CNS, including vasculopathy and HZO)		
Adult	Acyclovir IV 10 mg/kg every 8 h	Intravenous therapy should be continued until significant improvement of disease, and then oral medication may be given. For CNS infection may consider 14–21 days of IV therapy, followed by oral therapy.
Pediatric	Acyclovir IV 45–60 mg/kg/day in three divided doses	

Modified from Pergam and Limaye [62]. See text for references

Follow renal function carefully on therapy. Dosages are for GFR≥50, adjustment is necessary for renal insufficiency

VZV, varicella zoster virus; HZ, herpes zoster; HZO, herpes zoster opthalmicus; PO, orally; IV, intravenously

disease [62]. Also, patients with ocular or facial nerve involvement are at risk for persistent sequalae, so should receive initial IV therapy, with transition to oral therapy after initial stabilization. Those with suspected VZV vasculopathy should receive IV therapy, the duration of which is not well established. Most experts would treat until symptoms resolve, and for a minimum of 2–3 weeks with longer courses sometimes needed. The use of steroids has been advocated by some in the setting of complex vasculopathy that does not respond initially to antiviral therapy or has the potential for significant permanent neurologic sequelae, with no controlled trials evaluating their efficacy [63].

The majority of cutaneous dermatomal HZ is treated with oral antiviral agents, acyclovir, valacyclovir, or famciclovir. As with HSV, antiviral therapy should be given for at least 7 days or until lesions have crusted over, which may be delayed in immunocompromised hosts. IV therapy is recommended for young children and/or those who cannot tolerate oral therapy.

Controlled trials of adjunctive therapies (e.g., steroids, gabapentin, and amitriptyline) given during the HZ episode to prevent PHN have not been conducted in transplant recipients. Due to their uncertain effectiveness and potential toxicities, these agents are not recommended routinely.

Clinical Pearls

- Posttransplant patients who develop primary varicella should be treated with intravenous acyclovir.
- Localized nonsevere dermatomal HZ can be treated with oral therapy in most adults.
- Patients with severe HZ disease should receive IV acyclovir as initial therapy.
- Patients with HZ involvement of the eye(s) should be assessed by ophthalmology.

Prevention

Primary Infection

Acute primary infection with HSV or VZV can be morbid in the transplant recipient. Therefore, pretransplant assessment for prior infection is important. For HSV, patients should be asked about prior orolabial, genital, perianal, or other recurrent mucocutaneous reactivation. For varicella, many patients may recall having had chicken pox or exposure to someone with chicken pox as a child. Alternatively, some recipients may have had a prior episode of shingles. HSV primary infection can be asymptomatic, so it is important to remember that many patients are seropositive even without recollection of having had herpes lesions. While asymptomatic VZV infection is uncommon, adult recollection of prior disease may be inaccurate, with 71–93% of adults with negative or uncertain history being seropositive [64]. Even with a reported history of infection or immunization, all transplant recipients should have IgG serologic testing for HSV and VZV. Serology is usually adequate to

evaluate for evidence of prior infection; however, some patients with hematologic malignancy may have immunoglobulin deficiencies and negative serology.

HSV

There is no FDA-approved vaccine to prevent HSV infections, though there are some candidates in the pipeline. Current HSV prevention techniques are focused on behavioral and antiviral methods. Seronegative transplant recipients should be counseled regarding the risks of HSV-1 and HSV-2 acquisition. It is important to avoid contact with persons with active lesions, as these patients are highly infectious. However, persons may acquire HSV from asymptomatic individuals, so providers are encouraged to provide standard counseling to recipients regarding HSV acquisition. The virus can be acquired from persons who have never had lesions. Condoms are effective, but do not completely protect against HSV transmission. In serodiscordant couples, daily antiviral therapy taken by the seropositive partner can prevent HSV-2 transmission to the seronegative partner [65]. This may be considered as an option, but has not been evaluated in the SOT population. There are no controlled studies looking at the efficacy of postexposure prophylaxis to prevent HSV acquisition, so it is not routinely recommended.

VZV

The incidence of primary VZV in transplant recipients remains low. However, VZV is highly transmissible via the airborne route; therefore, prevention of primary infection in seronegative patients relies most heavily on vaccination rather than behavioral interventions. Thankfully, there are effective vaccines to prevent primary infection with VZV (Varivax, ProQuad). Because the only current preparations are live vaccines, timing of immunization needs to be considered carefully in the transplant population (Table 5). Each transplant patient should be evaluated individually, with the risks and benefits weighed with regard to the potential for adverse outcome from the vaccine, the likelihood of response to immunization, and risk of acquisition of VZV in the community. It should be noted that there have only been rare cases of Oka strain disseminated disease after immunization, even in the most profoundly immunocompromised patients [66]. Additionally, because acyclovir is active against the Oka strain, it can be used for treatment of complications of the vaccine in the rare event this should happen [67]. Unfortunately, antiviral resistance in the Oka strain has now been reported [68]. Seronegative patients who receive the primary immunization series should have serology checked to confirm adequate response to vaccine, which may be poorer in immunocompromised patients [69]. However, care should be taken in interpretation of a negative test given the reduced sensitivity of some assays [51].

Seronegative patients who are not able to be immunized should take particular care to avoid situations where they may be exposed to persons with primary varicella. Additionally, they should avoid close contact with persons with shingles as there has been transmission from patients with the rash of HZ. A very important part of pretransplant counseling is ensuring contacts of transplant recipients are up to date on their immunizations. Preventing primary VZV disease in close contacts can

be an effective way to keep transplant patients safe, so eligible contacts (>1 year old, no history of disease, no contraindication) should be vaccinated with the live-vaccine series. Some practitioners express concern with immunizing close contacts of immunosuppressed patients with a live vaccine out of concern the potential to transmit the vaccine strain to the compromised host. Transmission of the vaccine strain is extraordinarily rare, and it is significantly higher risk for contacts to remain unvaccinated and potentially bring the highly-transmissible wild-type varicella into the home should this occur [70]. Vaccinees should keep the site covered, particularly if a localized rash develops and transplant patients should be isolated from contacts who develop a significant rash. Close contacts who are eligible should be considered for the adjuvanted zoster vaccine as well (Shingrix®, GlaxoSmithKline).

Pretransplant Vaccination (Table 5)

SOT

Pretransplant immunization in the SOT population is more straightforward than in the HSCT population. Seronegative patients without significant immunocompromise can be safely immunized prior to transplant. Response rates are lower in end-stage organ disease, so the full two-dose series should be given [71]. The vaccination series should be completed at least 4 weeks prior to transplant. The majority of patients ineligible or unable to be immunized will be unlikely to be able to get the primary series after transplant unless a non-live vaccine is deemed effective (see below).

Table 5 VZV Immunization in seronegative SOT and HSCT

		Pretransplant	Posttransplant
SOT		Varivax, preferred pretransplant	Varivax may be safe in select posttransplant patients on stable, low-dose immunosuppression. Ongoing study of RZV in VZV seronegative patients (Clinical trials.gov NCT03685682)
HSCT	Autologous	Varivax, two shot series (though one is better than none). Prior to stem-cell harvest, if possible	Varivax, two shot series, when eligible for live-virus vaccination[a]
	Allogeneic	No recipient vaccine	Varivax, 2 shot series, when eligible for live-virus vaccination[a]

Varivax: two-shot series recommended, 4 weeks apart for >12 years old, 3 months apart for 1–12 years old. Proquad may be considered in eligible children. RZV (recombinant zoster vaccine, Shingrix®). Hold acyclovir during live-vaccine administration

[a]2-1-5 Rule = Not until 2 years post HSCT and >1 year off all immunosuppressive therapy and at least 5 months since last dose of IVIG/VZIG or most recent plasma transfusion. Check varicella serology at least 1–2 months after second dose of Varivax to ensure seroconversion. Make sure close contacts are immunized.

HSCT

Immunization of the allogeneic HSCT recipient prior to transplant will likely not provide reliable immunity after transplant so is not routinely recommended. There has been no study of immunization of the allogeneic DONOR against varicella, but this could be a viable option to improve immunity or responses to vaccination after transplant given data with other vaccines [72]. Further research is necessary before making this recommendation. Seronegative autologous transplant patients should receive the primary immunization series if there is enough time prior to transplant or chemotherapy to wait the approximately 4 weeks necessary to avoid immunosuppression after each immunization in the two-shot series. If possible, the entire two-shot series should be given prior to transplant; but if not feasible, a single shot is preferred to none. Some autologous patients may be on maintenance immunosuppression, or their primary disease/prior chemotherapy may be so immunocompromising that the live-virus vaccine should be avoided. If there is no good time to safely administer the vaccine, it is reasonable to wait until after transplant. As stated, the risk of vaccine must be taken into account on an individual basis. In general, immunizations in autologous patients should be attempted prior to stem cell harvest to optimize the likelihood of improved immunity after transplant; however, there are no studies of this method with primary VZV. Many patients are on acyclovir prophylaxis prior to transplant. This medication should be held with live-varicella immunization as it decreases the efficacy of the immunization because the Oka strain is susceptible. Additionally, patients should not receive the primary VZV immunization if they have had IVIG within the past 5 months; however, in a seronegative patient who may be eligible for the primary vaccine series, the lower likelihood of response should be evaluated with regard to the risk of potential primary VZV infection in the future.

Posttransplant Vaccination (Table 5)

SOT

The live varicella vaccine has been given safely to very select post-SOT patients, mainly pediatric patients on lower immunosuppression [71]. Current guidelines recommend vaccination for only select kidney and liver transplant recipients who are seronegative posttransplant and receiving long-term, low-level immunosuppression [62]. Given the impressive humoral (anti-gE) as well as cell-mediated immune responses to Shingrix® (aka, adjuvanted vaccine, or recombinant zoster vaccine (RZV), GlaxoSmithKline), there is a current study looking at this vaccine in seronegative post-transplant patients (Clinical trials.gov NCT03685682).

HSCT

Seronegative HSCT recipients are usually eligible to receive live virus vaccines after transplant assuming they are 2 years out from transplant, immunosuppressive medications have been discontinued for at least a year and they have not received

IVIG for at least 5 months [73]. Even though immune reconstitution occurs earlier after autologous transplantation, there has been no delineation between allogeneic and autologous transplant with regard to timing of administration of live vaccines after transplant.

Posttransplant Postexposure prophylaxis for VZV

Seronegative transplant recipients are at risk for developing severe primary infection after exposure and should receive postexposure prophylaxis after significant exposure (Table 6) [74]. While cell-mediated immunity is important to prevent reactivation of VZV, antibody is a better correlate of protection against primary infection. Therefore, the mainstay for postexposure prophylaxis in high-risk individuals is the administration of immunoprophylaxis in the form of VZV-specific antibodies or with nonspecific immunoglobulin preparations [31]. VARIZIG™ (Saol Therapeutics) is the only VZV-specific immune globulin preparation available currently and recommended within 10 days of exposure [74].

Antiviral agents have been used successfully either alone or in combination with immunoprophylaxis [75]. Therefore, antivirals are recommended if immunoprophylaxis is not able to be given within 10 days of exposure or as an adjunct to immunoprophylaxis in high-risk patients. Current guidelines suggest the use of valacyclovir due to improved oral bioavailability, but acyclovir is likely effective as well [62]. There have been no controlled trials of antiviral medication, so timing of administration is based on case series and expert opinion. Historically, antivirals were recommended starting day 7 after exposure and for 7 days of treatment [76]. However, due to concerns about early and prolonged viral replication, some experts recommend starting earlier and continuing for longer [77]. Additionally, immunoprophylaxis has been suggested to delay viral production so a longer course is often given in the setting of immunoprophylaxis [77].

Patients who are seropositive for varicella are presumed to be protected against new infection. However, some patients with profound immunosuppression early

Table 6 Postexposure prophylaxis for VZV seronegative transplant recipients

VZV-infected exposure	*Primary infection*: primarily airborne, also direct contact with lesions *HZ*: direct contact with active lesions or airborne material from rash
Definition of contact	*Outpatient*: household contact, nontransient face-to-face contact *Inpatient*: exposure in the same room, face-to-face contact with an infectious staff member or patient, visit by a contagious person
Prophylaxis:	*Immunoprophylaxis*: VARIZIG within at least 10 days of exposure; IVIG if VARIZIG not available. *Antiviral*: If unable to give immunoprophylaxis within 10 days. Also, may be used as an adjunct to immunoprophylaxis, particularly if IVIG is used. Valacyclovir either for a 7-day course of therapy beginning 7–10 days after VZV exposure or, alternatively, from day 3 to 28 following exposure.

VZV seropositive HSCT patients on high-dose steroids or T-cell depleted grafts should be considered for immunoprophylaxis if they have a known VZV exposure. See text for references

after transplant or in the setting of treatment of rejection or graft versus host disease may be at risk of VZV acquisition even if seropositive, though this is rare. These patients are commonly on antiviral prophylaxis that may protect against VZV replication; however, it is recommended to follow them closely if they are exposed. HSCT patients are at higher risk than SOT, so postexposure immunoprophylaxis should be considered in patients on high-dose steroids and those with T-cell depleted grafts if they have a high-risk exposure [73].

Clinical Pearls

- HSV prevention is through mostly behavioral changes, but antiviral prophylaxis in the seropositive partner may also be considered.
- The only current option for immunization for VZV seronegative patients as a live vaccine and HSCT and SOT patients have different recommendations around transplant.
- VZV seronegative patients unable to safely receive Varivax should receive postexposure prophylaxis for high-risk exposures.
- Some highly immunocompromised seropositive HSCT patients should receive postexposure prophylaxis for high-risk exposures

Prevention of Reactivation

As seen in the epidemiologic curves, reactivation of HSV and/or VZV occurs most frequently within defined time frames of immune compromise. Therefore, most seropositive transplant recipients should receive some form of preventive antiviral therapy during the highest-risk periods. A discussion of HSV and VZV prevention would not be complete without mention of CMV prevention because (a) CMV can be highly morbid in the transplant population, (b) most transplant recipients get some form of CMV prevention modality, and (c) many of the anti-CMV medications have activity against HSV and VZV. Use of a CMV universal prophylaxis regimen with activity against HSV and VZV usually obviates the need for specific prophylaxis against these viruses. However, as preemptive regimens evolve and new drugs are developed specific for CMV and without activity against HSV and VZV (Table 7), clinicians will need to modify prevention algorithms.

In SOT, VZV reactivation occurs at a steady rate for years after transplant, so preventive antivirals are not usually guided by VZV risk given that there are no data to support the many years of antiviral treatment that would be required to prevent HZ after SOT [53, 62]. For HSCT, most significant HSV reactivation typically occurs early during neutropenia, with varicella risk generally more significant and prolonged than HSV after transplant, so antiviral prophylaxis duration usually centers around HZ risk. Moving forward, the use RZV as a preventive modality will hopefully reduce the risk of HZ such that extended antiviral prophylaxis for VZV may not be necessary in many transplant recipients, but there are currently not

Table 7 Currently available therapies for CMV and adequacy against HSV/VZV

CMV therapy	Adequate for HSV/ VZV?
Ganciclovir	Yes
Valganciclovir	Yes
Foscarnet	Yes
Cidofovir	Yes
Letermovir	No
Brincidofovir	Yes [78]
Maribavir	No

enough data to support attenuation of antiviral prophylaxis regimens in recipients of RZV after transplant.

Antiviral Medication

SOT

As stated, many SOT recipients receive antiviral medication to prevent CMV replication, the majority of which also covers HSV. Additional HSV and VZV-specific prophylaxis may be necessary in patients not receiving agents active against these viruses. Table 8 outlines recommended antiviral prophylaxis regimens and duration depending on the serologic status of the recipient. Typically, one month if HSV/VZV prophylaxis is given to recipients not on CMV prevention with activity against these viruses, though some centers give longer courses (e.g., 3 months) [53]. New epidemiologic data may help guide future recommendations [2]. Some centers will give about a month of antiviral therapy to HSV seronegative recipients not on HSV/VZV-active CMV therapy even if VZV seronegative out of concern for the rare potential transmission of HSV from the organ. In addition to the immediate post-transplant period, patients should receive HSV/VZV-active antiviral medication during immunosuppression intensification for organ rejection, especially with cytolytic therapies such as antithymocyte globulin and alemtuzimab. Antiviral dosing is garnered from studies of similarly immunosuppressed patients and has been successful in practical use. Increased doses of acyclovir or valacyclovir should be used for patients with a history of frequent and/or severe recurrences, and some clinicians opt to give chronic suppression to patients who have an episode of severe HSV disease after transplant.

Pediatric patients are more likely to be HSV and VZV seronegative. Aside from immunization against VZV in seronegative children, antiviral prophylaxis in pediatric patients is usually driven by serostatus. Dosing for antivirals is based on studies in immunosuppressed children and IV formulations may need to be used in children not able to reliably take p.o. medications. Though cidofovir has in vitro activity against HSV and could be used weekly in children, breakthrough HSV stomatitis has been reported with this regimen [79].

Table 8 Antiviral prophylaxis for HSV and VZV after transplant

	Serology	Antiviral prophylaxis	Comments
SOT	HSV+ VZV+/−	CMV prophylaxis[a] or Acyclovir 400–800 mg twice a day Valacyclovir 500 mg twice a day Pediatric dosing: <40 kg: Acyclovir (60–90 mg/kg PO in three divided doses) Valacyclovir (20 mg/kg PO twice a day, 3mo to 11 years) For IV, 5 mg/kg every 8 h	Administer for at least 1 month During treatment of rejection episodes (for at least 1 month) See also VZV pre/post vaccine prevention
	HSV− VZV+	CMV prophylaxis[a] In patients not on CMV prophylaxis there is no research, but some centers give VZV prophylaxis for 1 month after transplant	RZV after transplant, if eligible
	HSV− VZV−	In patients not on CMV prophylaxis, some centers give a short course of antiviral prophylaxis around transplant due to very low HSV risk from organ	See also VZV seronegative prevention
HSCT	VZV+ HSV+/−	Acyclovir 800 mg twice a day Valacyclovir 500 mg twice a day Unable to take p.o.: IV acyclovir 5 mg/kg IV every 12 h or 250 mg/m^2 IV every 12 h	Prophylaxis for at least one year, also during treatment of GvHD Consider RZV after transplant
	VZV− HSV+	Acyclovir 400 mg twice a day Valacyclovir 500 mg twice a day Unable to take p.o.:IV acyclovir 5 mg/kg IV every 12 h or 250 mg/m^2 IV every 12 h	From start of conditioning to engraftment or resolution of mucositis See also VZV seronegative prevention
	VZV− HSV−	No HSV/VZV-specific prophylaxis	See also VZV seronegative prevention

HSV, herpes simplex virus; VZV, varicella zoster virus; CMV, cytomegalovirus; SOT, solid organ transplant; HSCT, hematopoietic stem cell transplant; PO, orally; IV, intravenously, RZV, recombinant zoster vaccine

[a]CMV prophylaxis with recommended doses of ganciclovir, valganciclovir, valacyclovir or acyclovir are adequate for HSV prevention. If agent without HSV/VZV activity used for CMV prophylaxis (Table 7), additional HSV-specific prophylaxis is necessary. Dosages are for GFR>50, adjustment is necessary for renal insufficiency. Stop HSV/VZV prophylaxis if patient on treatment for CMV with activity against HSV/VZV (e.g., ganciclovir, valganciclovir, foscarnet, and cidofovir)

HSCT

Antiviral therapy significantly decreases HSV and VZV reactivation in HSCT patients [57]. The majority of HSCT patients are either getting preemptive prevention for CMV or letermovir, so will need some antiviral medication with activity against HSV and VZV. Some patients are on prophylaxis with acyclovir or valacyclovir prior transplant as a part of treatment protocols, this can just be continued into transplant. HSV risk is greatest early after transplant, so antiviral

therapy should be started with conditioning and continued at least through engraftment or when mucositis resolves. In VZV seropositive patients, antiviral therapy should be continued for an extended duration. At least one year has been considered to be the norm due to the high rate of HZ without antiviral therapy or with stopping antiviral therapy earlier than a year after transplant [13]. Some centers continue treatment for at least a year, or 6 months after completion of anti-T cell therapy, whichever is longer. One study used CD4 count as a marker for discontinuation, but patients had an unacceptably high rate of reactivation after treatment cessation [14]. In the future, immunologic biomarkers (e.g., VZV-specific immunity) may be used to determine when to stop antiviral therapy, but no such studies have been done to date. Finally, some patents may receive therapy for CMV reactivation that is active against HSV and VZV; acyclovir or valacyclovir can be stopped during these periods.

Clinical Pearls

- Most transplant patients should receive some antiviral prophylaxis with activity against HSV and VZV.
- Clinicians should be aware that some CMV prophylaxis does not have anti-HSV/VZV activity.
- HSV/VZV prophylaxis should be resumed during intensification of immunosuppression.

VZV Vaccination (Table 9)

Until 2017, the only commercially available vaccine to prevent HZ reactivation was the live-attenuated Oka vaccine (Zostavax®, Merck and Co.), which had incomplete response rates and was contraindicated in most transplant patients [80]. Since its approval, the new adjuvanted subunit varicella vaccination (Shingrix®, GlaxoSmithKline Biologicals) has been a complete game-changer with regard to prevention of VZV reactivation and postherpetic neuralgia. In immune competent patients, it is >90% effective in preventing HZ episodes and postherpetic neuralgia [81]. Studies are ongoing in transplant patients, but preliminary reports suggest good safety and efficacy such that current recommendations favor the use of the RZV over the live attenuated version [82]. Guidelines and recommendations can often lag behind treatment practice, but practically speaking, the live-attenuated vaccine is no longer used in transplant patients. Additionally, previous receipt of Zostavax® does not provide reliable long-term HZ prevention; therefore, patients (SOT and HSCT) eligible by CDC or other guidelines should receive RZV regardless of prior Zostavax® immunization.

Due to the adjuvant, RZV is associated with frequent injection site and systemic reactions such as fatigue, myalgias, headache, and fever. Because it is not a live vaccine, there is no concern with progressive clinical VZV disease or transmission. Patients should be counseled to expect the common side effects and treat them with supportive care.

Table 9 VZV immunization in seropositive SOT and HSCT patients

		Pretransplant	Posttransplant
SOT		RZV (where eligible, >50 years old). Some centers give RZV to all VZV seropositive adults ≥18-years old prior to transplant, further research ongoing.	RZV likely safe in low-risk, postrenal transplant patients. Safety and efficacy of RZV not confirmed in controlled trials in other organ recipients, some centers give to high-risk (NCT 03993717, NCT03493776, peds NCT 04006808),
HSCT	Autologous	Consider RZV if eligible based on ACIP guidelines and significant duration before transplant, otherwise wait until after transplant. If administered, consider prior to stem cell harvest.	RZV for all ≥18yo; 50–70 days after transplant and 1–2 months later
	Allogeneic	No recipient vaccine ? donor vaccination	No data, suggested to give to patients >50 years old, >2 years from transplant, off immunosuppression, no GvHD

RZV, recombinant zoster vaccine (Shingrix); SOT, solid organ transplant; HSCT, hematopoietic stem cell transplant. See text for references

SOT

Pretransplant Vaccination

Where possible, SOT patients who are eligible should receive the RZV prior to transplant [62]. RZV is recommended for the pretransplant population >50 years of age; however, studies are ongoing in younger patient populations. The vaccine should be given at least a few weeks prior to transplant to give an opportunity for immune response and to get past the phase of vaccine side effects prior to transplant. If vaccine is given closer to transplant, there is no contraindication to getting the transplant since this is not a live vaccine.

Posttransplant Vaccination

Despite the excitement at the prospect of having a non-live vaccine to give to transplant patients, there are theoretical risks that a potently adjuvanted vaccine could increase the risk of acute or chronic allograft rejection. Therefore, some centers are not routinely giving this immunization to all posttransplant patients until more research is done. To date, the only published trial in SOT is a randomized double-blind placebo-controlled study of the safety and immunogenicity of RZV in renal transplant patients that were highly selected based on factors that put them at low risk for rejection [83]. This study showed excellent immunogenicity and no increased risk of rejection or adverse events. Efficacy to prevent clinical HZ disease was not assessed. Additional ongoing research will hopefully answer questions regarding safety and efficacy in higher-risk patients in the coming years. At the

current time, it is reasonable to consider giving the RZV to renal and other transplant patients at low risk for rejection as defined by published literature, though some centers are using RZV in patients at higher risk for HZ (lung, heart). It should be noted that some patients are on anti-CMV therapy with activity against VZV for extended courses after transplant (e.g., lung recipients), so are generally protected against HZ reactivation during antiviral treatment. In these patients, it may be preferable to wait until closer to cessation of antiviral therapy to consider immunization as patients will have more time since transplant and likely be more clinically and immunologically stable. RZV can be given to patients taking antivirals because there is no known attenuation of vaccine response by antiviral medication to RZV. Unfortunately, there is significant variability between transplant centers in immunization practices after transplant; more research is needed to assist with standard practice guidelines.

HSCT

Pretransplant Vaccination

To date, there has been no evaluation of vaccination in the pretransplant setting as a preventive therapy for HZ after HSCT. However, some patients receiving chemotherapy and biological medications for their primary disease may be candidates for immunization prior to the decision to pursue transplantation. This is an area ripe for research. In the allogeneic recipient, recovery of cell-mediated immunity to varicella is highly variable though poorly characterized in the modern era. Patients undergoing a T-cell depleted allo-HSCT may not recover cell-mediated varicella responses unless they have clinical reactivation of VZV [84]. Non-T-cell depleted patients may reconstitute cell-mediated immunity, but recent data are sparse and GvHD prophylaxis likely attenuates this [85]. Currently, donor VZV serostatus is not routinely tested in allogenic donors and it is not known if boosting cell-mediated VZV-specific immunity with RZV in a donor will assist in reconstituting recipient immunity after transplant.

Autologous transplant patients were the subjects of a trial of a gamma-irradiated killed varicella immunization (that is not currently available), the first in a four shot series of immunizations was given prior to transplant [86]. HZ prevention efficacy of this series was similar to the efficacy of two-shots of RZV given after transplantation [82]. Therefore, given that this preparation is not available, requires more injections, and lacks improved efficacy, most autologous transplant recipients can wait until after transplant to receive HZ immunization. Another area for research is the efficacy of immunization in the autologous transplant patient prior to stem-cell harvest. This method has shown efficacy in improving response to other immunizations given after transplant and should be considered for evaluation in the future [87, 88].

Posttransplant

Safety and efficacy of HZ vaccination has been shown in two randomized trials in autologous transplant patients. The first, mentioned previously, showed 64%

reduction in HZ events with the use of a irradiated virus vaccine [86]. The second, a double-blind randomized placebo-controlled study of RZV demonstrated a 68% reduction in HZ events posttransplant (ZOE-HSCT) in patients ≥18 years old [82]. In this trial, the first vaccine was given between days 50 and 70 posttransplant, with the second dose 1–2 months after. In addition to the reduction in HZ episodes, this study showed a marked improvement quality of life in patients who developed HZ [89]. Therefore, it should be given to all autologus patients ≥18 years old (though insurance may not cover those <50 years old at this time).

There has been no study of RZV in VZV seropositive allogeneic HSCT patients. Therefore, it is not currently recommended until 2 years post HSCT, greater than 8 months off immunosuppressive therapy and no flare-up of GVHD. However, other adjuvanted vaccines with strong adjuvants have been used safely in allogeneic HSCT, so in time, it is likely that RZV may be used sooner after transplant. It is currently recommended to continue VZV prophylaxis until one month after first vaccination.

Due to the low cost and safety of acyclovir for extended courses, this remains the standard of care until there are more data to support the use of HZ immunization without antiviral medication after transplant. Additionally, given the lack of good markers of VZV-specific immunity and the lack of complete protection by the vaccine, further study is needed to elucidate which patients may be able to stop antiviral medications earlier than usual.

Clinical Pearls

- RZV has replaced Zostavax to prevent HZ reactivation.
- It will be important to keep abreast of the latest research in the use of RZV in transplant patients.
- Until further research is done, patients receiving RZV in the peritransplant period should take the recommended antiviral prophylaxis.

Special Considerations

Infection Control

HSV has not been shown to be transmitted via the airborne route, so patients with active lesions do not need to be on airborne precautions in the healthcare setting. Usual contact precautions are recommended when dealing with active lesions.

For VZV, all immunosuppressed patients admitted to the hospital with primary or reactivation disease should be placed on airborne and contact isolation precautions until all lesions are crusted. Patients with localized zoster lesions should also have them covered to decrease transmission risk.

Susceptible patients (seronegative, highly immunocompromised) who are exposed to VZV should remain in airborne and contact precautions from day 10 to 21 while in the hospital after exposure to the index patient. Patients who receive passive immunoprophylaxis (VARIZIG, IVIG) should remain in precautions

until day 28 [31]. Consideration should be given to vaccination of seronegative close contacts and household members of patients with primary or disseminated disease [90].

Pregnancy

With increasing numbers of transplant patients pursing pregnancy, this population deserves special mention. Unfortunately, there has been no targeted research regarding HSV and VZV in pregnant transplant recipients; therefore, most recommendations are similar to those in nonpregnant adults with the exception that VZV seronegative women considering pregnancy are not currently candidates for the primary live-attenuated vaccine series. Transplant patients may have more frequent and severe HSV recurrences, so may need to be on suppressive therapy for delivery. CDC and ACOG have excellent recommendations for management of these infections in pregnancy [91, 92]. Acyclovir and valacyclovir are safe in pregnancy, though doses may need modification due to organ dysfunction or level of immune compromise.

IV Acyclovir Shortage

Unfortunately, there have been a number of recent shortages of intravenous acyclovir. When IV acyclovir is not available, alternative agents may be necessary to use. In less severe disease, consideration can be given for high-dose oral valacyclovir therapy, particularly in HSV where the IC50 is lower for acyclovir. Nevertheless, in transplant recipients where disease may progress rapidly, an initial course with an alternative IV treatment may be necessary to stabilize the infection, with subsequent transition to an oral regimen (Table 10). In patients with severe mucositis or esophageal HSV disease who may have odynophagia, oral acyclovir suspension may be attempted, but IV therapy with alternative agents may be necessary.

Cutting Edge Dreams

- Next-Generation sequencing may become a promising diagnostic technique to rapidly detect virus in tissue and determine virus susceptibility [58].
- CRISPR/Cas9 could potentially be used to cure herpes virus infections [93].

Table 10 Treatments for disseminated, visceral or CNS HSV and VZV during an IV acyclovir shortage

Medication	Dose
Ganciclovir	5 mg/kg iv every 12 h
Foscarnet	Infants and children: 60 mg/kg q 12 h Adults: 90 mg/kg q 12 h or 60 mg/kg q 8 h
Cidofovir	Typically, not used, does not cross blood-brain barrier

- In vitro HSV may be used improve outcomes from transplantation. The HSV-TK suicide gene has been inserted into donor stem cells for transplant as a way to provide a mechanism to downregulate the donor cells. By inserting the HSV-TK mechanism into donor cells, they become susceptible to ganciclovir so that if donor cells cause problems (e.g., GvHD), ganciclovir can be used to down-regulate the activity donor cells that have the HSV-TK to decrease the immunologic damage caused by these cells [94].

Conclusion

The alpha-herpesviruses have the potential to produce significant morbidity and mortality in transplant patients. With attention to pre- and posttransplant diagnostic and prevention techniques, these effects can be minimized. Thankfully, there are many new and exciting diagnostic, therapeutic, and preventive modalities in development that will likely change clinical practice considerably in the coming years.

Key Points

- HSV and VZV continue to cause significant disease in transplant recipients.
- Diagnosis is often made on clinical grounds, with laboratory support.
- As treatment options expand, novel therapies will need to be evaluated in transplant patients.
- Vaccination has the potential to become a cornerstone of prevention.
- Care providers are encouraged to incorporate the ongoing advances in diagnosis, treatment and prevention into their practice.

Introduction

Transplantation of solid organs (SOT) or hematopoietic bone marrow and stem cells (HSCT) is a growing field with international impact. Refinements in both broad arms of transplant medicine in the past half-century have led to improved patient outcomes in previously fatal pediatric and adult diseases, enabling survival and return to function for countless patients. In both cases, the use of immune suppression is critical in the management of the transplanted tissue, whether solid or hematologic. Advancements in T-cell-targeted therapy – from steroids to cyclosporine to tacrolimus – have improved survival and patient outcomes. These improvements come at the cost of susceptibility to infection. Herpesviruses such as Epstein-Barr virus (EBV) remain major challenges in the posttransplant period, with both acute and chronic complications and mortality. The most extreme form of EBV infection results in the transformation of the host B cell into a lymphoproliferative condition, with many similarities to de novo neoplastic disease. Posttransplant lymphoproliferative disorder (PTLD) refers to this heterogeneous group of diseases that occur in the setting of SOT or HSCT, as described in the WHO classification (Table 1) [1]. While EBV-negative PTLD does occur, EBV is the most important pathogen, associated with the development of PTLD, accounting for more than 90% of cases of PTLD in these patient populations.

This chapter will focus on the epidemiology, diagnosis, and management of EBV-driven PTLD. While EBV-negative PTLD often occur late after transplant in adult recipients, they are beyond the focus of this discussion. While the current work will summarize prior and current understanding and management of EBV-driven PTLD, we acknowledge the work done on guidelines for patients with PTLD after bone marrow and stem cell transplant [2] as well as solid organ transplant [3]. Recommendations of the authors also reflect the recommendations of a 2019 consensus conference on the diagnosis, management and prevention of EBV-positive and EBV-negative PTLD in children undergoing SOT cosponsored by the International Pediatric Transplant Association whose final recommendations are expected in 2020.

Disease Epidemiology

Epstein-Barr virus ubiquitously infects more than 90% of the adult population worldwide. EBV is usually spread via infected saliva but is also less commonly spread via sexual intercourse, blood products, and passenger leukocytes

Table 1 Histological classification of posttransplant lymphoproliferative disorders (PTLD). (World Health Organization 2016 [1])

Architecture	Pathological type	Immunohistochemistry	EBV association	Genetic findings
Nondestructive	Plasmacytic hyperplasia	No diagnostic value	≈100%	None
	Infectious mononucleosis			
	Florid follicular hyperplasia			
Destructive	Polymorphic	B and T cells	>90%	Variable
	Monomorphic (B- and T/NK-cell types)	DLBCL	EBV+ and EBV−	Yes
	Classical Hodgkin lymphoma	CD20-CC30+	>90%	Yes

accompanying transplanted organ. Exposure to EBV begins early in infancy with peaks of EBV infection occurring between the ages of 2 and 4 and around the age of late adolescence and young adulthood. In developing countries, the majority of infants and young children are infected with EBV. In contrast, in developed countries, 50% of adolescents and young adults remain EBV seronegative. As many as 95% of middle-aged adults will be EBV seropositive in both developing and developed countries.

Among infants and young children, primary EBV infection usually is asymptomatic or results in nonspecific symptoms. In contrast, about 25% of adolescents and young adults experiencing primary EBV infection will develop the classical syndrome of infectious mononucleosis [4–6]. Subsequently, EBV establishes lifelong asymptomatic latent infection in majority of immunocompetent individuals after the resolution of primary infection. Among immunocompromised patients such as recipients of SOT or HSCT, clinical manifestations of EBV infection range from asymptomatic EBV DNAemia through classical syndrome of infectious mononucleosis and end-organ-specific disease to PTLD including true malignancies.

Terminologies to define conditions of EBV infection used in this chapter includes **EBV infection** defined by the presence of evidence of current or past EBV infection; **EBV disease defined by the presence of** symptomatic EBV infection typically with the presence of concurrent EBV DNAemia and/or EBV-infected cells in the tissue; **EBV positive (+) PTLD** with histopathological evidence of EBV, typically with positive EBV-encoded small RNAs (EBER) staining identified within PTLD specimen. **EBV-negative (−) PTLD** are those lesions without evidence of EBV.

EBV Infection and PTLD After SOT

In the SOT setting, EBV can frequently be transmitted through the graft, especially in EBV-mismatched (donor seropositive/recipient seronegative; D+/R−) organ recipients. Less frequently, transmission can also occur via non-leukoreduced

blood products. EBV can also be spread to EBV-naïve SOT recipients via saliva or sexual transmission, though this typically occurs beyond the first posttransplant year. Primary EBV infection after SOT is the major risk factor for EBV disease, persistent detection of EBV DNA in blood (DNAemia), and development of PTLD.

EBV disease not meeting the definition of PTLD may manifest as a nonspecific febrile illness, adenopathy/adenitis, hepatitis, or enteritis as well as involving other organs. Incidence of EBV disease exclusive of PTLD is reported as high as 15% after pediatric liver transplant in one study but has not been fully described in other organ recipients and adult cohorts potentially due to a lack of accepted definitions categorizing EBV disease not meeting the diagnostic criteria for PTLD.

The presence of EBV DNAemia typically precedes the development of EBV disease and PTLD; hence, measurement of EBV genome in blood by quantitative nucleic acid test (NAT) (e.g., PCR) has been the standard of care over last two decades [5]. The presence of a high or rising level of DNAemia in a patient with compatible symptoms is a sensitive predictor of the presence of EBV disease including PTLD; however, it cannot be used alone as a diagnostic marker for PTLD due to the lack of specificity [7].

The incidence of PTLD after SOT follows a bimodal distribution; early PTLD refers to PTLD occurring within the first 1 to 2 years after SOT; late-onset PTLD refers to PTLD occurring >1–2 years, typically between 5 and 15 years after SOT. The highest incidence of PTLD after SOT is seen in the first year after transplant, typically among EBV-mismatched (D+/R−) patients. The overall incidence of EBV + PTLD after SOT ranges from 1% to 20%. The majority of early PTLD have a polymorphic B-cell phenotype containing EBV genome, while late-onset PTLD may or may not be driven by EBV and are typically characterized by extra nodal disease, monomorphism, and worse prognosis. This is especially true among adults who were EBV seropositive prior to transplant [8–10]. The cumulative incidence of EBV-PTLD increases over time after transplantation [1]. Of note, recent studies have shown an approximately 50% decrease in the overall incidence of both EBV+ and EBV− PTLD in the 2000s as compared to the 1990s. This may be attributable at least in part to the EBV viral load monitoring to inform preemptive reduction in immunosuppression or preemptive use of the anti-CD20 monoclonal antibody rituximab and lowering the target levels of immunosuppressants [8, 11].

Risk Factors for PTLD After SOT

The risk of developing EBV-related disease is most significant in children. Pediatric SOT recipients, who are often EBV seronegative (R−) at the time of transplantation, are at least a tenfold higher risk of EBV-related complications including PTLD than their adult EBV seropositive counterparts. Of interest, some data suggests that young age (e.g., <1 year of age) adds to the risk in combination with EBV seronegativity though young age alone in EBV seropositive patients does not add to the risk for EBV-associated PTLD [12]. While at reduced risk, EBV seropositive SOT recipients (R+) experience 1–2% risk for PTLD at 10 years posttransplant [8]. While EBV-

Table 2 Cumulative 1-year and 5-year incidence of PTLD in pediatric and adult SOT recipients by transplanted organs, 2017 OPTN/SRTR annual report [13–16, 18]

Organ	Pediatric 1 year (%)	Pediatric 5 years (%)	Adult 1 year (%)	Adult 5 years (%)
Heart	1.2	4.0	0.2	1.1
Intestine	3.9[a]	6.9[a]	3.9[a]	6.9[a]
Kidney	0.9	1.8	0.2	0.6

Pancreas isolated	NA	NA	1.8	2.6

[a]Intestine only shows combined pediatric and adult data

PTLD account for the majority of these, EBV+ PTLD do occur in these seropositive SOT recipients, likely due to the reactivation of latently infected EBV or acquisition of a new EBV strain. Except for the receipt of an intestinal allograft, specific risk factors for the development of EBV+ PTLD in R+ patients have not been defined.

Besides EBV serostatus and recipient age, the incidence of PTLD varies according to several factors including the type of organ transplanted, which may, in fact, reflect differing levels of target immunosuppression and lymphoid load in different types of allograft. Generally, intestinal transplant recipients are at the highest risk (incidence up to 20%) for the development of PTLD, followed by lung recipients (6–10%). Recipients of pancreas (1–6%), heart (3–5%), and liver (2–3%) transplants are at moderate risk, while kidney transplant recipients are at relatively low risk (1–2%) (Table 2) [13–18]. PTLD lesions in SOT recipients are most often of recipient origin, though lesions that are limited to the graft occurring early after transplant are predominantly of donor origin.

Immunosuppression is an important risk factor for the development of PTLD. Among biologic therapies, lymphocyte-depleting agents such as OKT3 and rabbit anti-thymocyte globulin (ATG) have been historically associated with increased risk for PTLD, though some recent study, assessing the risk of usage of ATG, shows inconclusive results [19]. In contrast, the use of the anti-CD52 monoclonal antibody, alemtuzumab, has not appeared to change the risk of PTLD. Among other newer biologic agents, belatacept was associated with a higher incidence of EBV+ PTLD presenting predominantly as primary central nervous system (CNS) lymphoma observed in kidney recipients who were EBV seronegative (R−) prior to transplant [19]. This risk was significant enough to warrant a black box warning for its use in EBV-negative or EBV-unknown organ transplant recipients. The introduction of tacrolimus was associated with an increased incidence of PTLD which was felt to be attributable to its much higher potency compared to cyclosporine A. Despite the continued predominant use of tacrolimus, the incidence of PTLD, especially EBV+ and early PTLD, has been decreasing [11]. This may reflect learned experience with reducing tacrolimus dosing over time in response to lower maintenance targets or the presence of elevated or rising EBV load. The final class of immunosuppressants is the antiproliferative agents such as mycophenolate and sirolimus for which positive

effects against the development of PTLD have been observed for each of these agents in in vitro studies [20]. However, these potential beneficial effects have not been confirmed in clinical trials.

Attempts to quantify the risk associated with specific immunosuppressive agents used for induction or maintenance therapy have often led to inconsistent results though biologics as a class and the use of tacrolimus are of particular concern. As or more likely, the risk of PTLD attributable to these agents reflects their contributions to the net state of immunosuppression rather than a specific type of immunosuppressive agent that patients may be on. Indeed, the duration of immunosuppression is also an important risk factor for the development of late-onset PTLD as well as other malignancies, as demonstrated by the continuous increase of the cumulative incidence of PTLD over time. This observation highlights the need for studies to find ways to measure and ultimately optimize the intensity of long-term immunosuppression in individual patients.

The measurement of EBV DNA in the peripheral blood has been used as a marker of risk for EBV-associated PTLD since the 1990s. While the test typically performs well for its negative predictive value for EBV-associated PTLD, it lacks specificity. Sequential monitoring of SOT recipients has identified patients who develop persistently high degree of EBV DNAemia who have been defined as chronic high EBV load carriers. Retrospective studies have demonstrated a significantly high rate of late-onset EBV+ PTLD among these high-load carriers after pediatric heart transplantation although this was not observed in EBV high-load carriers who were recipients of other organs [21–24]. High-load carriers were more likely to be EBV seronegative prior to and experience primary EBV infection after transplant. They may develop their persistent high-load carrier state after either asymptomatic or symptomatic infection including PTLD. For the latter, the persistent EBV load may persist or recur after the resolution of clinical symptoms and findings of EBV and PTLD. Recognition of chronic high-load carriers with a potentially higher risk for PTLD has led physicians to decrease immunosuppression in response to high levels of EBV DNAemia. This may contribute to the recently decreased incidence of EBV+ PTLD among pediatric heart, liver as well as in other pediatric and adult transplant recipients [8, 11, 25].

EBV Infection and PTLD After HSCT

EBV disease and PTLD is a complication seen in allogeneic but not autologous stem cell recipients. The epidemiology of EBV disease and PTLD after allogeneic HSCT differs from that of SOT, reflecting the different biology associated with immunological reconstitution with donor blood cells following HSCT. EBV disease manifestations are similar to those seen in SOT recipients though the disease may progress rapidly [26]. In most cases, both the virus and the EBV-infected B cells in PTLD developing after HSCT originate from the donor. This is likely explained by the intense conditioning regimens used in HSCT recipients, which usually eradicates host immune cells including EBV-infected B cells. Therefore, in

contrast to SOT, EBV status of the recipient does not impact the risk for EBV+ PTLD after HSCT [2].

The reported incidence of EBV DNAemia ranges from 1% to 60%, while the overall incidence of PTLD after HSCT is less than 1%. However, the incidence may increase up to 8% among HSCT recipients with known risk factors such as T-cell depletion of the donor marrow, ATG use, unrelated or HLA-mismatched grafts, and age 50 years or older at HSCT and second HSCT [27]. As noted, PTLD is very rare following autologous BMT. Since cord blood does not contain EBV-infected B cells, it was first felt PTLD would not occur with this source of stem cells. However, the incidence of PTLD following cord blood transplant is similar to matched related donors, and may represent either EBV(−) PTLD or exposure and acquisition of EBV after the transplant [10].

Donor preparation strategies that specifically deplete T cells such as ATG confer a higher risk for PTLD compared to methods that deplete all lymphocyte types such as alemtuzumab and posttransplant cyclophosphamide. It is believed that depletion of both B and T lymphocytes from the donor lowers the risk of PTLD compared to those that only deplete T cells. The development of graft-versus-host disease (GVHD) does not appear to be a risk factor for PTLD, though the agents used to prevent and/or treat GVHD, such as anti-T cell antibodies do increase the risk of PTLD.

The time period of risk for PTLD after HSCT is relatively limited. EBV DNAemia may be initially recognized 3–4 weeks after HSCT; the majority of PTLD cases are diagnosed within 6 months with the peak incidence occurring in the third month posttransplant [27]. Elevation of EBV loads occurs when EBV-infected B cell proliferation precedes recovery of EBV-specific immunity. Elevation of EBV loads may persist while under immunosuppressive therapy which is often used up to 1 year after HSCT to suppress T-cell proliferation and their function. The risk of EBV disease and PTLD becomes lower once engraftment and functional recovery of immune cells are achieved.

Clinical Impacts on Transplantation

Disease Presentation and Spectrum

EBV infection and disease are caused by either primary infection, reactivation, or acquisition of a new EBV strain. The latter would only be known in the context of research studies. In SOT recipients, primary EBV infection is often derived from the donor allograft and tends to present with clinically significant symptoms, compared to frequently asymptomatic reactivation occurring among EBV seropositive recipients (R+). On the other hand, the majority of EBV disease and PTLD after HSCT is due to reactivation of donor-derived EBV transmitted by EBV-infected B cells. As noted earlier, the clinical spectrum of EBV infection ranges from asymptomatic infection to clinically significant and potentially life-threatening disease in recipients of SOT or HSCT. This includes the spectrum of PTLD ranging from an indolent self-

limited lymphoproliferation in a localized nodule to fulminant, disseminated disease [28].

Clinical symptoms attributed to EBV include nonspecific febrile illnesses seen with CMV or other viruses, the classic symptoms seen with infectious mononucleosis, those attributed to end-organ involvement, and symptoms associated with malignancy such as weight loss, night sweat, and prolonged low-grade fever. Infection with EBV has been associated with hemophagocytic lymphohistiocytosis (rare), the development of allograft rejection, GVHD, and opportunistic infections. The symptoms and physical findings of EBV disease meeting and not meeting criteria for PTLD may overlap, and the differences between those meeting criteria versus not may reflect histologic but also biologic differences within the EBV-infected and transformed B cells over a continuum. Recipients with a range of EBV clinical syndromes may present with fever alone, or in combination with lymphadenopathy (both superficial and deep), tonsillitis, splenomegaly, enteritis (bloody diarrhea), hepatitis (elevated liver function test and cholestasis), or pneumonitis (cough, increased work of breath). The CNS may also be involved as an isolated site (meningoencephalitis or PTLD) or as part of disseminated disease and is generally associated with very poor outcomes. From a laboratory perspective, patients may present with anemia, leukopenia, and thrombocytopenia as well as the markers of end-organ involvement noted above. While the presence of these findings in association with an elevated EBV load raises the suspicion for EBV disease and PTLD, their nonspecific nature requires definitive tissue diagnosis to confirm these diagnoses (see section "Diagnosis of EBV Disease and PTLD").

Outcome of PTLD After SOT and HSCT

PTLD has been a significant cause of mortality after SOT. Historically, the 1-year survival rate after diagnosis of PTLD was about 70% with 5-year survival rates as low as 50%. However, in more recent reports published using standardized therapies for PTLD including reduction of immunosuppression, rituximab (anti-CD20 monoclonal antibody), and chemotherapy, the 5-year overall survival rate is as high as 80% [29]. In addition to the direct effects of PTLD on patient survival, the presence of PTLD can also have a negative impact on graft survival. This is partially explained by factors resulting in an increased risk for graft damage including reduction of immunosuppression leading to rejection and toxicity from chemotherapeutic agents (see section "Management and Prevention of EBV Disease and PTLD").

Outcome of EBV+ PTLD after HSCT has been significantly improved over the last two decades. Mortality rates of PTLD were historically as high as 80% after HSCT. However, the use of preemptive rituximab and access to adoptive T-cell therapy significantly improved the overall survival rate, with rates as high as 90% now being reported [30]. However, it is important to note that unlike PTLD occurring in SOT recipients, the practice of diagnosing "probable" PTLD

(significant lymphadenopathy, hepatosplenomegaly, or other end-organ manifestations without tissue biopsy, together with significant EBV DNAemia) is more widely accepted and reflected in the management of PTLD after HSCT including the use of rituximab and/or adoptive T-cell therapy. While the survival rate reaches 90% for HSCT recipients with probable PTLD, rates of 60–70% are reported for those with proven PTLD.

Diagnosis of EBV Disease and PTLD

Approaches to the diagnosis of EBV infection and the classification of disease (from asymptomatic DNAemia to confirmed PTLD) involves several different tools, including serology, nucleic acid detection, cell-mediated immune responses, histologic examination, and radiographic imaging.

Serologic Testing

Assessment of EBV infection using antibody response is the oldest modality for detection. While useful in earlier decades, issues with sensitivity and specificity limit this diagnostic. It remains a critical part of the pretransplant assessment, allowing providers to determine risk based on the serologic status of donor and recipient. Antibody testing of recipient after transplant can be complicated by exposure to passive antibody from blood products including the administration of intravenous immunoglobulin, loss of titers in the face of protein-losing conditions, or blunted immune responses due to antilymphocyte-targeted therapies. Thus interpretation of EBV serology remains challenging, with some correlations (such as lack of anti-EBNA and the development of PTLD) not validated in larger cohorts [31]. Nucleic acid detection has replaced serology as the primary method for diagnosis and monitoring posttransplant.

Nucleic Acid Detection

The routine use of nucleic acid amplification and detection in the last two decades has led to dramatic improvement in the understanding and diagnosis of EBV infection and PTLD. While the initial description focused on pediatric SOT recipients [32], subsequent work has identified viral load monitoring as a key tool for HSCT, SOT, and other immunocompromised patient populations [33]. As data has accumulated on the correlation between elevated EBV loads and the development of PTLD, one of the primary challenges has been the interpretation of varying loads across different centers and reports. Rigorous study of standard samples revealed large differences between absolute values reported by various laboratories, as high as 3.3-fold in one study [34]. While these same data identified good reliability of loads

over time within single centers, the need for more standardization was clear. The establishment of the 1st WHO International Standard for Epstein-Barr virus for nucleic acid amplification has led to reduced interlaboratory variation, but the challenge of true international standard measurements is ongoing, and the implementation of the use of the standard is far from universal [35, 36]. Additional controversy remains regarding the appropriate sample for evaluation, as different studies have examined whole blood, peripheral blood cells, or plasma. While whole blood samples may have higher loads and become detectable earlier, plasma values may have more utility for detection of disease states like PTLD [7]. Examination of this dilemma continues. At a minimum, clinicians should understand what fluid compartment their lab is testing to ensure accurate comparisons over time.

A major challenge of viral load monitoring continues to be relevant breakpoints for the diagnosis of disease given diverse patient states and transplant types. While EBV loads have shown promise as a guide for preemptive therapies against PTLD [3], the performance of assays across centers and the standardization of these approaches continues to develop. Interpretation of loads in diagnosis is influenced strongly by serostatus prior to transplant, type of organ or HSCT, immune suppression, and prior EBV loads. There is clearly no universally applicable EBV load for the accurate prediction of EBV disease including PTLD in solid organ and stem cell transplant recipients. While patients with active disease and PTLD generally have elevated loads compared to those without disease, the sensitivity and specificity of this assertion have areas of weakness. Low or even negative serum loads do not rule out PTLD [33], highlighting that any EBV load measurement must be considered in the clinical context of the specific patient. At the other end of the spectrum, interpreting disease risk in specific patients with persistently elevated loads also is a challenge. These high-load carriers experience a dramatically different risk of PTLD across organ type and in HSCT versus SOT recipients. As an example, pediatric heart transplant high-load carriers have a relatively high rate of PTLD progression, while pediatric kidney recipients do not [21, 24]. As data accumulates regarding the risk of progression of these patients, more effective preventive therapies may be available.

Questions remain regarding adjunctive EBV loads in non-blood specimens. While prior studies had showed promise for the use of BAL and CSF specimens for diagnosis and monitoring of PTLD, further studies have yielded no clear evidence supporting their use by consensus guidelines [3].

Cell-Mediated Immune Responses

While EBV load measurement is a critical tool in diagnosis, data exists to suggest that simultaneous measurement of EBV-specific immune response would be a valuable parallel measure for the severity of infection and risk of PTLD. Smets and colleagues showed that the use of an EBV-specific T-cell ELISPOT assay correlated with EBV loads had a high predictive index for PTLD in pediatric liver transplant [37], suggesting that with the development of a standardized measure of

cellular immunity, PTLD prediction might be improved. While other reports on other laboratory techniques for assessing EBV immunity have been published [38], none have proved to be scalable to an international level. One of the simplest candidate measures was CD4+ T-cell numbers, which were shown to predict PTLD occurrence in a single center study [39]. However, few studies have examined individual markers in a multicenter trial or across SOT types or simultaneously with HSCT patients, so the utility of these observations remains low. Nonetheless further work on identifying adjunct biomarkers of cell-mediated immunity has promise for improving further diagnostics [40].

Tissue Histopathology

Histopathological examination remains the gold standard for PTLD diagnosis. Diagnostic endoscopy, bronchoscopy, cardiac catheterization, or interventional radiology biopsies are critical for the diagnosis of PTLD, and the importance of obtaining adequate specimen from suspicious masses cannot be overstated. Biopsy often helps to distinguish between rejection and PTLD, as well as infectious conditions and PTLD. Pathologic specimens also clarify the form of PTLD; whether the PTLD is polymorphic or monomorphic; which cell type is present within the PTLD, such as malignant lymphoma, Burkitt lymphoma, T/NK-cell lymphoma, plasmacytic lymphoma, smooth muscle tumor, and other rare forms (Table 1). Treatment regimens, response, and outcomes differ according to these different classifications. The prognostic factors for poor survival includes, but not limited to, advanced age, high performance status, elevated lactose dehydrogenase level, multifocal disease, monomorphic PTLD, and non-B-cell PTLD [41]. A key aspect of examination of tissue samples is screening for the presence of EBV genetic material. The most commonly used probe is RNA in situ hybridization targeting EBER. Examination of EBER+ cells in samples can distinguish which lymphocytes may be involved, while flow cytometry and CD20+ staining provides information on cell phenotypes and potential sensitivity to treatment agents such as rituximab. Biopsy specimens should undergo review by pathology staff with experience in the evaluation of EBV disease and transplant pathology. The WHO consensus definitions for the definition of PTLD [1] are a useful reference for these studies and should be used to classify any PTLD to clarify standard treatment algorithms.

Radiographic Imaging

Patients with suspicion for PTLD – whether based on symptoms or EBV load determination in specific patients – warrant radiologic evaluation for assessment of disease. While sonography can play a role in identifying potential sites of involvement, body imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is critical. Assessment of neck, chest, abdomen, and pelvis preferentially employs CT, and high-resolution thin-cut scans of the chest are the most useful

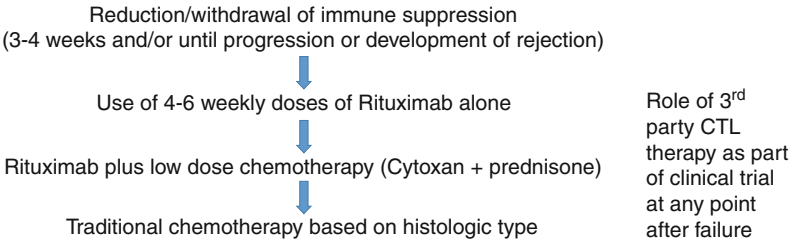
modality for identifying parenchymal lung nodules and mediastinal adenopathy. Examination of the central nervous system relies on MRI, and gadolinium enhancement can be useful in distinguishing between suppurative processes and PTLD. Many authors recommend evaluation of the brain along with the chest and abdomen in the staging and diagnosis of suspected PTLD, given the prognostic implications of CNS involvement. Musculoskeletal lesions – whether in the pelvis, spine, or extremities – are often best imaged with MRI as well.

The role of positron emission tomography (PET) scanning in the evaluation for EBV disease is evolving. The use of PET and PET/CT for the evaluation of solid tumors is well established and plays an increasing role in the diagnosis, staging, and follow-up of PTLD lesions [42]. The use of PET/CT has high specificity and sensitivity for diagnosis (estimated at ~90%) and can be useful for the follow-up evaluation of specific lesions. Given the overlap of infection and PTLD, care in the evaluation of PET images from patient should be taken to avoid confusion of presumed PTLD with sites of infection, as PET/CT is not as useful in diagnostic narrowing given the appearance of infectious states. PET as a guide for biopsy is a key use of this modality. Caution should always be exercised given the radiation exposure required for PET and PET/CT, which is higher than most other radiologic modalities.

Management and Prevention of EBV Disease and PTLD

The Management of EBV Disease Including PTLD

The optimal treatments for each of the components of the spectrum of EBV disease including PTLD have not been fully established. While substantial literature is available describing potential treatments and outcomes of patients meeting diagnostic criteria for PTLD in recipients of both SOT and HSCT, little experience has been published describing the approach to patients with EBV disease not meeting these criteria. While reduction of immunosuppression is generally accepted as the first step for the entire spectrum of EBV-associated disease, the role of additional therapeutic options is less clear. Potential treatment strategies vary according to factors including histological features, disease stage, localization of the tumor, and comorbid conditions. Even for patients with biopsy-confirmed EBV+ PTLD, much of the published literature is based on case series drawn from individual centers, though recent multicenter studies in adults have begun to better define optimal strategies and chemotherapeutic regimens for those who fail to respond to the reduction of immune suppression as well as those with concerning histologic findings (e.g., Burkitt Lymphoma). Treatment approaches are different for recipients of SOT compared to HSCT. While detailed recommendations describing specific chemotherapeutic regimens are beyond the scope of this chapter, the following sections will provide an overview of generally accepted stepwise approach primarily focused on the management of EBV+ PTLD in the two patient populations. An algorithmic approach to the management of EBV+ PTLD in SOT (pediatric and adult) and HSCT recipients is shown in Figs. 1, 2, and 3.



*Potential Exceptions to Standard Algorithm include: Burkitt PTLD, Hodgkin PTLD, T/NK cell lymphomas (monomorphic phenothpe), CNS PTLD and also plasmacytoma

Fig. 3 General algorithm for the treatment of EBV+ PTLD* in children and adults post-HSCT

EBV Disease and PTLD Treatment in SOT

Reduction of Immunosuppression

With few exceptions, the initial approach to managing patients with EBV disease including PTLD after SOT is reduction of immunosuppression whenever the graft function allows, or biopsy-proven histologic criteria do not warrant immediate progression to alternative therapies (e.g., rituximab or chemotherapy). The goal of reducing immunosuppression is to allow the patient to develop sufficient EBV-specific CTL function to control the EBV-driven proliferative process. The EBV section of the AST ID Guidelines recommends potentially using this approach for patients with non-Hodgkin lymphoma (NHL), but the Guideline specifically states that it has not been validated for some pathologic subtypes such as Burkitt and Hodgkin lymphomas and accordingly does not recommend this for theses classifications [3]. Having said this, the Guidelines do not provide specific recommendations on how much or which agent to reduce for individual patients receiving various immunosuppressive agents after undergoing different types of SOT but rather recommend reducing immune suppression to the lowest tolerated level for nearly all (early and late) B-cell PTLD in patients who do not have rapidly progressive disease. For some recipients, this might include complete withdrawal of immune suppression with such decisions often decided by center-specific protocols. Reported response rates for reducing immunosuppression vary greatly, ranging from 20% to 89% [43, 44]. In the absence of disease progression or development of rejection, most experts would recommend at least a 2–4-week trial of reduction or withdrawal of immune suppression prior to moving to more aggressive interventions.

Rituximab

Both the EBV section of the AST ID Guidelines and the IPTA-sponsored consensus conference on EBV and PTLD recommend the use of the anti-CD20 monoclonal antibody rituximab as the next step in the sequential approach to the management of EBV-associated PTLD for patients failing to respond to the reduction of immunosuppression. The use of rituximab (typically given as six weekly infusions) in this setting has been associated with an overall survival of 60–75% in pediatric SOT recipients [45]. Assessing the experience in adult SOT recipients is more challenging as clinical trials often include patient with both EBV+ and EBV− PTLD in whom response to rituximab monotherapy may differ by EBV status. Reported rates of response of PTLD to rituximab alone in adult SOT recipients have ranged from 25% to 60% [46, 47]. More recently, Trappe and colleagues conducted a phase II trial where patients initially received a 4-week course of rituximab with those achieving complete remission given four additional doses of rituximab at 3-week cycles, while those with evidence of progression were treated with CHOP – 25% of enrolled participants experiencing long-lasting remission without the use of chemotherapy. Again, the interpretation of these results may be impacted by the inclusion of both EBV+ and EBV− PTLD [29].

Chemotherapy

For pediatric SOT recipients, Gross et al. carried out a multicenter, phase II study using low-dose cyclophosphamide and prednisone every 3 weeks for six cycles for children with PTLD who failed to respond to the reduction or withdrawal of immune suppression, achieving an overall survival of 75% [48]. This was followed by a subsequent phase II study where rituximab was added to the low-dose chemotherapy regimen, and an 85% overall survival was achieved with fewer relapses compared to their earlier protocol with chemotherapy alone [49]. An interesting observation was that 75% of patients with radiographic evidence of persistent disease at completion of therapy achieved a complete remission at 1 year without any further therapy, suggesting a delayed immunologic effect of the rituximab and or CTL recovery. Of interest, the IPTA EBV PTLD Consensus Conference recommended this as the next sequential step for children with EBV-associated PTLD failing rituximab alone with progression to standard-dose chemotherapy for those failing this approach. However, data supporting the use of rituximab in combination with low-dose chemotherapy with Burkitt lymphoma-like PTLD are lacking. The Consensus Conference recommended direct progression to appropriate, standard-dose chemotherapy used for immunocompetent patients diagnosed with Hodgkin, T-cell, or plasmacytoma-like PTLD. No data are available assessing this approach in adult SOT recipients.

For adults failing rituximab or with aggressive PTLD forms, treatment with standard-dose chemotherapy is recommended. However, what the best chemotherapeutic regimen for the various EBV-driven PTLD phenotypes is less clear. Published reports on the treatment of PTLD in adults report complete remission rates ranging from 42% to 92% using a wide-range chemotherapeutic agents and combinations [7]. Of interest, once again, these reports typically included patients with both EBV+ and EBV− PTLD though the EBV status of the PTLD did not appear to impact response rates when evaluated. The EBV section of the AST ID Guidelines recommends the use of R-CHOP 21 for adult SOT recipients with CD20+ PTLD failing rituximab. They recommend the use of chemotherapy regimens used in immunocompetent patients with similar tumor phenotypes for patients with CD20 negative B-cell (including plasmablastic, plasma cell myeloma, plasmacytoma-like PTLD), T-cell, Hodgkin, and Burkitt lymphoma-like PTLD. Of concern, the use of traditional chemotherapy regimens in SOT recipients is associated with high rates of treatment-related morbidity and mortality compared to immunocompetent patients, with infectious sequelae an important contributor to both of these.

Additional Strategies

Radiation and surgery. The use of surgical resection or radiation for the treatment of PTLD has usually been limited to cases of isolated lesions or for debulking tumor burden at the time of making a diagnosis. Surgical intervention may also be required in fulminant cases when airway compromise is present due to mass effect or if gastrointestinal perforation has occurred. Since PTLD is most often a systemic disease, surgery alone is not likely to be successful long term. Radiation therapy is

most likely to be considered in the setting of CNS PTLD. A case series of 34 patients with CNS PTLD found a 5-year survival of approximately 50% with a reasonably high response rate to radiotherapy with or without concomitant treatments [50]. Though response to chemotherapy was less successful than radiotherapy, the authors still recommended that systemic chemotherapy should be considered for patients with CNS PTLD in the absence of systemic contraindications [51].

Antiviral agents and intravenous immunoglobulin. Historically, the antiviral agents, acyclovir and ganciclovir, have sometimes been used, with or without intravenous immune globulin (IVIG), in the treatment of EBV-associated PTLD. The rationale for the use of antivirals is that while latent virus-driven lymphoproliferation predominates in PTLD lesions, evidences of lytic virus gene and protein expression have been seen in some cases. However, evidence to support the use of antiviral agents (with/without immune globulin) in the absence of other interventions (e.g., reduction of immunosuppression or anti-CD20 therapy) is lacking. While some investigators have begun to explore strategies that utilize agents to induce the lytic cycle of EBV in combination with antiviral agents (e.g., arginine butyrate or bortezomib) [52, 53], evidence to date has not confirmed the effectiveness of this approach.

EBV-specific CTL therapy. As with recipients of HSCT (see below), the use of EBV-specific CTL therapy has been considered as a potential treatment for SOT recipients. While the generation and use of EBV-specific CTL therapy have been well established for HSCT recipients, this strategy has not been easily translated to SOT. This may be explained by the fact that most PTLD in SOT recipients are of recipient origin who develop EBV+ PTLD because of the lack of effective EBV-specific immunity under the presence of extrinsic immunosuppression. While some efforts using recipient cells which underwent ex vivo stimulation prior to infusion have been undertaken, limited published results to date have generally been disappointing [54]. Of interest, the use of third-party class 1 matched generated allogenic T cells coming from a donor bank for treatment of PTLD in SOT [43] demonstrated a response rate greater than 50% in patients with refractory PTLD [55]. At present, it would seem that the use of EBV-specific CTL therapy would best be carried out as part of formal clinical trials to confirm their effectiveness in SOT recipients. To that end, the Children's Oncology Group as well as a number of third-party commercial providers is currently planning or conducting studies to assess the effectiveness of this approach. Refer to Fig. 4 for an example of the method for generating EBV-specific T cells.

EBV Disease and PTLD Treatment in HSCT

Treatment of EBV in HSCT recipients includes any interventions use for patients with probable or proven EBV disease including PTLD. This includes those patients who fail preventive strategies (see below). Treatment strategies include the use of rituximab, reduction of immune suppression, EBV-specific CTL therapy, and chemotherapy. Per the ECIL Guidelines, reduction of immune suppression is defined as

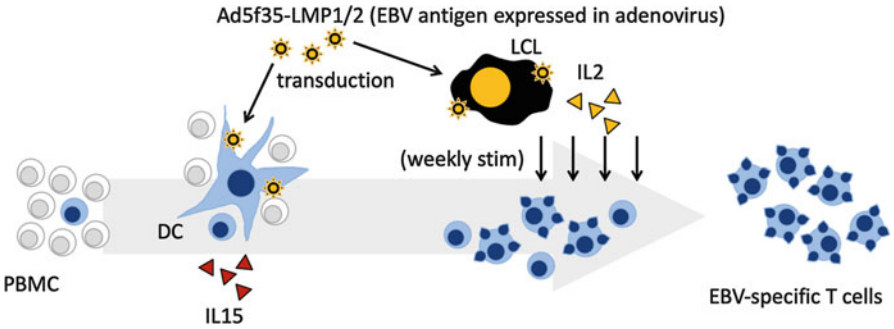

Fig. 4 Stepwise approach to cytotoxic EBV-specific T-cell creation, through the creation of lymphoblastoid cell lines (LCL) and dendritic cell (DC) stimulation of PBMC-harvested T cells, using a genetically modified adenovirus expressing EBV antigen (The authors acknowledge Dr. Catherine Bollard and Russell Cruz for developing and providing us with this figure)

a sustained decrease of at least 20% of the daily dose of immunosuppressants with the exception of low-dose corticosteroid therapy [2], and this strategy is combined with the other potential treatment options. The use of rituximab alone is associated with positive outcome in 65% of HSCT recipients treated for EBV+ PTLD. This rate rises to as high as 75% when rituximab is combined with reduced immune suppression, and the use of this combination is recommended by the ECIL when using rituximab to treat PTLD. The use of EBV-specific CTL therapy has positive outcomes in 68–85% of patients treated for EBV+ PTLD, with persistence of EBV-CTLs in vivo for up to 10 years with minimal toxicity including no significant GVHD [56]. While there are no published comparisons of these two treatment options, the limited availability of EBV-specific CTL therapy impacts the potential benefit of this approach compared to rituximab. The ESIL Guidelines recommend rituximab as the treatment of choice for probable or proven PTLD. Rituximab, in combination with reduced immune suppression, is given once weekly for up to four doses while monitoring EBV load in the peripheral blood. However, the presence of CNS involvement with EBV+ PTLD warrants consideration of initial use of chemotherapy with/without rituximab consistent with standard CNS lymphoma treatment protocols. For those failing to respond to rituximab plus reduction of immune suppression, the ESIL Guidelines recommend the use of EBV-specific CTL or, if not available, unselected donor lymphocyte infusions (DLI) to give a graft-versus-PTLD effect. Of note, a prior history of GVHD is typically considered as a contraindication to the use of DLI. More recently, the use of third-party EBV-specific CTLs may offer treatment options for HSCT recipients of cord blood transplants, with EBV-negative donors or when the donor is not available as a source of lymphocytes. Another potential use of third-party CTLs would be when there is not enough time to prepare EBV-specific CTLs from the donor due to rapid progression of EBV+ PTLD. Better response rates are noted with closer HLA matches, and no immediate or delayed toxicity using third-party EBV-CTLs has been described [55]. The use of chemotherapy with/without rituximab is recommended for those failing these second

options or if they are not available or if DLI is contraindicated. As with EBV+ PTLD after SOT, the use of antiviral therapy and/or IVIG is of unproven benefit and not recommended.

Prevention of EBV and PTLD

The impact of EBV-associated PTLD in children and adults undergoing SOT and HSCT has prompted interest in the prevention of EBV infection and its complication with a growing literature addressing the potential efficacy and impact of preventive strategies against EBV. However, published data derived from prospective randomized comparative trials are generally lacking, and most studies draw results and conclusions from either retrospective comparisons with historical controls or uncontrolled case series. While there is some overlap in the approach to prevention in SOT and HSCT recipients, major differences in the source of immune response (e.g., donor or recipient) and the competency of their immune systems to generate an adequate immune response over time lead to differing approaches and potential efficacies of strategies in the two populations. In general, potential prevention strategies against EBV can be categorized as immunoprophylaxis, chemoprophylaxis, or preemptive therapies initiated in response to the presence of or changes in quantitative measurement of EBV load in the peripheral blood (Table 3). In addition

Table 3 Preventive strategies against the development of EBV disease and PTLD for recipients of solid organ and stem cell transplantation
