Uncomplicated *P. falciparum* malaria should be treated with oral artemisinin-based combination therapy (ACT): a fixed-dose combination of an artemisinin (artemether, dihydroartemisinin, etc.) derivative with a longer-acting antimalarial drug that has a different mode of action (lumefantrine, piperaquine, etc.). Severe *P. falciparum* malaria cases and any complicated/severe malaria cases must be treated with intravenous artesunate (the fastest parasite-clearing drug) and managed in an intensive care setting. (Boxes 2, 3). If artesunate is not available, use artemether in preference to quinine for treating severe malaria in adults and children. If only parenteral quinine is available, it should be given with careful monitoring [54].

P. vivax and *P. ovale* infections transmitted by blood/organs do not need primaquine for radical cure, because hypnozoites develop only from vector-borne disease. Nevertheless, liver hypnozoites may remain dormant in the transplanted liver and may cause relapses in the recipient. A course of primaquine (avoided in glucose-6-phosphate dehydrogenase (G6PD)-deficient individuals) may need to be added to the antimalarial regimen in order to obtain a complete cure. Also, single dose of tafenoquine on day 1 or day 2 decreases the risk of *P. vivax* recurrence noninferior to primaquine [55, 56]. Tafenoquine as primaquine is restricted to patients with normal G6PD activity. No experience with tafenoquine has been published yet in transplant population.

Drug toxicity and drug interactions (antimalarial and immunosuppressive drugs) must be evaluated [6] (see Table 3):

- Chloroquine, quinine, mefloquine, piperaquine, and lumefantrine are cardiotoxic and may increase the risk of arrhythmia. Chloroquine and mefloquine could cause prolonged QT interval with calcineurin inhibitor co-administration.
- An increase in the concentration of calcineurin inhibitors has been observed with doxycycline, chloroquine, mefloquine, and primaquine. Elevated mTOR inhibitor levels have been described with doxycycline and mefloquine.
- Everolimus, tacrolimus, mycophenolic acid, and rapamycin have shown in vitro and animal model intrinsic antimalarial activity against *P. falciparum* and against both chloroquine-sensitive and chloroquine-resistant parasites [57].

Table 3 Interactions between antimalarial drugs and immunosuppressive drugs used in transplantation. (Adapted from Buchan and Kotton. Clin Transplant 2019 [59])

Malarial drugs	Calcineurin inhibitors	m-TOR inhibitors
Atovaquone-proguanil	No significant interactions	
Chloroquine	May ↑ cyclosporine levels Can interact with tacrolimus to prolong QT	Everolimus may increase chloroquine levels
Doxycycline	No significant interactions	
Hydroxychloroquine	May ↑ cyclosporine levels	
Mefloquine	Can interact with tacrolimus to prolong QT	Everolimus may increase mefloquine levels
Primaquine	May ↑ cyclosporine levels Can interact with tacrolimus to prolong QT	

Prevention in Travelers

Transplant candidates and recipients traveling to the tropics should be encouraged to consult specialists before their travel. Review of cohorts of transplant recipients shows that they tend to have minimal or suboptimal preparation prior to travel, with limited pre-travel vaccination, medication, and education [58]. Malaria remains one of the most serious infections for travelers to tropical countries. The majority of patients with severe malaria are tourists or VFR migrants acquiring the infection in West Africa. Malaria prevention is strongly recommended for SOT travelers to areas at risk [59]. Insect repellents (N,N-diethyl-D-methylbenzamide (DEET) or picaridin) together with long-lasting insecticide-impregnated bed nets and chemoprophylaxis when indicated are the cornerstone of preventing malaria when traveling. However, routine chemoprophylaxis is not recommended for recipients staying longer or living in endemic countries. Full guidelines on immunosuppressed patients and malaria prevention are provided by the CDC [1].

The recommendations for malaria chemoprophylaxis for transplant recipients are the same as for conventional travelers. Due to drug interactions, transplant recipients should consider starting malaria chemoprophylaxis at least several days prior to travel in order to monitor the concentration of immunosuppressive drugs in case of interactions (see interactions in the text).

Recommendations in the Transplantation Setting

Recommendations include screening potential donors and candidates who are at risk for malaria infection (migrants/travelers who have been in endemic areas in the last 3 years) using microscopy (thick and thin blood films), RDTs, and PCR-based techniques (microscopy alone is not considered to be sensitive enough) [6].

Infected Donors

Recommendations about the deferral period for malaria "infected donors" vary among regions and countries, based on endemicity, availability of donor screening, and the level of risk of malaria transmission that is to avoided [6].

In some transplant centers, the time of deferral is similar to blood donors.

But in other countries and regions, due to organ shortage and the possibility of efficacious therapy and strict follow-up, national guidelines allow transplantation if the donor was asymptomatic and malaria is not the cause of death.

In deceased donors, if malarial tests are positive and malaria is not the cause of death, organs could be accepted, and prompt start of malaria treatment should be initiated in the recipients. Close follow-up of the recipient after transplantation is advised.

For living donors, if there are signs of recent malaria, the organ may be accepted only if adequate testing has been performed and antimalarial treatment has been given. Confirmation of negative parasitemia after treatment (peripheral blood tests, RTDs, and molecular tests) is needed to accept the organ. Follow-up in the recipient after transplantation is advised.

Preemptive treatment of malaria for transplant recipients is not recommended. If the donor has arrived recently (up to 3 weeks) from a high-risk area for malaria, preemptive treatment may be considered as the donor may be infected, but parasites are not detectable in blood because they are multiplying in the liver (hepatic schizogony). Another situation where preemptive therapy has been used is in asymptomatic SOT recipients from a multiorgan donor who transmitted malaria to other recipients. Preemptive treatment should follow the same drug regimens, dose, and duration as the treatment of symptomatic disease.

Presumptive treatment without laboratory confirmation should be considered for urgent and severe patients with a high clinical suspicion of malaria if there are difficulties in obtaining prompt laboratory confirmation. This practice may lead to wrong treatment of the underlying disease and is only acceptable in exceptional circumstances.

An *infected recipient* must be diagnosed (by blood smear or RDT) as soon as possible, as an early treatment usually results in prompt and uneventful recovery.

Key Points

- Malaria infection has been reported both in solid organ and hematopoietic stem cell transplant recipients.
- Modes of acquisition could be donor-derived, transfusion-transmitted, reactivation of previous malaria episode, and de novo infection.
- In the different steps of the transplant process (pretransplant donor and candidate screening; blood, tissue, and organ selection; and during the follow-up period after transplantation), malaria infection must be excluded in those at epidemiological risk of malaria (migrants/travelers/residents who have been in endemic

areas in the last 3 years) and/or signs or symptoms suggestive of *Plasmodium* sp. infection.

- Screening must be performed with microscopy (thick and thin blood films), RDTs, and PCR-based techniques.
- High sensitivity laboratory techniques for diagnostic are recommended (PCR-based techniques) to detect asymptomatic, low, and mixed parasitemia.
- *P. vivax* and *P. ovale* infection could reoccur due to hypnozoite stage of these species in the liver.
- Pre-travel health advice is strongly recommended in SOT and HSCT recipients who are traveling to malaria-endemic areas.

Box 1 Definitions According to the WHO Malaria Terminology [5]

A *malaria case* is the occurrence of malaria infection in a person in whom the presence of malaria parasites in the blood has been confirmed by a diagnostic test

Submicroscopic malaria is a case with low-density blood-stage malaria infection that is not detected by conventional microscopy but could potentially be transmitted.

A *chronic case* is the long-term presence of parasitemia that is not causing acute or obvious illness but could potentially be transmitted.

Recrudescence is the recurrence of asexual parasitemia due to incomplete clearance of asexual parasites of the same genotype that caused the original illness after antimalarial treatment.

Relapse is attributed to activation of hypnozoites of *P. vivax* or *P. ovale* acquired previously. Hypnozoites can remain dormant in host hepatocytes for variable periods (3 weeks–1 year or longer), before activation and development into a preerythrocytic schizont.

Recurrence is the reappearance of asexual parasitemia after treatment, due to recrudescence, relapse, or a new infection.

Cure is the elimination from an infected person of all malaria parasites that caused the infection. When applied to *P. vivax* and *P. ovale* malaria, the term is equivalent to *radical cure* (elimination of both blood-stage and latent liver hypnozoites).

Drug resistance is the ability of a parasite strain to survive and/or multiply despite the absorption of a medicine given in doses equal to or higher than those usually recommended. Drug resistance arises as result of genetic changes that confer reduced susceptibility. There are alarming reports of reduced susceptibility of *P. falciparum* to artemisinin compounds in the Greater Mekong subregion.

Treatment failure is the inability to clear malarial parasitemia or prevent recrudescence after administration of a normally effective dose of antimalarial medicine, regardless of whether clinical symptoms are resolved. Drug failure may be due to deficient absorption, unusual rate of degradation, or excretion of the drug and resistance of the parasite.

Box 2 Treatment of Uncomplicated Malaria in Adults [52]

Treatment of uncomplicated malaria

If species differentiation is not available or unclear treat as *P. falciparum* malaria

P. falciparum

Artemether/lumefantrine: 1 tablet = 20 mg artemether/120 mg lumefantrine. Standard 3-day regimen: 1 dose at 0, 8, 24, 36, 48, 60 h. dose adjusted to weight: ≥35 kg = 4 tablets, for 6 doses, total 24 tablets ∗∗ ***or***

Dihydroartemisinin/piperaquine: 1 tablet = 40 mg dihydroartemisinin and 320 mg piperaquine. Standard 3-day regimen: 1 dose at 0, 24, and 48 h. dose adjusted to weight: ≥75 kg = 4 tablets, for 3 doses, total 12 tablets; 36–74 kg = 3 tablets, for 3 doses, total 9 tablets ***or***

Atovaquone/proguanil: 1 tablet = 250 mg atovaquone and 100 mg proguanil. Standard 3-day regimen: 1 dose at 0, 24, and 48 h. dose adjusted to weight: >40 kg = 4 tablets, for 3 doses, total 12 tablets. Very high treatment failure rates due to resistant *Plasmodium falciparum* parasites have been reported in the greater Mekong region. Prefer to treat with A/P.

P. vivax/P. ovale

Dihydroartemisinin/piperaquine: Standard 3-day regimen: 1 dose at 0, 24, and 48 h. more rapid parasite clearance compared to chloroquine. Preferred drug in *P. vivax* as treatment failure after CQ treatment has been reported in many countries from all over endemic areas ***or***

Atovaquone/proguanil: Standard 3-day regimen: 1 dose at 0, 24, and 48 h ***or***

Artemether/lumefantrine: Standard 3-day regimen: 1 dose at 0, 8, 24, 36, 48, and 60 h ***or***

Chloroquine (CQ): Tablets of chloroquine are commercialized as different chloroquine salts: 250 mg chloroquine diphosphate, 200 mg hydroxychloroquine sulfate, 200 mg hydroxychloroquine all three equivalent to 155 mg chloroquine base per tablet and 136 mg chloroquine sulfate equivalent to 100 mg chloroquine base per tablet. Standard 2–3-day regimen: First dose of 10 mg base/kg (600 mg for adult) at 0 h, followed by 3 doses of 5 mg base/kg at 6–12, 24, and 48–36 h ***followed by***

Primaquine: 1 tablet = 26.3 mg or 13.2 mg primaquine phosphate equivalent to primaquine base 15 or 7.5 mg. Standard 14-day regimen: 0.5 mg base/kg (max 30 mg)/day for 14 consecutive days for *P. vivax* is mostly recommended, but 0.75 mg/base is preferred in eastern Indonesia and Papua New Guinea 0.25 mg base/kg (max 15 mg)/day for 14 consecutive days is enough for *P. ovale*. Check for glucose-6-phosphate-dehydrogenase (G6PD) deficiency.

P. malariae

Long half-life drugs as CQ or DHA/PPQ are preferred over short-life drugs as A/L or A/P due to the longer erythrocytic cycle.

(continued)

Box 2 (continued)

Chloroquine: Standard 2–3-day regimen: First dose of 10 mg base/kg (600 mg for adult) at 0 h, followed by 3 doses of 5 mg base/kg at 6–12, 24, and 48–36 h ***or***

Dihydroartemisinin/piperaquine: Standard 3-day regimen: 1 dose at 0, 24, and 48 h ***or***

Artemether/lumefantrine: Standard 3-day regimen: 1 dose at 0, 8, 24, 36, 48, and 60 h ***or***

Atovaquone/proguanil: Standard 3-day regimen: 1 dose at 0, 24, and 48 h

P. knowlesi

Artemether/lumefantrine: Standard 3-day regimen: 1 dose at 0, 8, 24, 36, 48, and 60 h ***or***

Dihydroartemisinin/piperaquine: Standard 3-day regimen: 1 dose at 0, 24, and 48 h ***or***

Chloroquine: Standard 2–3-day regimen: First dose of 10 mg base/kg (600 mg for adult) at 0 h, followed by 3 doses of 5 mg base/kg at 6–12, 24, 48–36 h ***or***

Atovaquone/proguanil: Standard 3-day regimen: 1 dose at 0, 24, and 48 h

**Doses may need to be adjusted for liver and kidney function. Check dosing before prescribing*

**Some authors now recommend to extend the standard 3-day regimen by adding 4 additional doses at 72, 84, 96, and 108 h: total 10 doses (40 tablets) over 5 days in male European patients [60]

Box 3 Treatment of Severe Malaria in Adults [52]

Treatment of severe malaria∗

***P. falciparum* (*P. knowlesi*)**

First-line treatment artesunate i.v.: Adults and children >20 kg: 2.4 mg/kg. No dose adjustment in the case of hepatic or renal impairment.

Switch to oral therapy as soon as the patient tolerates oral medication (but not before completing at least 48 h of i.v. treatment) and give a complete course of: Artemether/lumefantrine ***or*** dihydroartemisinin/piperaquine or ∗atovaquone/proguanil. ∗*preferred drug if infection has been acquired in Southeast Asia (risk of artemisinin-resistant P. falciparum strains)*.

If the situation does not allow for switching to oral therapy, continue i.v. artesunate for a total of 7 days and ***add*** doxycycline i.v. (100 mg every 12 h for a total of 7 days) ***or*** clindamycin i.v. (10 mg/kg loading dose, followed by 5 mg/kg every 8 h for a total of 7 days)

2nd-line treatment quinine dihydrochloride salt i.v. drug is labeled with the mass of drug expressed in salt rather than base (the active drug). Quinine

(continued)

Box 3 (continued)
dihydrochloride is available as solution of various strengths in distilled water: 500 mg salt = 413 mg base in vials at 1 ml; 600 mg salt = 496 mg base in vials at 2 ml; 1000 mg salt = 826 mg base in vials at 2 ml; 1200 mg salt = 1000 mg base in vials at 5 ml: Loading dose (must not be used if patient received mefloquine within preceding 24 h) of 20 mg/kg over 4 h followed by 10 mg/kg over 4 h starting 8 h after initiation of treatment [alternately 7 mg/kg over 30 min followed by 10 mg/kg over 4 h directly after the loading dose] and followed by 10 mg/kg over 4 h every 8 h [alternately 4 h drug administration and 4 h drug free interval], max. Dosage 600 mg every 8 h. switch to oral medication as soon as possible (but not before completing at least 48 h of i.v. treatment) and give a complete course of*:* **Artemether/lumefantrine *or* dihydroartemisinin/piperaquine *or* atovaquone/proguanil *or* quinine sulfate p.o.** (10 mg salt (=8.3 mg base)/kg every 8 h (max. Dosage: 600–650 mg every 8 h) for a total of 7 days) ADD either **doxycycline p.o.** (100 mg every 12 h for a total of 7 days) ***or*** **clindamycin p.o.** (5 mg/kg every 8 h for a total of 7 days)

P. vivax

As in P. falciparum, followed by **primaquine** for eradication of the hypnozoites

[*]***Doses may need to be adjusted for liver and kidney function. Check dosing before prescribing***

Criteria for the definition of severe malaria*:*

- *Cerebral malaria: Impaired consciousness (somnolence, coma), convulsions*
- *Respiratory distress: Hypoxia, pulmonary edema, acute respiratory distress syndrome ARDS*
- *Renal failure: Urine output <400 ml/24 h in adults (children: <12 ml/kg/24 h) or serum creatinine >265 μmol/l [>3.0 mg/dl] despite adequate volume repletion*
- *Liver failure: ASAT or ALAT >3 times upper normal limit or jaundice/bilirubin >50 μmol/l [>3 mg/dl]*
- *Acidosis: Arterial pH <7.3, plasma bicarbonate <15 mmol/l, BE >8 mmol/l, hyperlactatemia or hyperkalemia >5.5 mmol/l*
- *Hypoglycemia: Blood glucose level <2.2 mmol/l. Shock-circulatory collapse (<90/60 mmHg) despite adequate volume repletion*
- *Severe anemia: Hemoglobin <80 g/dl*
- *Impaired coagulation: Spontaneous bleedings, disseminated intravascular coagulation (DIC)*
- *Hyperparasitemia: ≥2% in patients from malaria non-endemic regions, ≥5% in patients from and permanently living in a malaria holo−/hyperendemic region*

Adjunct treatment of severe malaria: *If patient is unconscious, monitor Glasgow Coma Scale and consider cranial CT and lumbar puncture to rule out meningitis.*

Corticosteroids and mannitol are contraindicated in adult patients with cerebral malaria and cranial hypertension. Both drugs prolong coma and worsen prognosis. The use of prophylactic anticonvulsants is contraindicated as their use is associated with increased mortality. If the patient is in shock, consider blood culture and empirical coverage for gram-negative sepsis. Limit fluid replacement to diuresis and compensation for perspiration/fever. Malaria patients are prone to fluid overload and pulmonary edema. A central venous catheter (monitoring of CVP) or a PiCCO catheter may facilitate guiding fluid management. Avoid NSARDs because of the associated renal toxicity and risk of renal failure. Acetaminophen/paracetamol 1gr every 6 h for 72 h has renoprotective effect in patients with severe malaria treated with i.v. artesunate. Consider physical measures to control hyperpyrexia. Exchange transfusion/erythrocytapheresis (automated ET). If the patient is treated with i.v. artesunate, there is no evidence for additional efficacy of exchange transfusion. Some specialist still opts for ET in the case of extreme hyperparasitemia (>30%). If the patient is treated with i.v. quinine (because artesunate is not available), consider ET in severe malaria cases presenting with a parasitemia > 10% and organ complications. Switching from parenteral to oral therapy is mostly possible around the fourth day, after stabilization of the patient (able to swallow, no vomiting) and once the parasitemia has fallen below 1%.

Introduction

Intestinal parasitic infections are an uncommon cause of diarrheal illness in transplant recipients in the United States. However, the frequency is higher in developing countries and places with poor sanitation because transmission primarily occurs via consumption of contaminated food or water. In a series of 60 renal transplant recipients in India, 20% tested positive by stool examination for *Cryptosporidium* spp., while 12% were positive for *Giardia* [1]; in the United States, the prevalence in similar cohorts is generally less than 1%. One meta-analysis demonstrated that *Cryptosporidium* spp. are by far the most common intestinal protozoans reported worldwide in transplant recipients, followed by *Blastocystis* spp., with *Giardia* spp. the third most common [2]. *Strongyloides stercoralis* is the most common intestinal helminth reported in this cohort, with only a few case reports of other helminths.

Increasing globalization and travel places transplant recipients at higher risk for intestinal parasites in several ways, including (1) acquiring de novo parasitic infections during posttransplant travel to developing settings; [3] (2) exposure to a close contact who became infected with an intestinal parasite during travel; or (3) living in/receiving a transplant in a highly endemic country, through de novo infection of the recipient or a donor-derived infection. Donor-derived intestinal parasitic infections are important considerations, especially given that patients infected with intestinal parasites are often asymptomatic and routine screening for them is not always performed. Intestinal or liver transplants are of particular concern for the transmission of intestinal parasites, and transmission of *Cryptosporidium* spp., *Giardia* spp., and *Cystoisospora belli* in this manner has been reported [4–7]. Finally, exposure in early life or subsequent travel to a highly endemic area prior to transplant can result in asymptomatic infection which can reactivate after transplant; this can even occur years after initial infection.

While many intestinal parasites are more prevalent in developing settings, others have a global distribution. For example, *Cryptosporidium* spp. are common worldwide, and *Giardia* spp. are frequently acquired from drinking contaminated stream water even in the United States. Furthermore, imported food products can be a source of domestic acquisition of an intestinal parasite, as has occurred repeatedly with imported produce-associated outbreaks of *Cyclospora*.

In some cases, intestinal parasitic infections cause more severe disease in transplant recipients than in immunocompetent hosts, including prolonged and severe diarrhea, dehydration, and malnutrition. In others, intestinal parasites can even cause extra-intestinal manifestations such as biliary, hepatic, or pulmonary disease.

Diagnosis and appropriate treatment of intestinal parasitic infections are often delayed, in part because the low prevalence of parasitic infections in the United

States leads to decreased clinical suspicion. In addition, many conventional diagnostic tests do not specifically evaluate for intestinal parasites and are often insensitive and nonspecific. Fortunately, the increasing availability of molecular diagnostics has improved the accuracy of the assays used for some of the intestinal protozoa (e.g., *Cryptosporidium* spp., *Giardia,* spp., and *Entamoeba histolytica*), but these panels remain far from comprehensive. Diagnostic delays may also stem from the nonspecific nature of the pathological findings seen on intestinal biopsies in transplant recipients infected with intestinal parasites, which can also resemble the findings of rejection or graft-versus-host disease (GVHD).

Intestinal Protozoa

Protozoa are unicellular eukaryotes which feed off other organisms and alternate between proliferative trophozoite and dormant cyst stages. Infections with most protozoa do not cause eosinophilia. Of note, microsporidia can cause intestinal disease in transplant recipients; however, although formerly classified as protozoa, microsporidia are now classified as fungi and are thus instead discussed in ► Chap. 46, "Management of Mucorales Infections in Transplant Patients."

Cryptosporidium spp.

Epidemiology

Cryptosporidium spp. are coccidian protozoan parasites that typically infect the small intestine. In developing countries this is the second most common infectious cause of diarrhea and malnutrition in children. *Cryptosporidium* spp. are distributed globally; though transmission is more common in tropical areas, outbreaks and sporadic cases are also frequent in the United States. *Cryptosporidium* spp. are spread by fecal-oral transmission. Typically, this occurs through ingestion of oocysts in contaminated water and occasionally food. A very small inoculum (only about 10–50 oocysts) is required for productive infection, and a single individual can shed billions of oocysts during the illness.

Immunocompromised hosts often shed *Cryptosporidium* oocysts for prolonged periods. Furthermore, oocysts can live in the environment for months and are resistant to some filtration systems and disinfectants, including chlorine and iodine [8]. Outbreaks among immunocompetent hosts commonly occur in the United States due to contaminated drinking water supplies, swimming pools, and daycare centers, with the most famous example being the 1993 *Cryptosporidium* outbreak in Milwaukee that sickened over 400,000 people due to contamination of the drinking water supply.

Additionally, unlike *Cyclospora cayetanensi*s and *Cystoisospora belli*, *Cryptosporidium* oocysts do not require incubation in the environment before becoming infectious but rather are excreted as mature cysts. This results in the capacity for direct transmission between hosts and contributes to the highly infectious nature of

Cryptosporidium spp. This has important implications for potential nosocomial spread, particularly given the large number of oocysts shed by ill individuals, the low required inoculum, and the environmental resistance of cysts to disinfection. Additionally, in the case of *C. hominis* (which predominantly infects humans), direct person-to-person transmission can occur. *C. parvum* is found in both humans and other mammals and can therefore also be spread from close contact with infected animals. Humans are also rarely infected with other species in the *Cryptosporidium* genus [9].

Cryptosporidium infection is best prevented through avoidance of contaminated water and food. This includes the avoidance of swallowing water from streams, lakes, or swimming pools, as well as safe food handling practices. While chlorine-resistant, *Cryptosporidium* can be killed by boiling or can be filtered by water filters with <1 micron-sized pores [10].

Clinical Presentation

The incubation period for *Cryptosporidium* spp. infection is typically 7–10 days; the clinical illness is largely the same for the different species in the genus. In immunocompetent individuals, *Cryptosporidium* infection typically causes a self-limited illness lasting 1–2 weeks consisting of watery diarrhea, abdominal pain, nausea, and vomiting. In immunocompromised hosts (best described in patients with HIV/AIDS), infection can cause a more prolonged and severe watery diarrhea with associated malabsorption and weight loss.

Extra-intestinal complications rarely occur and typically involve the biliary tract. As infection spreads up the biliary system, it can result in cholecystitis, cholangitis, and pancreatitis. Very rarely, *Cryptosporidium* has also been identified in respiratory secretions; while it is uncertain whether this represents pathogenic infection, *Cryptosporidium* is a postulated cause of respiratory disease in some immunocompromised patients. Finally, *Cryptosporidium hominis* (but not *C. parvum*) has also been associated with a reactive arthropathy [11–13].

Diagnosis

Classically, *Cryptosporidium* spp. are diagnosed by microscopic examination of stool specimens stained with a modified acid-fast stain, as the oocysts are partially acid-fast (Fig. 1). However, immunofluorescence microscopy appears to be a more sensitive and specific means of diagnosis via stool examinations. Stool antigen detection is also nearly as accurate as immunofluorescence microscopy (and superior to acid-fast examination). A modified acid-fast stain can also be used to evaluate for oocysts in biliary samples when there is a suspicion for biliary disease; notably stool samples can be negative for oocysts in such cases. Finally, although not a specific finding, stool specimens typically lack fecal leukocytes or blood in patients infected with *Cryptosporidium* spp. [14].

Although previously limited to research settings, stool polymerase chain reaction (PCR) assays are becoming more widely available and are the most sensitive means of diagnosing cryptosporidiosis. The commercially available BioFire FilmArray GI Panel evaluates for 22 of the most common pathogens responsible for diarrheal

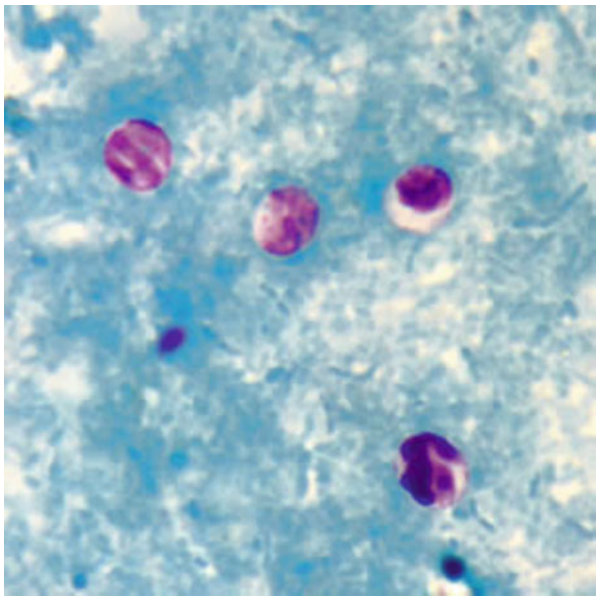

Fig. 1 Multiple small (4–6 μm) *Cryptosporidium* spp. oocysts stained red on modified acid-fast stain. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/cryptosporidiosis/index.html)

illness, including *Cryptosporidium* spp., and in one validation study had a sensitivity of 100% and specificity of >99% and can be performed in just 1 h [15]. The BD MAX Enteric Parasite Panel and the Luminex xTAG GI Pathogen Panel had slightly lower sensitivity and similar specificity values when compared to the BioFire assay (Table 1) [17].

Treatment

In immunocompetent hosts, *Cryptosporidium* infection is typically self-limited, and treatment is generally unnecessary. If antiparasitic treatment is considered, nitazoxanide is preferred; paromomycin is an alternative (Table 2) [18, 19]. However, the efficacy of antiparasitic therapy is uncertain. In some studies, treatment has resulted in an apparent clinical benefit; for example, in one RCT involving patients with diarrhea due to *Cryptosporidium* in Egypt, symptoms resolved after 7 days in 80% of patients treated with nitazoxanide compared to only 40% of patients who received placebo, and *Cryptosporidium* oocyst clearance was significantly faster in the nitazoxanide arm [20]. However, a Cochrane review found that neither nitazoxanide nor paromomycin treatment resulted in symptomatic improvement compared to placebo among patients with cryptosporidial diarrhea, although faster oocyst clearance was observed in some groups after treatment with nitazoxanide [21]. The side effects of these and other antiparasitic medications are outlined in Table 3.

In patients with HIV/AIDS, the mainstay of treatment is reconstitution of the immune system via antiretroviral therapy (ART). Antiparasitic treatment is also typically given to HIV-infected patients, and first-line therapy is nitazoxanide for 14 days, although the data supporting a clinical benefit are sparse.

Table 1 Diagnostic testing of protozoa infections

Protozoan	Microscopic stool examination	Trichrome or modified acid-fast stain recommended[a]	Stool Antigen	Serology	Peripheral Eosinophilia	Detected by BioFire FilmArray GI Panel	Detected by Luminex xTAG Gastrointestinal Pathogen Panel	Detected by BD MAX Enteric Parasite Panel

[b]Ag detection assays can also be used on stool, serum, or abscess material

Table 2 Treatment of intestinal protozoa infections. (Adapted from Kappagoda et al. [18] and Gilbert et al. [19])

Protozoan	Preferred regimens	Alternative regimens	Additional treatment regimens for transplant recipients
Cryptosporidium spp.	Consider Nitazoxanide 500mg PO BID for 3 days (not clearly superior to placebo)		1. Nitazoxanide 500–1000mg PO BID for 14 days *OR* 2. Nitazoxanide + azithromycin for 6–8 weeks *OR* 3. Paromomycin + azithromycin ~Decrease immunosuppression if possible
Cyclospora cayetanensis	TMP-SMX-DS 1 tab PO BID for 7–10 days	1. Ciprofloxacin 500mg PO BID for 7 days *OR* 2. Nitazoxanide 500 mg PO BID for 3 days (limited anecdotal success)	1. Consider increasing TMX-SMX-DS dose to 1 DS tab PO QID and/or increasing duration to 4 weeks ~Decrease immunosuppression if possible 2. Consider secondary prophylaxis with TMP-SMX 1 SS tab PO daily
Cystoisospora belli	TMP-SMX-DS 1 tab PO BID for 7–10 days	1. Pyrimethamine 50–75 mg PO daily (+ folinic acid 10–25 mg PO daily) for 3–4 weeks *OR* 2. Ciprofloxacin 500mg PO BID for 7 days	1. Consider increasing TMX-SMX-DS dose to 1 DS PO QID and/or increasing duration to 4 weeks. ~Decrease immunosuppression if possible 2. Consider secondary prophylaxis with TMP-SMX 1 SS tab PO daily
Giardia spp.	1. Tinidazole 2g PO single dose *OR* 2. Metronidazole 500mg PO TID for 5–7 days	1. Nitazoxanide 500mg PO BID for 3 days *OR* 2. Albendazole 400mg daily for 5 days	Consider combination therapy for refractory disease: 1. Metronidazole plus paromomycin *OR* 2. Albendazole plus metronidazole *OR* 3. Nitazoxanide plus a second agent

(continued)

Table 2 (continued)

Protozoan	Preferred regimens	Alternative regimens	Additional treatment regimens for transplant recipients
Blastocystis spp.	Identify and treat concomitant pathogens. Consider: 1. Metronidazole 500 mg PO TID for 10 days, *OR* 2. Tinidazole 2g PO once, *OR* 3. Nitazoxanide 500 mg PO TID for 3 days	1. Iodoquinol 650 mg PO TID for 20 days *OR* 2. TMP-SMX-DS 1 tab BID for 7 days *OR* 3. Paromomycin 8–12 mg/kg PO TID for 7 days	
Entamoeba histolytica – asymptomatic carrier	Luminal agent: 1. Paromomycin 8–12 mg/kg PO TID for 7 days *OR* 2. Iodoquinol 650 mg PO TID for 20 days	Diloxanide furoate 500 mg PO TID for 10 days	
Entamoeba histolytica – amebic colitis	1. Tinidazole 2 g PO daily for 3–5 days *OR* 2. Metronidazole 500–750 mg PO TID for 7–10 days followed by luminal agent (see above)	Nitazoxanide 500 mg PO BID for 3 days	
Entamoeba histolytica – amebic liver abscess or other disseminated disease	1. Tinidazole 2 g PO daily *OR* 2. Metronidazole 500–750 mg PO TID; length dependent on clinical response followed by luminal agent (see above)		
Dientamoeba fragilis	1. Iodoquinol 650 mg PO TID for 20 days *OR* 2. Paromomycin 8–12 mg/kg PO TID for 7 days	1. Metronidazole 500–750 mg PO TID for 10 days 2. Treatment failure: combination iodoquinol plus paromomycin or tetracycline. Search for and treat concomitant pinworm infection	
Balantidium coli	1. Tetracycline 500 mg PO QID for 10 days *OR* 2. Metronidazole 750 mg PO TID for 5 days	1. Iodoquinol 650 mg PO TID for 20 days *OR* 2. Nitazoxanide 500 mg PO BID for 3 days	

Abbreviations: *PO* oral administration, *BID* twice a day, *TMP-SMX* trimethoprim-sulfamethoxazole, *TID* three times a day, *QID* four times a day, *DS* double strength, *mg* milligrams, *kg* kilograms

Table 3 Common adverse effects of antiparasitic medications. (Adapted from Kappagoda et al. [18])

	Gastrointestinal adverse effects	Non-gastrointestinal adverse effects	Other considerations
Metronidazole	Nausea, anorexia	Metallic taste, myelosuppression, peripheral or optic neuropathy, seizures, disulfiram reaction if taken with alcohol	
Tinidazole	Nausea, anorexia	Metallic taste, peripheral neuropathy, disulfiram reaction	Similar to but better tolerated than metronidazole
Nitazoxanide	Nausea, vomiting, abdominal pain, diarrhea	Headache, yellow sclera	
Paromomycin	Nausea, vomiting, diarrhea, abdominal cramps	Nephrotoxicity or ototoxicity if intestinal absorption occurs (rare)	
Iodoquinol	Nausea, abdominal cramps	Acne, iododerma (papular/pustular rash), thyroid gland enlargement, optic neuritis or peripheral neuropathy	Use with caution in patients with liver or thyroid disease; contraindicated in patients with iodine intolerance. Currently unavailable commercially in the United States; may be available from Expert Compounding Pharmacy
Diloxanide	Nausea, vomiting, diarrhea, flatulence		Currently unavailable commercially in the United States; may be available from Expert Compounding Pharmacy
Albendazole	Nausea, vomiting, abdominal pain, hepatitis	Headache, myelosuppression, alopecia	Take with a fatty meal to improve absorption. Possible teratogenicity
Mebendazole	Nausea, vomiting, diarrhea		Possible teratogenicity. Currently unavailable commercially in the United States; may be available from Expert Compounding Pharmacy

(continued)

Table 3 (continued)

	Gastrointestinal adverse effects	Non-gastrointestinal adverse effects	Other considerations
Ivermectin	Nausea, vomiting, diarrhea, hepatitis	Dizziness	
Praziquantel	Abdominal pain, nausea, hepatitis	Mild dizziness, headache, rash	Reduce dose in patients with liver disease
Niclosamide	Nausea, vomiting, abdominal pain	Headache	Currently unavailable commercially in the United States; may be available from Expert Compounding Pharmacy
Pyrantel pamoate	Nausea, vomiting, abdominal pain, diarrhea	Headache, dizziness, rash	
Trimethoprim-sulfamethoxazole	Nausea, vomiting, diarrhea, pancreatitis	Myelosuppression, hemolysis with G6PD deficiency, renal injury, hyperkalemia and cardiac arrhythmias, rash	Should not be given to pregnant women in the first trimester or near term
Ciprofloxacin	Nausea, vomiting	Tendinopathy, neuropsychiatric symptoms, arrhythmias	Should not be taken with dairy products, antacids, multivitamins, or other substances containing divalent cations which inhibit absorption. Often avoided in pregnant women

Much of the practice regarding the treatment of *Cryptosporidium* infections in transplant recipients is based upon the experience with AIDS patients, where re-establishment of a functioning immune system is the cornerstone to successful therapy. In contrast, it is not usually possible to achieve this goal entirely in the transplant population. If possible, immunosuppression should be decreased. There are no clinical trials evaluating the efficacy of antiparasitic therapy in transplant recipients. However, given the severity of disease in this population, the challenges of reversing immunosuppression, and the evidence that antimicrobials may speed oocyst clearance, antiparasitic therapy is usually recommended for transplant recipients with cryptosporidiosis (typically with prolonged courses and combination therapy). Treatment options include nitazoxanide monotherapy for at least 14 days or either nitazoxanide or paromomycin combined with azithromycin (Table 2) [11, 22].

Cryptosporidiosis in Transplant Recipients

Overview

Cryptosporidium is the most common intestinal parasite diagnosed in transplant recipients. Despite likely underdiagnosis, the reported incidence of symptomatic cryptosporidiosis is higher in transplant recipients than that of the general population, and in some regions, *Cryptosporidium* spp. are implicated in a quarter of cases of infectious diarrhea in transplant recipients [11, 23–25]. *Cryptosporidium* has been identified in the stool of over half of renal transplant recipients with acute diarrhea in Pakistan (although coinfection with another gastrointestinal pathogen was present in 12.5% of these patients) [26].

Cryptosporidiosis can be mistaken for other causes of posttransplant diarrhea, including drug toxicity [27] and graft-versus-host disease (GVHD). Furthermore, transplant recipients with cryptosporidiosis are at risk for both more prolonged diarrhea and extra-intestinal complications than immunocompetent hosts.

Cryptosporidium as a GVHD Mimic

Cryptosporidium infection is recognized as a complication after HSCT and is a frequent mimic of GVHD or can occur contemporaneously with GVHD [28]. Pathologic findings in both GVHD and *Cryptosporidium* infection consist of inflammation and apoptosis of epithelial crypt cells. The presence of cysts in tissue specimens can confirm the diagnosis, but these are not always seen [29–33]. PCR is highly sensitive and can be helpful in determining the presence of this protozoal infection in this population [30, 31].

It is important to identify *Cryptosporidium* as a cause of diarrhea since management involves tapering immunosuppression along with antiparasitic treatment, in contrast to the increased immunosuppression that is typically employed in the treatment of GVHD.

Cryptosporidium and Renal Failure

Although *Cryptosporidium* has been reported after liver, pancreas, and heart transplants, the majority of cases reported in SOT recipients have occurred after kidney transplants. In one review of 47 cases of cryptosporidiosis in SOT recipients (41 of which were kidney transplants) in France, watery diarrhea occurred in most patients, but acute kidney injury also occurred in 15 (32%) of 47 cases. The median time from transplant to infection was 3.4 years, and the median time from symptom onset to diagnosis was 10 days (range 2–110 days); this report emphasizes the importance of maintaining a high index of suspicion for the possibility of cryptosporidiosis, even years after transplant [34].

Tacrolimus use seems to increase the risk of cryptosporidiosis compared to cyclosporine use among transplant recipients. Tacrolimus use also seems to predispose transplant recipients with cryptosporidiosis to a higher risk of graft dysfunction [11, 23, 35].

Small case-series have also suggested that higher rates of cryptosporidiosis are observed in non-transplant patients on hemodialysis compared to controls [36, 37]; it

is unclear whether this is due to a relative immunocompromised state, nosocomial acquisition, or other risk factors. Regardless, this highlights a potential role for screening for *Cryptosporidium* spp. prior to renal transplant.

Extra-intestinal Manifestations of *Cryptosporidium*

Cryptosporidium spp. can also cause several extra-intestinal manifestations, including cholangitis, pancreatitis, reactive arthritis, and pneumonia [38]. Although rare in immunocompetent hosts, extra-intestinal complications are more common in immunocompromised hosts. Biliary infection is the most common extra-intestinal manifestation and can lead to sclerosing cholangitis [39]. In a report of 47 cases of cryptosporidiosis in SOT recipients, 9% had extra-intestinal involvement (three with biliary involvement and one with pulmonary involvement), a higher rate than seen in immunocompetent patients [34]. Sclerosing cholangitis has also been repeatedly documented as a complication of cryptosporidiosis after liver transplant, particularly in children [40, 41]. The diagnosis of biliary involvement should be based not only on elevated liver enzymes but also upon radiographic evidence of biliary duct abnormalities. The biliary tree is a potential reservoir for *Cryptosporidium* spp., leading to late relapse; nitazoxanide is the preferred agent for biliary cryptosporidiosis, given its biliary excretion [11].

HSCT and *Cryptosporidium* in Hyper-IgM Syndrome (HIGM1)

Patients with hyper-IgM syndrome (and thereby CD40 ligand deficiency) are highly susceptible to recurrent and severe *Cryptosporidium* infections, often complicated by sclerosing cholangitis (along with other infections such as *Pneumocystis* pneumonia, histoplasmosis, and leishmaniasis). HSCT has been used as a curative treatment for HIGM1; however, immunosuppression after allogeneic HSCT itself poses a risk of infection, including from *Cryptosporidium* spp. Patients with HIGM1 have died after HSCT from severe cryptosporidiosis, and other patients have recovered from persistent, severe *C. parvum* infection after HSCT [42]. Another case report describes a child with CD40 ligand deficiency complicated by liver failure from sclerosing cholangitis secondary to *Cryptosporidium* infection who underwent successful liver transplant followed by HSCT with no recurrence of cryptosporidiosis [43].

Cyclospora cayetanensis

Epidemiology

Cyclospora cayetanensis is a coccidian protozoan that parasitizes the small intestine. *Cyclospora* is spread by fecal-oral transmission and has a worldwide distribution but is more common in Latin America, India, and Southeast Asia. Humans are the only known host. The organism is transmitted sporadically in the United States, where outbreaks have been associated with contaminated food often traced to produce imported from Latin America, such as contaminated raspberries, basil, lettuce, and cilantro [44]. In the United States, most cases are reported during the spring and summer months, and outbreaks have occurred

almost every year since the mid-1990s. Similar to *Cystoisospora* (but in contrast to *Cryptosporidium* spp.), oocysts shed in the stool must incubate in the environment for several days before becoming infectious, so direct human-to-human transmission does not occur. Additionally, cysts mature best under hot, humid conditions, so transmission is facilitated in the tropics and during warm, rainy months in temperate regions. *Cyclospora* is relatively resistant to chlorine, so public water supplies are susceptible to contamination [45].

Clinical Presentation

Patients infected with *Cyclospora* can be asymptomatic or can develop a self-limited illness in immunocompetent hosts. The infection is often more severe in young children or elderly adults. The median incubation period is seven (range 2–14) days. Though usually self-limited, a prolonged waxing and waning course can occur; in one series, the average duration of symptoms was >3 weeks, and in another, symptoms typically lasted 10–12 weeks. Common symptoms include watery diarrhea, nausea, flatulence, abdominal cramping, fever, and weight loss. Patients may develop steatorrhea secondary to malabsorption. In immunocompromised hosts, *Cyclospora* typically causes a chronic, watery diarrhea which can lead to dehydration and malnutrition; occasionally patients can also have mucus or blood in the stool. It can also mimic irritable bowel syndrome (IBS) [45]. Biliary disease is occasionally seen with *Cyclospora* infection, including acalculous cholecystitis in HIV/AIDS patients [46].

Diagnosis

PCR assays are a highly sensitive and specific method for detecting *Cyclospora* infection and are becoming more widely available. As with *Cryptosporidium*, *Cyclospora* is included in the commercially available BioFiire FilmArray GI Panel, and in one validation study, this assay had a sensitivity and specificity approaching 100% [15]. However, the Luminex xTAG and BD MAX panels do not include *Cyclospora* (Table 1). When PCR is not available, direct visualization with traditional laboratory techniques can be used. The diagnosis of cyclosporiasis is made by identifying oocysts on stool exams stained with a modified acid-fast stain; however, this technique is not sensitive, and multiple stool samples may be necessary in order to make a diagnosis. *Cyclospora* oocysts (diameter 8–10 microns) are round and partially acid-fast, similar in appearance to *Cryptosporidium* spp. oocysts (diameter 5 microns) which share these characteristics but are smaller (Fig. 2). Modified safranin staining or fluorescence microscopy is an alternative method that can be used to detect *Cyclospora* oocysts. There are no serologic assays for *Cyclospora* [14] (Table 1).

Treatment

Patients with symptomatic *Cyclospora* infections should be treated with antimicrobial therapy. First-line treatment for immunocompetent patients is with trimethoprim-sulfamethoxazole (TMP-SMX). One RCT of 40 expatriates in Nepal infected with *Cyclospora* reported that patients were clinically improved and

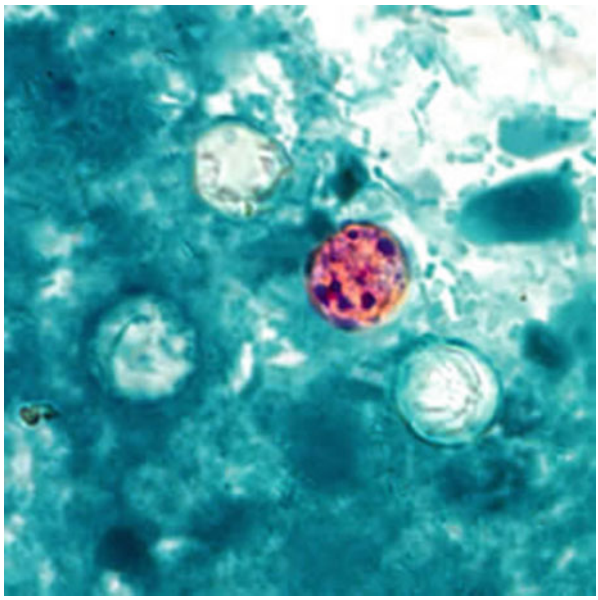

Fig. 2 Variable staining of only one of four *Cyclospora cayetanensis* oocysts (7.5–10 μm in size) on modified acid-fast stain. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/cyclosporiasis/index.html)

oocysts had become undetectable after 7 days of treatment in 94% of patients treated with TMP-SMX, compared to only 12% of patients in the placebo group [47].

Ciprofloxacin is also active against *Cyclospora*, although it appears to be inferior to TMP-SMX. In a small RCT of HIV-infected patients with cyclosporiasis, ciprofloxacin was compared to TMP-SMX. Over 95% patients who received TMP-SMX experienced resolution of diarrhea and clearance of oocysts after 7 days of therapy, compared to only 70% in the ciprofloxacin group [48]. Nitazoxanide is also an alternative, based on a study in which 71% of children infected with *Cyclospora* experienced clearance of oocysts from their stool after treatment with nitazoxanide [49] (Table 2).

Cyclospora in Transplant Recipients

Case reports suggest that infection with *Cyclospora* may be more severe and protracted in transplant recipients than in normal hosts [3, 50, 51]. One small outbreak of *Cyclospora* infection involved three individuals who traveled together to Indonesia and experienced acute diarrhea. Two of the individuals were immunocompetent and experienced 2–4 weeks of symptoms, which resolved without treatment. The third individual was a renal transplant recipient who was on tacrolimus, mycophenolic acid, and deflazacort; he developed protracted diarrhea lasting several months, lost 15 pounds of weight, and required two hospitalizations for dehydration. The patient did not respond to courses of ciprofloxacin or metronidazole, and his symptoms only resolved after treatment with TMP-SMX for 10 days [50]. Diarrhea lasting 2 months (associated with a 20-pound weight loss and multiple hospitalizations) was also observed in another renal transplant recipient who was infected with *Cyclospora*.

This patient improved after receiving 10 days of TMP-SMX [51]. In both cases, the diagnosis of *Cyclospora* was delayed and only made after colonoscopic biopsy revealed the parasite. Although there are few case reports involving *Cyclospora* in transplant recipients, these presentations support the idea that this cohort is more vulnerable to severe disease from this infection.

In immunosuppressed patients, higher doses and/or longer courses of antimicrobials may be needed to effectively treat cyclosporiasis, and reduction of immunosuppression is integral to successful treatment strategies. Most data come from the HIV/AIDS population; extrapolation to the transplant population is imperfect, but little primary data exist in the latter cohort. While most patients in one series of patients with HIV/AIDS who had cyclosporiasis initially responded to oral TMP-SMX therapy, recurrence was seen in 43% of cases within a month of the completion of therapy. The optimal dose and duration of TMP-SMX for immunosuppressed patients with cyclosporiasis are uncertain; after treatment, secondary prophylaxis with TMP-SMX should be considered to prevent relapse in those who remain substantially immunosuppressed (Table 2) [52].

Cystoisospora belli

Epidemiology

Cystoisospora (formerly *Isospora*) *belli* is a coccidian protozoan which parasitizes the small intestine. It is transmitted via the fecal-oral route, typically from consumption of contaminated food or water. While transmission occurs worldwide (including several outbreaks that have occurred in the United States), incidence is higher in developing settings and tropical and subtropical regions. Unlike *Cryptosporidium* and *Cyclospora* (which are commonly found in immunocompetent hosts as well), *Cystoisospora* is found mostly in immunocompromised individuals. Unlike *Cryptosporidium* spp. (but similar to *Cyclospora*), *Cystoisospora* oocysts require incubation in the environment in order to become infectious, so direct human-to-human transmission does not occur. However, oocysts can remain viable in the environment for months; institutional outbreaks have been reported related to contamination of the environment with oocysts. Sporadic cases among immunocompetent individuals are rare in the United States. Humans are the only known hosts for *C. belli* [9, 39].

Clinical Presentation

Many carriers of *C. belli* are asymptomatic. Among symptomatic individuals, the incubation period is typically 7–10 days, and symptoms in immunocompetent individuals include watery diarrhea with abdominal pain, nausea, vomiting, and weight loss. Fever is rare and extra-intestinal disease is very rare. More chronic cases occasionally occur and can mimic celiac sprue and irritable bowel syndrome or cause malabsorption [39]. While illness is self-limited in most immunocompetent individuals, immunocompromised patients are at particular risk for symptomatic and severe cystoisosporiasis.

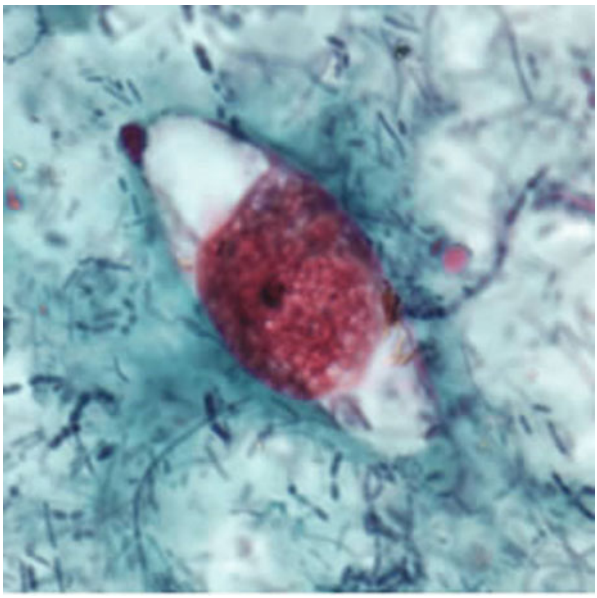

Fig. 3 Safranin stain of an immature *Cystoisospora belli* oocyst which is ellipsoidal containing a sporoblast and is much larger in size (25–30 μm) than the other intestinal coccidian oocysts. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/cystoisosporiasis/index.html)

Diagnosis

Diagnosis is traditionally made by identification of oocysts on stool examination stained with a modified acid-fast stain (or specific fluorescent techniques). *Cystoisospora* oocysts are elliptical and much larger (10–20 × 20–30 μm) than those of *Cryptosporidium and Cyclospora* (Fig. 3). PCR assays have been developed for detecting *Cystoisospora* DNA in stool samples, but they are not widely available and notably are not included in commercially available stool GI PCR panels; stool examination therefore remains the mainstay of diagnosis. In cases where intestinal biopsy is performed, histopathology classically shows mucosal atrophy, villous blunting, crypt hypertrophy, and lamina propria inflammation [14, 39]. Unlike most other protozoa (aside from *Dientamoeba fragilis*), *Cystoisospora* can also cause peripheral eosinophilia (Table 1).

Treatment

As with *Cryptosporidium* spp., infection with *Cystoisospora* is often self-limited in immunocompetent hosts and frequently resolves without treatment; when used, first-line treatment in immunocompetent patients is TMP-SMX (Table 2). Alternatives to TMP-SMX include ciprofloxacin or pyrimethamine (given with folinic acid), although these are considered second-line. In one small RCT of HIV-infected patients with *Cystoisospora*, symptom resolution and microbiologic cure were inferior among those patients treated with ciprofloxacin compared to those treated with TMP-SMX [48].

Immunocompromised patients infected with *Cystoisospora* should always be treated given the potential for severe disease. While there has been some success with short-course, twice-daily dosing regimens of TMP-SMX, the recommended

dose based on experience with HIV patients is one DS tab four times a day for up to 4 weeks. Secondary prophylaxis has been effective in decreasing the rate of recurrence in HIV-infected patients. In a trial of AIDS patients infected with *Cystoisospora*, secondary prophylaxis with TMP-SMX (one DS tab three times a week) or pyrimethamine/sulfadoxine (once weekly) was 100% effective in preventing recurrent diarrhea compared to a 50% recurrence rate in a placebo arm [53]. In HIV-infected patients with CD_4 counts <200, secondary prophylaxis is therefore recommended [54]. Although secondary prophylaxis has not been studied in the transplant population, extrapolation from consensus HIV guidelines and case reports of transplant patients suggests that secondary prophylaxis should be considered in such patients. In addition to antiparasitic medications, decreasing immunosuppression in transplant recipients when possible is another important component of the treatment of *Cystoisospora* infection and for preventing relapse [39].

Cystoisospora in Transplant Recipients

Cystoisospora can cause severe and recurrent disease in immunocompromised individuals and is a well-documented cause of prolonged diarrheal illness in patients with HIV/AIDS. Although uncommon, extra-intestinal cystoisosporiasis (such as cholecystitis and reactive arthritis) occurs in AIDS patients as well [55–57]. Although classically associated with HIV/AIDS, *Cystoisospora* infection causing prolonged diarrhea, weight loss, and recurrent infection has also been reported in patients with HTLV-1, non-Hodgkin's lymphoma, acute lymphoblastic leukemia, and thymoma [58–61].

There are two reported examples of suspected donor-derived infections of *Cystoisospora* in solid organ transplant recipients. In one case, infection occurred 1 month after intestinal transplant (both the donor and recipient were from a highly endemic region of northern Argentina). The recipient was treated with TMP-SMX four times daily for 10 days, then twice daily for 3 weeks, and then daily for 1 month with resolution of symptoms [7]. This case highlights the potential risk of donor-derived intestinal parasites with intestinal transplants [4, 5]. In another case, *Cystoisospora* organisms were incidentally found in the gallbladder of a combined liver-kidney donor. The recipient was treated with TMP-SMX four times a day for 10 days followed by twice daily for 3 weeks and did not develop clinical evidence of *Cystoisospora* infection [62].

Several other cases of cystoisosporiasis have been reported in liver and kidney transplant recipients, including three patients with a few weeks of diarrhea who had clinical and parasitologic response after just 7–10 days of TMP-SMX [63–65]. Another kidney transplant recipient presented with chronic diarrhea and was found to have both *Entamoeba histolytica* and *Salmonella enterica* serotype Typhi coinfections in addition to *C. belli*. This patient had persistent diarrhea despite treatment with both metronidazole and ciprofloxacin and only improved after receiving TMP-SMX [66], highlighting a failure of ciprofloxacin. Another case of cystoisosporiasis in a liver transplant recipient was treated with TMP-SMX at the low dose of one single strength tablet twice daily and experienced treatment failure [67].

Giardia spp.

Epidemiology

Giardia duodenalis (also known as *G. intestinalis* or as *G. lamblia*) is a protozoan flagellate which parasitizes the small intestine, causing both sporadic and epidemic diarrheal illness. Giardiasis is a water- and food-borne infection and an important cause of illness in international travelers. *Giardia* is found worldwide, although more commonly in developing settings with poor sanitation.

Giardia spp. have two morphological forms, cysts and trophozoites. Cysts are excreted in stool and can survive in moist environments for prolonged periods; they are the infectious form of the parasite. Trophozoites are pear-shaped, binucleate, multi-flagellated forms which are the active, invasive form of the parasite.

Infection occurs by fecal-oral transmission of cysts and in the United States is most often seen in outbreaks related to waterborne or daycare transmission, among international travelers, and in domestic hikers/campers exposed to contaminated water. Small mammals are common animal reservoirs and can maintain *Giardia* infection in the wild [9].

Giardia cysts are immediately infectious upon fecal excretion, so direct human-to-human transmission occurs, including via sexual transmission [68, 69]. *Giardia* is also resistant to chlorine, rendering waterborne transmission a major source of *Giardia* infection.

Humoral immunity is an important host defense against *Giardia* infection. Increased *Giardia* risk is associated with agammaglobulinemia, common variable immunodeficiency, and IgA deficiency. Although not well described in the literature, there is a theoretical increased risk of *Giardia* infection associated with medications that suppress humoral immunity.

Clinical Presentation

Half of individuals infected with *G. duodenalis* remain asymptomatic and clear of the infection; about 15% pass cysts while asymptomatic (sometimes for several months), and about 35% develop symptomatic infection. For this latter cohort, the incubation period averages 1–2 weeks, and acute infection with *Giardia* is classically characterized by foul-smelling diarrhea, bloating, flatulence, fatty (floating) stools, malaise, nausea, vomiting, and weight loss. Waxing and waning symptoms persist after the acute phase in half of symptomatic individuals and can last for months after clearance of the parasite due to acquired lactose intolerance and other etiologies. Chronic giardiasis can adversely affect growth and development in children, usually in the developing world.

Rarely, *Giardia* can cause biliary and pancreatic duct obstruction, leading to cholecystitis, cholangitis, pancreatitis, or granulomatous hepatitis. Hypersensitivity phenomena such as rash, urticaria, and reactive arthritis have also rarely been described in the setting of giardiasis. Previously infected individuals may report symptoms even years after effective treatment, sometimes leading to a diagnosis of irritable bowel syndrome [9, 13].

(Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/giardiasis/index.html)

Diagnosis

Direct microscopic examination of stool samples to detect cysts or trophozoites is the classical means of diagnosis for *Giardia* infections (Fig. 4). However, low sensitivity and the requirement for technical expertise are limitations of this method. Several different antigen detection assays are commercially available, including direct immunofluorescent assays (DFA), immunochromatographic assays, and enzyme-linked immunosorbent assays (ELISAs). In general, these methods are more sensitive and have faster turn-around times than conventional stool microscopy. Specificity and cost are usually comparable; many commercial stool assays test for both *Giardia* and *Cryptosporidium* simultaneously. After treatment, *Giardia* stool antigen tests may remain positive for a prolonged period due to shedding of killed parasites [14] (Table 1).

PCR assays have also been developed to detect *Giardia* in stool samples; while some remain research tools, three commercially available panels include *Giardia:* the BioFire FilmArray, the Luminex xTAG Gastrointestinal Pathogen Panel, and the BD MAX Enteric Parasite Panel (Table 1). These tests are highly sensitive and specific for *Giardia* [17].

Patients with giardiasis usually do not have peripheral leukocytosis nor eosinophilia. White cells in stool specimens are usually absent. Fecal fat excretion and other laboratory tests of malabsorption may remain abnormal for months or longer after infection.

Treatment

There are several options for treating giardiasis. A single 2-gram dose of tinidazole is the preferred regimen, with cure rates that exceed 90%. Alternatives include a 3-day

course of nitazoxanide or 5–7 day courses of metronidazole (Table 2). Alternatives also include quinacrine, furazolidone, albendazole, or paromomycin, all of which have slightly lower cure rates than tinidazole [70]. Secnidazole is a newer single-dose medication available for the treatment of giardiasis from the same drug class as tinidazole and metronidazole and is associated with cure rates of 80–100%.

For immunocompromised patients or those with recurrent or persistent symptoms (e.g., >1 week after completion of initial therapy) and persistent *Giardia* identified on stool studies, therapy with an agent from a different drug class or prolonged combination therapy should be considered, such as paromomycin + metronidazole, albendazole + metronidazole, or nitazoxanide + a second agent. Combination therapy can spare patients from the adverse effects associated with high doses or prolonged therapies of a single agent and target *Giardia* by different mechanisms with resultant increased potency. Several studies show that combination therapies have increased activity against *Giardia* in vitro and suggest that combinations of anti-*Giardia* medications can effectively treat cases of refractory giardiasis [71–75]. For prolonged symptoms, it is also important to consider the contribution of acquired lactase deficiency, which 20—40% of patients with giardiasis develop.

Giardia in Transplant Recipients

Giardia is an uncommon but well-recognized cause of diarrhea in both HSCT and SOT recipients. The incidence of *Giardia* as a cause of gastrointestinal illness in transplant recipients is largely dependent on the local prevalence; in one retrospective study in Brazil of 657 renal transplant recipients with diarrhea, only 3 patients (0.4%) had *Giardia*, while in a study of 150 renal transplant patients in Iran, 11 patients (7.4%) had *Giardia* [76, 77]. There is insufficient data regarding whether *Giardia* is more common in transplant recipients or whether prevalence in that cohort simply parallels the general population locally.

Diagnosis of giardiasis is frequently delayed as the infection is often initially misdiagnosed as GVHD, pretransplant mucosal injury from conditioning therapy, or other noninfectious causes of diarrhea [6, 78, 79]. The low sensitivity of stool examinations can also make diagnosis difficult, and cases are often diagnosed only when cysts or trophozoites are seen on intestinal biopsy, as has been described in multiple case reports involving transplant recipients [76, 78–80].

Donor-derived infection with *Giardia* from at least one pancreas-kidney donor to a recipient (who had no epidemiologic risk factors for *Giardia*) also highlights the need to consider this possibility in transplant recipients who do not otherwise have known risk factors for *Giardia* [6].

Blastocystis spp.

Epidemiology

Blastocystis spp. are found worldwide but are more common in developing countries where sanitation is poor; in some settings, nearly 100% of the population is infected. Although previously referred to as *Blastocystis hominis*, this parasite is now

classified into multiple subtypes, so the organism is now referred to as *Blastocystis* species instead. Transmission likely occurs via the fecal-oral route, and *Blastocystis* spp. infect both human and animal hosts; some evidence supports zoonotic transmission. Cysts do not require environmental incubation, so person-to-person transmission is theoretically possible.

Clinical Presentation

Blastocystis spp. infect the human cecum and colon, but there is conflicting evidence regarding whether *Blastocystis* is a true pathogen or is only a commensal organism that does not cause symptoms. When *Blastocystis* is detected in patients with gastrointestinal symptoms such as diarrhea, nausea, abdominal cramps, and flatulence, some studies have suggested that it is more likely a marker for another unidentified pathogen (oftentimes *Giardia*). However, there is increasing evidence supporting the pathogenic importance of *Blastocystis*. Most reports refuting the pathogenicity of *Blastocystis* cite similar prevalence of the organism in asymptomatic and symptomatic patients; however, these data do not necessarily rule out the pathogenicity and may simply reflect that not all infections with the organism are symptomatic – a characteristic that is true of several intestinal parasites including *Giardia*, *Cryptosporidium*, and others. Furthermore, studies suggest that different subtypes of *Blastocystis* may be associated with different risks of symptomatic infection. Most convincingly, several studies have demonstrated that treatment targeting this organism can result in both symptomatic cure and organism clearance; for example, in a RCT of 76 patients infected with *Blastocystis* alone, 88% of patients treated with metronidazole had resolution of symptoms, and 80% had clearance of oocysts, compared to 14% and 3%, respectively, in the placebo group [81, 82]. *Blastocystis* is therefore becoming increasingly recognized as a cause of symptomatic disease. Some studies have also suggested an association between *Blastocystis* infection and irritable bowel syndrome.

Diagnosis

Blastocystis spp. are traditionally diagnosed by identification of cysts on microscopic examination of stool (Fig. 5), although technical issues often render this difficult. Additional stains such as trichrome can assist in identification. Fecal leukocytes are generally absent. Some research PCR panels can detect *Blastocystis*, but these are not widely available (Table 1). Additionally, although *Blastocystis* itself likely causes GI symptoms, identification of *Blastocystis* should prompt evaluation for other intestinal pathogens.

Treatment

Patients with asymptomatic infection do not require treatment. When *Blastocystis* is thought to be pathogenic, a therapeutic trial is reasonable. First-line treatment options include metronidazole, single-dose tinidazole, or nitazoxanide, all based on placebo-controlled trials demonstrating symptomatic improvement and parasite clearance with these agents [82, 83]. Trimethoprim-sulfamethoxazole, paromomycin, and iodoquinol have also been associated with symptomatic improvement in small studies [81] (Table 2).

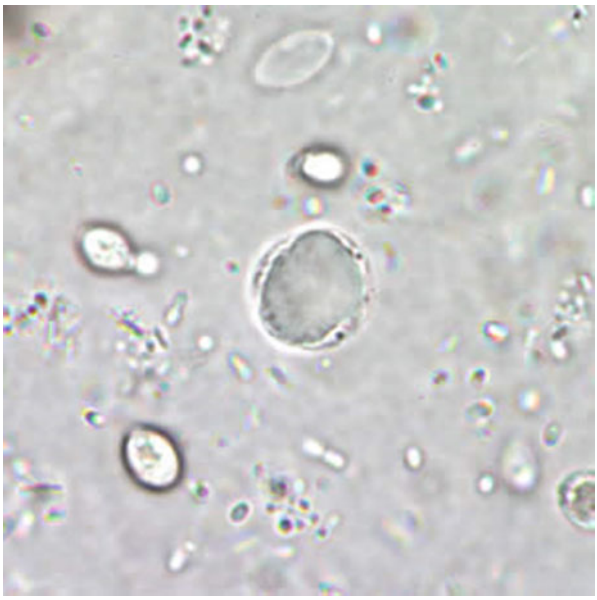

Fig. 5 Cyst-like forms of *Blastocystis* spp. on wet mount with central vacuole and multiple peripheral nuclei. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/blastocystis/index.html)

Blastocystis in Transplant Recipients

As with normal hosts, the pathologic significance of this organism in transplant recipients is often unclear and should prompt investigation for other infections. However, a handful of small cohort studies have shown that immunocompromised states (such as HIV infection, corticosteroid use, hematologic malignancy, and transplant) are associated with an increased risk of both *Blastocystis* infection and of such infections being symptomatic [84–87]. It is therefore reasonable to consider this as a possible infectious cause of diarrheal illness in transplant recipients that requires treatment, particularly if workup for other infections is negative. There have been a few reported cases of *Blastocystis*-associated diarrheal illness in transplant recipients, and in most such cases, GI symptoms and oocyst clearance were achieved after treatment with metronidazole (although in one patient, several weeks of metronidazole were required in order to achieve oocyst clearance and symptom response) [81, 84, 88, 89].

Entamoeba histolytica

Epidemiology

Entamoeba histolytica is a protozoan parasite that is a leading cause of diarrheal disease worldwide, particularly in developing countries where sanitation is poor. Globally, millions of people are infected with *E. histolytica*, with 55,000 deaths annually attributable to this parasite [90]. In developed countries, *E. histolytica* is seen mostly in institutionalized patients, homosexuals, and as an uncommon cause

of traveler's diarrhea, usually occurring in those who have spent weeks to months traveling. The parasite exists in a cyst stage (the metabolically less active but infectious form) and a trophozoite stage (the metabolically active form which causes invasive disease). Infection occurs by fecal-oral transmission via cysts in contaminated food or water. Cysts do not require environmental incubation and can also be sexually transmitted via fecal-oral contact [68, 69, 91]. Cysts can survive in the environment for weeks to months and are relatively resistant to chlorine but are susceptible to iodine.

Clinical Presentation

Infection with *E. histolytica* can lead to a wide spectrum of clinical presentations, including asymptomatic infection (90% of cases), mild diarrhea, dysentery, and toxic megacolon.

E. histolytica has tropism for the colon, and stools are often bloody. Malnutrition and weight loss occur in about half of cases, and about a third have fever. Patients who are very young, pregnant, immunosuppressed, malnourished, or alcoholic appear to be at higher risk for more severe disease. Amebiasis typically has a subacute onset, often over 1–3 weeks. Occasionally infection can result in chronic diarrhea mimicking IBS.

E. histolytica causes inflammation of the colon and can progress to fulminant colitis; a common complication is the formation of characteristic "flask-shaped ulcers" which can bleed or perforate. Fulminant colitis can also progress to toxic megacolon which has a high mortality rate. The formation of "amebomas" (intestinal masses caused by *E. histolytica* which can mimic a colonic neoplasm or appendicitis) is another possible complication of amebiasis.

E. histolytica infection can also lead to extra-intestinal complications, with the most common being liver abscesses. Amebic liver abscesses (ALA) are ten times more common in men than women, often in young adults and children; other risk factors include alcoholism, diabetes, pregnancy, malignancy, and corticosteroid use. Amebic liver abscesses typically cause fever and right upper quadrant abdominal pain, often without associated diarrhea. Hepatic dissemination can occur years after initial infection which is why remote exposures are still significant and even asymptomatic luminal disease should be treated (see below). Amebic liver abscesses are typically single lesions in the right hepatic lobe and have a classic "anchovy paste" appearance of necrotic debris on aspiration. Rarely hepatic abscesses can also rupture into the lung or pericardium [13, 39]. Leukocytosis is common, but eosinophilia does not occur and should prompt consideration of other diagnoses. Clinically, ALAs can be difficult to distinguish from pyogenic liver abscesses. Very rarely, *E. histolytica* can disseminate to the brain, skin, or other organs [13, 90].

Diagnosis

Available techniques for the diagnosis of amebiasis include nucleic acid detection, antigen detection, microscopy, and serology. When performed, colonoscopy can also aid in the diagnosis; colonoscopy can show flask-shaped ulcers grossly, a necrotic

ulcer base with surrounding minimal inflammation, and occasionally cysts or trophozoites microscopically.

PCR assays are the most sensitive and specific tests and can be performed on stool or other specimens (such as liver abscess fluid). PCR is highly specific and is 100 times more sensitive than fecal antigen tests [92]. PCR is also species-specific, detecting only *E. histolytica*, but not other nonpathogenic *Entamoeba* spp. Three commercially available panels (BioFire FilmArray, Luminex xTAG Gastrointestinal Pathogen Panel, and the BD MAX Enteric Parasite Panel) include assays for *E. histolytica* (Table 1). However, validation studies of sensitivity and specificity for BioFire and BD MAX were limited by low prevalence in the study setting [15, 16]. Luminex xTAG sensitivity was 100% and specificity was >99% [17].

Antigen detection assays are relatively easy to perform and are more sensitive and specific than stool microscopy but are still less sensitive than PCR. These assays are specific for *E. histolytica* and are not falsely positive in patients infected with nonpathogenic species such as *Entamoeba dispar*. Unlike serologic assays, they indicate active infection (not just prior exposure), which renders them useful in highly endemic areas. They can be performed on stool, serum, or liver abscess material [92].

Diagnosis of intestinal amebiasis was traditionally made by examination of stool specimens, but this method requires considerable expertise and is both insensitive and nonspecific. Examinations of wet mounts or stool stained with iron-hematoxylin or trichrome can be done to facilitate visualization of cysts or trophozoites (Fig. 6). However, several nonpathogenic *Entamoeba* species (*E. dispar*, *E. moshkovskii*, *E. bangladeshi*) are morphologically indistinguishable from *E. histolytica*. The finding of RBCs ingested within the cytoplasm of amebae suggests pathogenicity

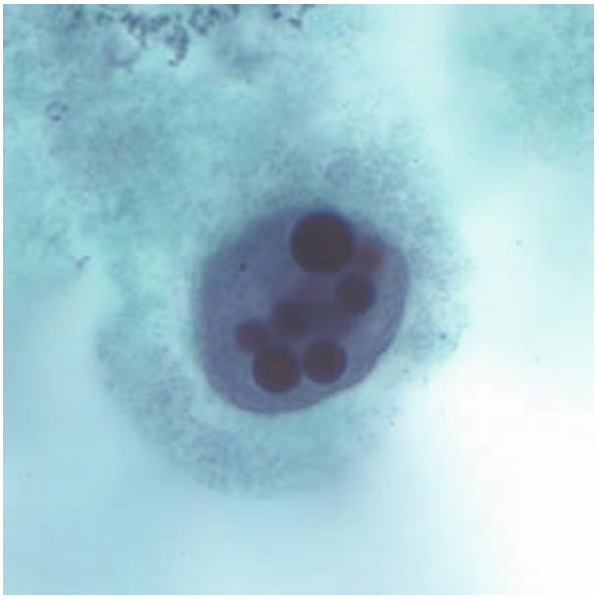

Fig. 6 Trichrome stain of *Entamoeba histolytica* containing multiple ingested dark erythrocytes. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/amebiasis/index.html)

and *E. histolytica* infection, although this finding is not entirely pathognomonic and can also be seen with *E. dispar*. In addition, WBCs are often absent in the stool of patients with *E. histolytica*, as the WBCs are destroyed by the trophozoites.

IgG antibodies against *E. histolytica* typically become detectable 5–7 days after infection and persist for years. However, serology is less useful for the diagnosis of acute intestinal disease because the sensitivity is not high early after infection, and a positive test is not specific for recent infection (as this can also indicate prior exposure). That said, serology can be helpful in travelers who live in developed countries with low epidemiologic risk of prior exposure. The sensitivity of serology is excellent in patients with amebic liver abscesses, rendering the negative predictive value in this clinical scenario quite high. Of note, *E. dispar* and other nonpathogenic species do not induce antibody development. Importantly, serologic assays can be falsely negative in immunosuppressed patients [92] (Table 1).

Treatment

All patients infected with *E. histolytica* should be treated with antimicrobials, including asymptomatic carriers because of the risks of subsequent invasive disease and of transmission to others. Different antimicrobials are required for treatment of the trophozoite (invasive) and cyst (luminal/infectious) forms of *E. histolytica*. Treatment of amebic colitis is with either tinidazole or metronidazole to kill the trophozoites; tinidazole is generally better tolerated (Table 2). Nitazoxanide might be an alternative to these agents, with high cure rates in a limited number of studies. To eradicate the luminal cyst forms, this course is followed by treatment with paromomycin; diloxanide and iodoquinol are alternatives but are not commercially available in the United States (except possibly from compounding pharmacies). Paromomycin commonly causes gastrointestinal side effects and so should not be started until after treatment with the anti-trophozoite agent is complete. Patients with amebic liver abscesses (and other forms of extra-intestinal amebiasis) are treated with the same agents, although often with longer courses; liver abscesses sometimes require drainage (e.g., those that are especially large, impending rupture, or responding poorly to medical therapy), although less commonly than with pyogenic liver abscesses. Patients who are asymptomatic cyst carriers only require treatment with a luminal agent such as paromomycin [90] (Table 2).

E. histolytica in Transplant Recipients

Although data are limited, immunosuppression may increase the risk for severe colitis from *E. histolytica* infection; one review described 24 cases of fulminant amebic colitis in patients who had all been exposed to corticosteroids. Although the rate of fulminant colitis in patients exposed to steroids or other forms of immunosuppression was not compared to immunocompetent patients, the majority of patients in this study received high-dose corticosteroids before they developed new or worsening symptoms, suggesting that the steroids contributed to the severity of the infection. All of the patients were given steroids due to an initial misdiagnosis of another cause of colitis or for another condition [93]. The clinical course of these patients varied from rapid clinical improvement in response to antiparasitic treatment

to prolonged diarrhea and even death in one patient [94–97]. Given the paucity of data regarding *E. histolytica* infection in transplant patients, it is unclear whether this cohort is at increased risk of severe infection. However, this review highlights the potential risk of adverse outcomes when patients with amebic colitis are treated with steroids, along with the potential pitfall of misdiagnosis of GVHD.

Data regarding the risk of extra-intestinal amebiasis in transplant recipients are even more scant. Extrapolating from another immunosuppressed population, there does not appear to be an increased risk of *E. histolytica* acquisition or extra-intestinal disease in HIV-infected patients [98].

Dientamoeba fragilis

Epidemiology

Dientamoeba fragilis is an intestinal protozoan flagellate that has a worldwide distribution, although it is more common in children and in developing countries. The organism infects the colon and is presumably spread by the fecal-oral route (although this has not yet been definitively determined), with incidence higher in areas with poor sanitation. *Enterobius vermicularis* (pinworm) has also been implicated as a possible transmission vector. Although *D. fragilis* infection can occur in the absence of pinworm, infection with pinworms may facilitate *D. fragilis* infection; therefore, identification and treatment of both infections may be necessary for cure [99, 100].

Clinical Presentation

As with *Blastocystis*, there are conflicting data regarding whether *D. fragilis* can cause symptomatic infection or is just a nonpathogenic colonizer. However, mounting evidence suggests that there is likely a spectrum of disease ranging from an asymptomatic carrier state to acute or chronic diarrheal illness. Intermittent diarrhea, abdominal discomfort, and fatigue are the most common symptoms. Associated symptoms can also include anorexia, weight loss, and nausea. Along with *Cystoisospora belli*, *Dientamoeba fragilis* is one of the few protozoa that can cause peripheral eosinophilia, which is reported in about half of infected patients; *D. fragilis* has also been identified as a cause of eosinophilic colitis [99, 100].

Diagnosis

Dientamoebiasis is traditionally diagnosed by stool examination. Cysts are rarely identified, and the trophozoite stage degrades after just 24–48 h outside the human body. Stool samples must therefore be quickly and carefully fixed and stained (e.g., with trichrome) to detect the fragile trophozoites (Fig. 7). Furthermore, stool concentration methods destroy the trophozoite, which is undetectable by these means. Overall, stool examinations are not sensitive for the diagnosis of *D. fragilis* [100]. Stool PCR assays for *D. fragilis* are the most sensitive and specific assays available, but this organism is not included in most commercially available GI PCR panels

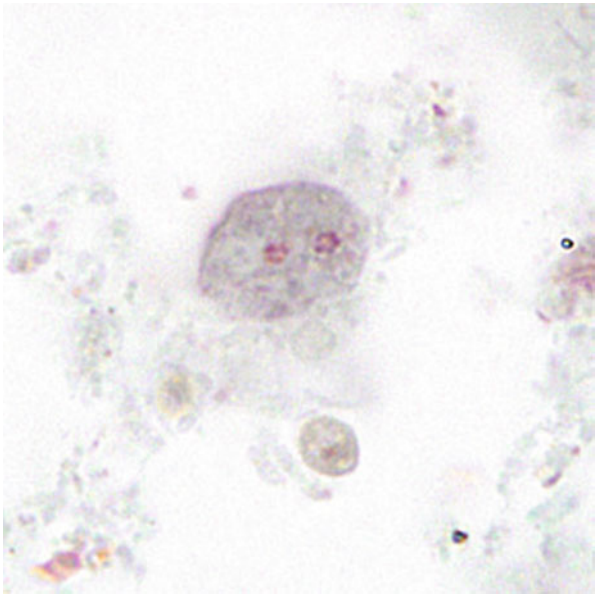

Fig. 7 Trichrome stain of the binucleate trophozoite of *Dientamoeba fragilis.* (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/dientamoeba/index.html)

including the BioFire FilmArray GI Panel. Furthermore, there is also a risk of false-positive results due to cross-reactivity with other trichomonada such as *Chilomastix mesnili*, a nonpathogenic intestinal protozoa [101] (Table 1).

Treatment

When *D. fragilis* is identified and considered etiologic in symptomatic patients, treatment options include paromomycin, iodoquinol, or metronidazole (Table 2). Secnidazole or ornidazole has also shown efficacy in single studies [100]. Treatment with paromomycin appears to result in reliable parasite clearance and symptom resolution; in one study, 98% of patients infected with *D. fragilis* who received paromomycin experienced clearance of the parasite, compared to a 41% clearance rate in patients who were not treated and a 57% clearance rate in patients treated with metronidazole [102].

Additionally, *D. fragilis* infection is frequently associated with (and perpetuated by) pinworm infection. Therefore, testing and treating for *E. vermicularis* are recommended in patients infected with *D. fragilis*.

D. fragilis in Transplant Recipients

There is minimal published literature that addresses *D. fragilis* infection in transplant recipients, aside from reports that simply describe the occasional identification of this organism in stool samples of immunocompromised patients [103]. One study in Argentina compared stool samples of 82 asymptomatic HIV-positive patients to 300 asymptomatic HIV-uninfected patients; the patients infected with HIV had higher rates of *D. fragilis* infection, but literature evaluating the risk of *D. fragilis* infection in HIV/AIDS is also limited [104]. Although it is unknown whether

immunocompromised patients are at higher risk of infection or symptomatic disease from *D. fragilis*, it should still be considered as a potential cause of diarrheal illness in transplant recipients.

Balantidium coli

Epidemiology

Balantidium coli is a ciliated protozoan parasite that is mostly found in tropical and subtropical regions. Transmission is by fecal-oral route via ingestion of cysts, and pigs and monkeys are common animal reservoirs. Close contact with pigs is therefore a risk factor for infection, although person-to-person transmission also occurs. *B. coli* cysts are resistant to chlorine [13, 105].

Clinical Presentation

B. coli infection causes a range of clinical presentations, from asymptomatic infection to acute colitis and rarely fulminant disease (e.g., severe dysentery with colonic ulcers, intestinal perforation, and sepsis). Case reports also describe pulmonary involvement from *B. coli*, presumed to be secondary to hematogenous spread in patients with fulminant disease. *B. coli* is uncommon and under-recognized. Occasionally, *B. coli* causes chronic colitis characterized by chronic abdominal pain and bloody diarrhea [13, 105].

Diagnosis

Diagnosis is by detection of trophozoites or cysts on stool examinations. *B. coli* trophozoites are large ciliates with a characteristic large vacuole which can be seen at low magnification (×100) on wet mount (Fig. 8). Repeated stool samples may be required to diagnose this infection due to intermittent excretion.

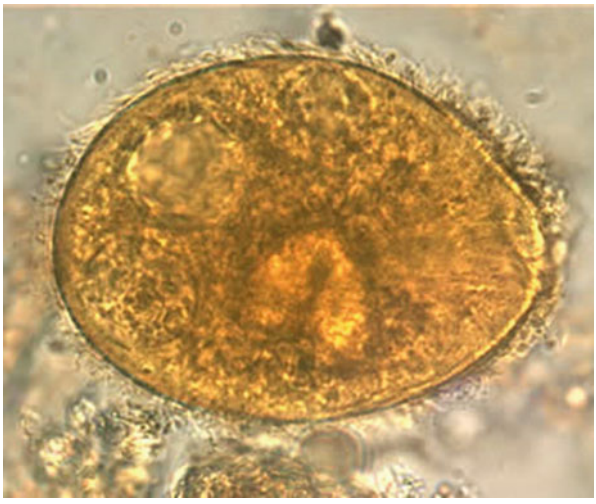

Fig. 8 Trophozoite of *Balantidium coli* on wet mount with characteristic cilia, bean-shaped nucleus, and large central vacuole. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/balantidiasis/index.html)

Treatment

First-line treatment is with tetracycline or metronidazole (Table 2). Alternatives include iodoquinol or nitazoxanide [106] (Table 2).

B. coli in Transplant Recipients

Although data in the transplant population is extremely limited, the risks of both infection and severe disease may be higher in immunocompromised hosts. Two cases of severe diarrhea due to *B. coli* in HIV-infected patients have been reported, and two other reports described *B. coli* infection leading to pulmonary disease in immunocompromised cancer patients [107–110].

Intestinal Helminths

Helminths are multicellular worms that range in size from microscopic to many meters in length. Tissue-invasive helminth infections usually cause peripheral eosinophilia, while helminth infections limited to the gastrointestinal tract usually result in low-grade eosinophilia at most (or no eosinophilia at all).

Over a quarter of people worldwide are infected with at least one helminth species. The most common intestinal helminths of humans are *Ascaris lumbricoides*, *Trichuris trichiura*, and the human hookworms [111]. The prevalence of helminths is highest in developing countries and in areas where sanitation is poor. In contrast, transplant services are more widely available in developed countries and are more accessible to people of higher socioeconomic status. Reports of helminths in transplant recipients are therefore uncommon. However, as transplants become more widely available globally, the number of transplant recipients with helminth infections will increase.

For transplant recipients with exposure to highly endemic areas, intestinal helminths should be considered in the appropriate clinical setting [112]. Recognition of exposure risk is critical since symptoms can be nonspecific, diagnostic tests are insensitive, and illness can occur even years after exposure.

In general, transplant is not a risk factor for the acquisition of intestinal helminth infections nor for severe disease once infected. Most helminths do not reproduce in humans, and adult worms die of senescence even in the absence of chemotherapy. Therefore, replication is not increased in immunosuppressed patients, and infection is not maintained after the natural lifespan of the adult worms passes, even in the absence of antiparasitic therapy. The major exception to this is *Strongyloides stercoralis,* as the risk of severe disease in transplant recipients with strongyloidiasis is much higher due to this organism's ability to "autoinfect" and thus replicate in humans, resulting in lifelong persistence of the infection in the absence of antiparasitic therapy. Dissemination of large numbers of organisms is therefore possible in the context of immunosuppression. Two other intestinal helminths with autoinfective cycles and the theoretical ability to cause hyperinfection are *Capillaria*

philippinensis and *Hymenolepis nana*, although hyperinfection in transplant recipients infected with these parasites has yet to be well documented.

Here we describe several intestinal helminths and review the few published case reports of helminthiases in transplant recipients.

Intestinal Nematodes

Intestinal nematodes (roundworms) are round, non-segmented worms with elongated, cylindrical bodies. The sexes are separate, with fertilized females producing eggs that subsequently give rise to larvae. After molting, larvae become adult worms.

Soil-Transmitted Helminths

Worldwide, the most common human intestinal helminths are *Ascaris lumbricoides*, *Trichuris trichiura* (whipworm), and the human hookworms *Ancylostoma duodenale*, *Ancylostoma ceylanicum*, and *Necator americanus*. These organisms are also termed the *soil-transmitted helminths* (STHs) because their eggs or larvae must develop in soil before becoming infectious. The soil-transmitted helminths (*Strongyloides stercoralis*, which is sometimes grouped with the STHs, excepted) do not reproduce in humans, and thus infection burden is limited to the inoculum acquired during initial infection. Because of this, even in the absence of effective chemotherapy, patients living in non-endemic areas who have not traveled abroad for many years are unlikely to have active infections, since these parasites would have already died of senescence by then.

Ascaris lumbricoides

Epidemiology

Ascaris lumbricoides is the most common helminth infection of humans, with an estimated prevalence of around 800 million persons globally; infection is most common in children. Ascariasis is globally distributed but is most abundant in developing countries in the tropics. Adult *Ascaris* worms are typically creamy or pink-white, non-segmented, and 15–45 cm long and live in the small intestine; they are one of the few grossly visible intestinal nematodes (Fig. 9). Eggs are passed in the feces of infected persons; once they reach warm, moist soil, they become infectious after an average of 2–6 weeks. Humans usually acquire the infection by ingestion of these eggs via contaminated food (or water); eggs then hatch in the small intestine and release larvae that penetrate the intestine and migrate to the lungs a few days later. Over the week or so that follows, they ascend the tracheobronchial tree, are swallowed, and return to the intestines, where they mature into adult worms. Egg production begins approximately 2 months after infection, and adult worms have a

Fig. 9 Adult *Ascaris lumbricoides* worm, which can grow up to 20–45 cm long. Note round, smooth, non-segmented appearance. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/ascariasis/index.html)

natural lifespan of 1–2 years. Each adult female worm can produce over 200,000 eggs daily. Humans can also become infected by the closely related helminth *Ascaris suum*, a parasite primarily of pigs. Although there has been debate about whether this represents a unique species, current consensus is that it indeed does.

Clinical Presentation

Most people infected with *Ascaris* are asymptomatic, although a small proportion develop pulmonary symptoms (such as a cough) while larvae migrate through the lungs 1–2 weeks after infection. Eosinophilia may accompany this, as can eosinophilic pneumonitis/Loeffler's syndrome. With most established infections, adult worms in the small bowel lumen provoke no symptoms or produce only mild abdominal pain, nausea, or anorexia. However, heavier infections can cause malnutrition, especially in children living in endemic areas. Other complications of chronic ascariasis are rare and are largely due to mechanical issues related to the presence of the large adult worms in the gut, such as intestinal, biliary, or pancreatic obstruction, appendicitis, and intestinal perforation. When these complications occur, they are more common in children from endemic areas. Occasionally, adult worms can pass per rectum, through the mouth or nose or tear ducts.

Diagnosis

Because of the large numbers of eggs produced by each adult female worm, eggs can be readily identified on microscopic stool examinations. PCR assay availability is expanding, but these are not yet in widespread use. Adults are so large that they are grossly visible in the stool, particularly after treatment causes excretion of the worms (Fig. 9).

Treatment

Treatment of ascariasis is with albendazole; single-dose regimens are highly effective, with cure rates that surpass 90–95%; 1–3-day courses of mebendazole are also acceptable. Pyrantel pamoate and ivermectin are also alternatives (Table 4). Common side effects for these and other anti-helminth medications are outlined in Table 3.

Ascaris in Transplant Recipients

There are few reported cases of ascariasis in transplant recipients. In one report from India, *Ascaris* infection was documented in 4 (1.3%) of 297 patients that had undergone HSCT, although this was likely an underestimate [113]. There are no reports which describe an increased risk of infection or severity in transplant recipients. This is similar to the HIV/AIDS patient population, in whom no demonstrable increased risk of infection or severity has been observed [111, 114].

One case report described ascariasis in a renal transplant recipient who developed obstructive jaundice and pancreatitis due to migration of *Ascaris* into the biliary tree [115]. While this is a well-known complication of ascariasis and unlikely to be a result of the patient's underlying immune status, it is a reminder to consider biliary ascariasis in patients with obstructive jaundice or pancreatitis when epidemiologic risk factors are present.

Another case report described numerous *Ascaris* adult worms being excreted after whole body radiation during the preparative regimen for an HSCT [116].

Hookworm Infection

Epidemiology

The human hookworms *A. duodenale*, *A. ceylanicum*, and *N. americanus* are small, gray-white nematodes about 1 cm long that live in the upper small intestine. Globally, around 500 million people are infected with hookworms, mostly in developing tropical areas. *A. ceylanicum* was once considered a primarily zoonotic hookworm that rarely infected humans but has more recently been recognized as a common human hookworm, especially in Asia. As with the other soil-transmitted helminths, eggs passed in the stool of infected persons must develop on soil (ideally warm, moist, and shady); they hatch there within 1–2 days, becoming larvae. Larvae then molt over 5–10 days, subsequently becoming infectious. Following contact with human skin, larvae enter the body and are carried to the lungs. They then move up the trachea, are coughed up and ingested, and migrate to the small intestine. Females start egg deposition 4–6 weeks after infection. Although *N. americanus* can only be transmitted via this percutaneous route, *A. duodenale* and *A. ceylanicum* can also be transmitted orally as well as percutaneously. The adult lifespan averages 3–5 years for *N. americanus* and 1 year for *A. duodenale* and *A. ceylanicum*.

Table 4 Treatment of helminth infections. (Adapted from Kappagoda et al. [18] and Gilbert et al. [19])

Helminth	Preferred regimens	Alternative regimens
Ascaris lumbricoides	1. Albendazole 400 mg PO once *OR* 2. Mebendazole (500 mg PO once *OR* 100 mg PO BID for 3 days)	1. Ivermectin 150–200 mcg/kg PO once *OR* 2. Pyrantel pamoate 11 mg/kg (max 1 g) PO daily for 3 days
Ancylostoma spp. *and Necator americanus*	1. Albendazole 400 mg PO daily for 3 days *OR* 2. Mebendazole 100 mg PO BID for 3 days	Pyrantel pamoate 11 mg/kg (max 1 g) PO daily for 3 days
Trichuris trichiura	Mebendazole 100 mg PO BID ×3–7days	1. Albendazole 400 mg PO QD for 3–7 days *OR* 2. Albendazole 400 mg *plus* oxantel pamoate 20 mg/kg (both PO daily for 2 days) *OR* 3. Albendazole 400 mg *plus* ivermectin 200 mcg/kg (both PO once)
Strongyloides stercoralis	Uncomplicated infection: ivermectin 200 mcg/kg PO daily for 2 days; consider repeating 2 weeks later in immunocompromised individuals. For hyperinfection, many authorities recommend treatment with ivermectin 200 mcg/kg (SQ/veterinary preparation or PO) daily *plus* albendazole 400 mg PO BID until 7–14 days after parasite clearance and possible intermittent secondary ivermectin prophylaxis subsequently	1. Albendazole 400 mg PO BID for 7–14 days *OR* 2. Thiabendazole 25 mg/kg PO BID for 3–7 days
Capillaria philippinensis	1. Mebendazole 200mg PO BID for 20 days *OR* 2. Albendazole 400 mg PO BID for 10 days	
Taenia saginata	Praziquantel 5–10 mg/kg PO once	1. Niclosamide 2 g PO once *OR* 2. Nitazoxanide 500 mg PO BID for 3 days
Taenia solium (intestinal infection)	Praziquantel 5–10 mg/kg PO once	1. Niclosamide 2 g PO once *OR* 2. Nitazoxanide 500 mg PO BID for 3 days
Taenia solium (cysticercosis)	1. Albendazole 400 mg PO BID for 2–4 weeks 2. Praziquantel 33 mg/kg PO TID for 1 day followed by 15 mg/kg PO TID for 2–4 weeks 3. Corticosteroids given before, during, and after treatment to decrease seizure risk ~Decision of whether and how to treat NCC is complex and discussed further in the text and in other sources	

(continued)

Table 4 (continued)

Helminth	Preferred regimens	Alternative regimens
Hymenolepis nana	Praziquantel 25 mg/kg PO once	1. Niclosamide 2 g PO daily for 7 days *OR* 2. Nitazoxanide 500 mg PO BID for 3 days
Diphyllobothrium latum	Praziquantel 5–10 mg/kg PO once	1. Niclosamide 2 g PO once *OR* 2. Nitazoxanide 500 mg PO BID for 3 days
Dipylidium caninum	Praziquantel 5–10 mg/kg PO once	1. Niclosamide 2 g PO once *OR* 2. Nitazoxanide 500 mg PO BID for 3 days
Fasciolopsis buski	Praziquantel 25 mg/kg PO TID for 1 day	

Abbreviations: *PO* oral administration, *BID* twice a day, *TID* three times a day, *mcg* micrograms, *mg* milligrams, *kg* kilograms, *NCC* neurocysticercosis, *SQ* subcutaneous

Clinical Presentation

Hookworms latch onto the intestinal wall where they release an anticoagulant to assist in sucking blood. They therefore cause iron-deficiency anemia as their primary pathophysiologic effect on the human host. During their migration through the lungs, they can also cause an eosinophilic pneumonitis (Loeffler's syndrome), which is less common and less severe than it is with *Ascaris*. Similar to the other STHs, most people infected with hookworm harbor light infections and are asymptomatic. Initial infection may be characterized by "ground itch," a pruritic maculopapular rash at the site of skin penetration. Serpiginous tracks (cutaneous larva migrans) on the skin occur with infection by animal hookworms (e.g., *Ancylostoma braziliense*) but not human hookworms. Epigastric pain, diarrhea, and anorexia may occur about 6–12 weeks after penetration, as larvae begin attaching to the small bowel mucosa. There are important clinical differences between the hookworm species: *N. americanus* is shorter, removes 5–10× less blood, and produces fewer eggs than *A. duodenale*. Some who are infected with adult hookworms experience chronic abdominal pain and eosinophilia. However, the most important manifestations of hookworm disease are iron-deficiency anemia and malnutrition. The anemia from hookworm infection develops gradually but can become severe.

Diagnosis

Diagnosis of hookworm infection is made by identification of eggs on microscopic stool examinations (Fig. 10); concentration techniques may be necessary for the detection of light infections because egg output is not as high as with other STHs. The use of PCR assays for the diagnosis of hookworm infections is becoming more common, but these are not yet in widespread use.

Treatment

Albendazole is the preferred antiparasitic drug for the treatment of hookworm infection. Single-dose albendazole regimens are reasonably effective and are commonly used; however, 3-day regimens yield higher cure rates (Table 4).

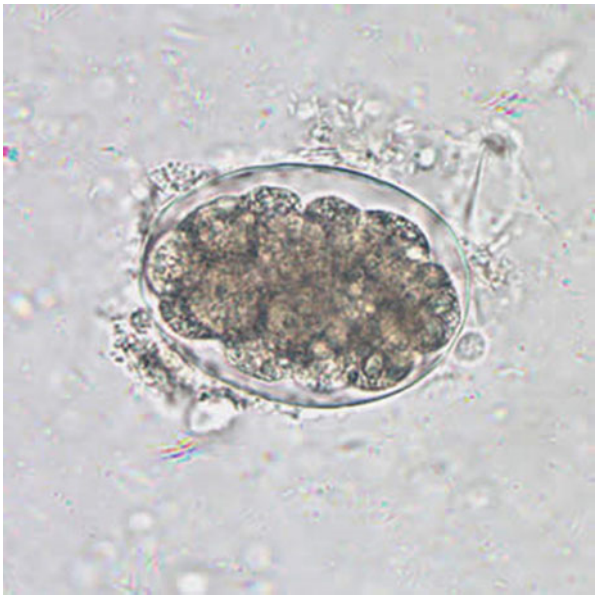

Fig. 10 Thin-walled hookworm egg on an unstained wet mount. *Ancylostoma* and *Necator* eggs are indistinguishable microscopically. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern, https://www.cdc.gov/dpdx/hookworm/index.html)

Hookworm in Transplant Recipients

As with most intestinal helminths, hookworm infection risk and severity are not known to be increased in transplant recipients. Published reports of hookworm infection in this population are scant, although one report describes an HSCT recipient who had a relatively severe case of colitis in the setting of hookworm infection. After developing diarrhea, this allogeneic HSCT recipient was initially thought to have GVDH; however, flexible sigmoidoscopy showed a live hookworm embedded in the intestinal mucosa with surrounding scattered erosions and mild distal sigmoid colitis. He received 7 days of mebendazole with rapid resolution of the diarrhea within 1–2 weeks and subsequent healing of colonic erosions [117]. The severity of diarrhea and colitis in this case was atypical for hookworm infection, which usually causes subacute symptoms and anemia. Furthermore, hookworm typically infects the small intestine, not the colon. This case raises the possibility that profound immunosuppression may worsen the severity of hookworm infection in some patients.

Trichuris trichiura (Whipworm)

Epidemiology

Trichuris trichiura is also known as the whipworm because of its long, whiplike head, which embeds into the intestinal mucosa. It is the third most common roundworm in humans. About 500 million people are infected with *Trichuris*, with highest prevalence in developing countries that have wet and warm tropical climates; children are more commonly infected than adults and are more likely to be

symptomatic from heavy infections. Adult worms are gray-to-pink and 3–5 cm long. They primarily reside in the cecum and ascending colon; with heavy infections, the distribution can extend to the entire colon. Eggs have a distinctive barrel-shaped appearance with a thick shell and bipolar plugs (Fig. 11). *Trichuris* eggs shed in the feces become infective within 2–4 weeks after reaching soil. After human infection occurs, oviposition begins 2–3 months later, and adult worms have a natural lifespan of 1–3 years. Fecal-oral transmission occurs by ingestion of eggs in contaminated food or water.

Clinical Presentation

Most patients with trichuriasis are asymptomatic, and some have mild eosinophilia. With heavy infections (particularly in children), chronic abdominal pain and diarrhea can result, as well as anemia, malnutrition, and growth retardation. The *Trichuris* dysentery syndrome can result, characterized by tenesmus and frequent stools containing mucus and blood. Recurrent rectal prolapse can occur, with adult worms often visible.

Diagnosis

Diagnosis is made by identification of characteristic barrel-shaped eggs with bipolar plugs on microscopic stool examination (Fig. 11). PCR assays using next-generation sequencing techniques are emerging for the diagnosis of trichuriasis but are not yet in widespread use.

Fig. 11 Egg of *Trichuris trichiura* on unstained wet mount; note the thick, barrel-shaped shell and bipolar plugs. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/trichuriasis/index.html)

Treatment

T. trichiura is more difficult to cure than the other STHs. Single-dose cure rates with albendazole or mebendazole are low; this parasite should therefore be treated with longer courses (at least 3–7 days) or combinations of antiparasitic drugs (Table 4). Overall, mebendazole is superior to albendazole for the treatment of *T. trichiura*, and standard courses are 3–7 days of therapy. Alternatives include combinations of albendazole plus oxantel pamoate or albendazole plus ivermectin; in theory, mebendazole could be substituted for albendazole in these regimens, but this has not yet been studied. Several studies suggest that combination regimens result in higher cure rates than single-dose regimens for trichuriasis (Table 4).

T. trichiura in Transplant Recipients

Infection risk and severity of trichuriasis are not known to be higher in transplant recipients, but data are limited. However, one report describes a renal transplant recipient who was treated for rejection with several immunosuppressive agents. He then developed chronic watery diarrhea, anemia, and acute kidney injury. Colonoscopy showed diffuse hyperemia and nonspecific colitis on biopsy, and stool examination showed *T. trichiura* eggs; symptoms resolved after treatment with mebendazole for 3 days [118]. This case raises the possibility that trichuriasis might be more severe in transplant recipients, especially when immunosuppression is increased in the setting of treatment for rejection.

Strongyloides stercoralis

S. stercoralis is an intestinal nematode that is primarily transmitted through skin contact with infested soil in much of the tropical and subtropical developing world. *S. stercoralis* infection is usually asymptomatic, but mild abdominal pain, diarrhea, or other gastrointestinal symptoms can be seen in a minority of infected patients; like with *Ascaris* and hookworm, acute infection can result in eosinophilic pneumonitis/Loeffler's syndrome. Unlike almost all other helminths, *S. stercoralis* can complete its life cycle in the human host through a process termed *autoinfection*, which results in several relatively unique characteristics among helminths including lifelong persistence in a host (in the absence of treatment), multiplication in the absence of exogenous reinfection, and potential person-to-person transmission. The primary medical importance of this parasite in the developed world lies in its potential to cause the hyperinfection syndrome (mostly in immunocompromised patients), wherein large numbers of larvae may disseminate throughout the body, with mortality rates of up to 70–80%; serologic screening of transplant candidates/recipients who have epidemiologic exposure is important, with treatment of all infected persons (with ivermectin; Table 4), in part to prevent the subsequent possibility of hyperinfection syndrome. Strongyloidiasis is a major concern in transplant recipients and is discussed in more detail in ► Chap. 53, "Strongyloides: Emerging Challenges and Prevention."

Other Intestinal Nematodes

Capillaria philippinensis

Epidemiology

Capillaria philippinensis is a parasite of fish-eating birds that is acquired through ingestion of undercooked or raw fish. Capillariasis is endemic mainly to Southern/Eastern Asia (especially Thailand and the Philippines), though infections have also occasionally been acquired elsewhere.

Clinical Presentation

The clinical presentation of patients infected with *C. philippinensis* can include chronic, watery diarrhea which can be severe and cause both dehydration and malnutrition. Fever, abdominal pain, and eosinophilia are often present. Untreated, the infection can be fatal within a few months. Similar to *Strongyloides*, *C. philippinensis* is one of the few intestinal helminths which can reproduce in humans via autoinfection (such that the burden of disease is not only a result of the initial inoculum). This can potentially result in hyperinfection with large numbers of worms disseminating throughout the body, especially in the setting of immune compromise, which makes this parasite a particular concern in transplant recipients.

Diagnosis

The diagnosis of *C. philippinensis* is made by identifying larvae or eggs on microscopic stool examinations. The eggs are oval and have bipolar plugs and can be confused with those of *T. trichiura* (Fig. 12).

Fig. 12 *Capillaria philippinensis* egg on unstained wet mount with bipolar prominences which can be confused with *Trichuris trichiura.* (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/intestinalcapillariasis/index.html)

Treatment

All infected patients should be treated, both to alleviate symptoms and prevent subsequent hyperinfection. Prolonged courses of albendazole or mebendazole are preferred; relapse is common (Table 4). Of note, a closely related helminth, *Capillaria hepatica*, also rarely infects humans through ingestion of food or water contaminated by infected animal stool and usually leads to hepatic egg deposition, resulting in fibrosis.

C. philippinensis in Transplant Recipients

Although the life cycle of *C. philippinensis* suggests that there is a risk of hyperinfection and dissemination in immunocompromised patients infected with this organism, there are no reported cases of capillariasis causing this syndrome in transplant recipients; this association therefore remains theoretical for now.

Intestinal Cestodes

Intestinal cestodes are tapeworms, characterized by long, flat, segmented bodies which reside primarily in the gastrointestinal tract. Cestodes attach via their head (scolex) to the intestinal wall, and distal to this are numerous segments (proglottids). These proglottids can detach from the rest of the worm in some species (e.g., *Taenia* spp.) and be excreted in the stool, where the grossly visible proglottids or the microscopic eggs they contain can be found; in other species (e.g., *Hymenolepis*), only the eggs are found in the stool.

Taenia saginata (Beef Tapeworm)

T. saginata occurs worldwide, with transmission intensity highest in developing countries and where consumption of undercooked beef is common. Human infection is acquired via consumption of undercooked beef infested with *T. saginata* cysticerci. About 50 million people are infected worldwide, with the highest prevalence in East Africa, Indonesia, and China. Humans infected with *T. saginata* usually only have a few tapeworms in their intestinal tract, although these can be 4 m in length or longer (Fig. 13). Adult *T. saginata* tapeworms begin oviposition 2–3 months after initial infection and have a natural lifespan of a few years. Most humans who are infected with *T. saginata* are asymptomatic. A minority develop abdominal pain, weight loss, or nausea, and some have low-grade eosinophilia. Some patients also notice proglottids in their stool or anus. Diagnosis is made through the identification of eggs or proglottids on stool examinations (Fig. 14); several specimens should be obtained to increase diagnostic yield, since excretion is intermittent. Molecular assays are being developed for the detection of taeniasis but are not yet in widespread use. Treatment is with praziquantel, which results in a high cure rate; niclosamide (and possibly nitazoxanide) is an alternative (Table 4).

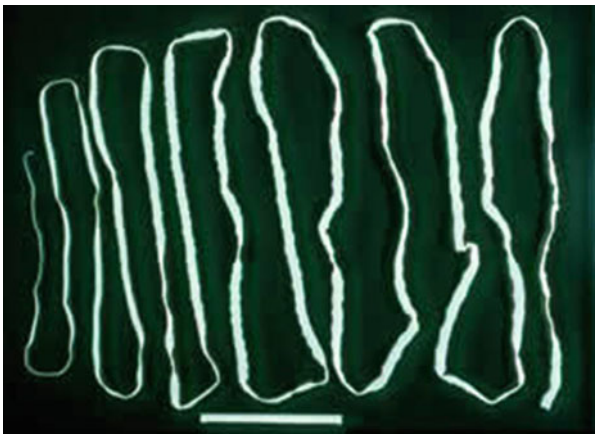

Fig. 13 *Taenia saginata* adult worm (about 4 m in length); note long, segmented, flat appearance. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/taeniasis/index.html)

Taenia solium (Pork Tapeworm)

Epidemiology

T. solium is endemic to much of the developing world, especially where free-range pigs are raised. Taeniasis, intestinal infection with the adult tapeworm, results from human consumption of undercooked pork infested with cysticerci (larval cysts). Cysticercosis (tissue infection with *T. solium* larval cysts) results from ingestion of *T. solium* eggs, which are spread by fecal-oral transmission from a person with intestinal taeniasis; the prevalence of cysticercosis is estimated at 50 million globally. Humans infected with *T. solium* usually have only a few tapeworms in their intestinal tract, although these are usually 3–6 m in length. Adult *T. solium* tapeworms begin oviposition 2–3 months after initial infection and have a natural lifespan of a few years.

Clinical Presentation

The clinical presentation of *T. solium* tapeworm carriers is similar to that of *T. saginata*. Cysticercosis involving the subcutaneous tissue or skeletal muscle is usually asymptomatic. With neurocysticercosis (NCC), cysts that disseminate to the CNS can cause seizures, hydrocephalus, or chronic meningitis.

Diagnosis

Diagnosis is by identification of eggs or proglottids on microscopic stool examinations for intestinal disease (Fig. 14). Of note, *T. solium* cannot be differentiated morphologically from *T. saginata*. Serology is an important means of diagnosis for cysticercosis due to *T. solium* and is highly sensitive, especially the enzyme-linked immunoelectrotransfer blot (EITB) assay. Brain imaging can be useful for the diagnosis of NCC, with CT scans revealing calcifications and MRIs revealing the cyst and sometimes the scolex; diagnostic criteria have been published that can aid with the diagnosis of NCC [119].

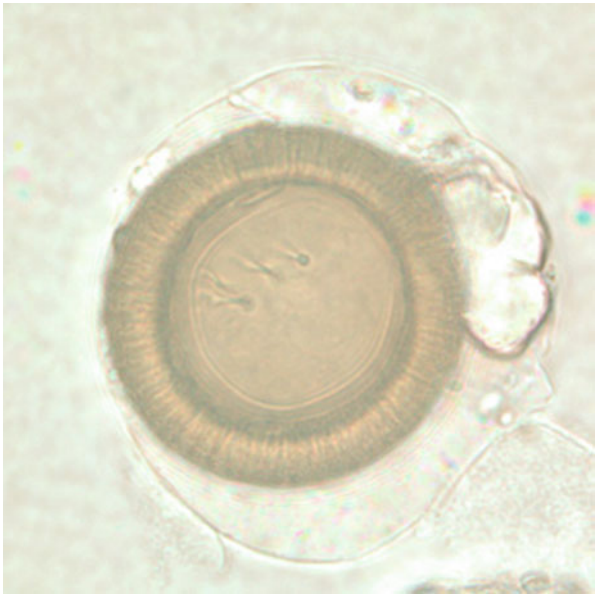

Fig. 14 Unstained wet mount of *Taenia* spp. egg with characteristic radially striated shell and refractile hooks. *T. saginata and T. solium* eggs are indistinguishable morphologically. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/taeniasis/index.html)

Treatment

Although intestinal *T. solium* infection is usually asymptomatic, patients should always be treated to prevent subsequent cysticercosis; most patients with intestinal taeniasis should be screened with brain imaging prior to treatment to identify potential NCC, which could change management. Praziquantel is the first-line treatment for intestinal taeniasis, with niclosamide (and possibly nitazoxanide) as alternative (Table 4). The decision to treat NCC with antiparasitic agents is complex and beyond the scope of this chapter; in general, the location, number, and type of cysts and clinical manifestations should be considered, with most authorities now recommending antiparasitic treatment for most forms of NCC. Corticosteroids are given concurrently with antiparasitic therapy to decrease the inflammatory response and risk of seizures as the parasite degenerates; patients should be screened for strongyloidiasis and tuberculosis prior to the administration of corticosteroids. In general, patients with intraparenchymal cysts should be treated with albendazole; emerging data indicate that albendazole plus praziquantel combination therapy may be superior to albendazole alone, especially if there are more than two cysts [120]. Patients with only intraparenchymal calcifications generally do not require antiparasitic therapy. Patients with subarachnoid cysts should generally receive prolonged courses of antiparasitic drugs plus corticosteroids. Surgical removal is indicated for intraventricular, intraocular, and spinal cysts. Intraocular cysts should be excluded before initiating antiparasitic therapy for cysticercosis. If present, intraocular cysts should be surgically removed before administration of antiparasitic treatment to avoid irreversible eye damage due to the resulting inflammatory response. Importantly, the index patient and close/household contacts should be

screened for intestinal taeniasis so that they may be treated with praziquantel to prevent ongoing transmission.

T. solium in Transplant Recipients

Globally, neurocysticercosis is common, and there have been cases reported in transplant recipients, including in two liver, one kidney, and two HSCT recipients. In one case, symptom onset was about 6 years after transplant [121], but in the others, neurologic symptoms began a few months after transplant [122–124]. Three of these five patients were treated with antiepileptics, antiparasitics, and corticosteroids with good clinical response. The other two had more complicated courses, as described below.

One liver transplant recipient who was found to have multiple small NCC cysts was treated with antiepileptics, steroids, and praziquantel 25 mg/kg three times a day. Four months later, the original cysts had regressed but new NCC cysts had developed. He was then treated for an additional 3 months with albendazole without recurrence of disease [123].

One HSCT recipient had a single NCC cyst incidentally noted on brain MRI 4 months after HSCT, with serologic testing also positive for *T. solium*. Antiparasitic/steroid treatment was deferred, and the cyst resolved spontaneously 7–8 months later [125].

The role of transplant in these cases is unclear, although the development of symptoms or new lesions shortly after transplant in some cases suggests the possibility of an etiologic role. However, more data are needed to evaluate the natural history of NCC in transplant recipients.

Hymenolepis nana

Epidemiology

Hymenolepis nana (the "dwarf tapeworm") is smaller than other cestodes (~0.5 cm long) and attaches to the ileum. Unlike other tapeworms, *H. nana* can complete its life cycle in a single host (through autoinfection). The natural lifespan of adult worms is only 4–6 weeks, but because of autoinfection, long-term persistence of the infection is possible within a given host. *H. nana* is one of the most common human tapeworm infections worldwide, with a prevalence of about 75 million. It is spread by the fecal-oral route and is thus most prevalent in warm, developing areas with poor sanitation; children are most commonly infected. Eggs are immediately infectious upon excretion in the stool and cannot survive more than 10 days in the external environment.

Clinical Presentation

Most patients infected with *H. nana* are asymptomatic, although with heavy infections (especially among children) chronic diarrhea or abdominal discomfort may be present.

Diagnosis

Diagnosis is made by the identification of eggs or proglottids on microscopic stool examinations which are evident about 3–4 weeks after initial infection (Fig. 15). Low-grade eosinophilia may be present in those infected with *H. nana*.

Treatment

Given the ability of *H. nana* to cause persistent or even increasing burden of infection with time (due to autoinfection), all infected patients should be treated. The preferred agent is praziquantel, although at higher doses than for other cestodes (Table 4). Niclosamide and nitazoxanide are alternatives, but longer courses are needed if one of these agents is used.

H. nana in Transplant Recipients

The risk of infection with *H. nana* does not seem to be increased in the transplant population. In a review of 706 stool samples from renal transplant recipients in Iran, only 2 (0.2%) samples were positive for *H. nana* [126].

Because *H. nana* is one of the few intestinal helminths which can complete its life cycle in the human host, hyperinfection is a theoretical possibility in immunocompromised patients. However, hyperinfection with *H. nana* in transplant recipients has not been described. One case report from Malaysia and another from India describe *H. nana* ova identified in the stool of renal transplant recipients. One patient had minimal symptoms [127], and the other had 4

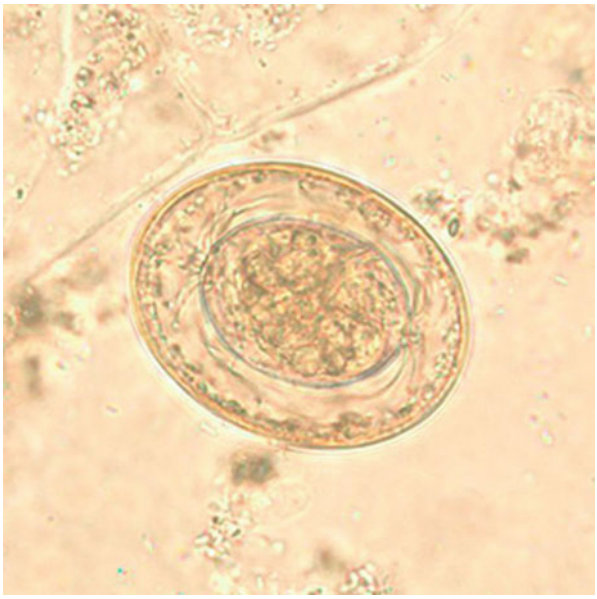

Fig. 15 *Hymenolepis nana* egg on unstained wet mount; note the bipolar filaments. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/hymenolepiasis/index.html)

weeks of abdominal pain and diarrhea, which resolved after treatment with nitazoxanide and praziquantel [128]. These reports are consistent with the natural history of *H. nana* infection in the general population, and there are no reports which suggest that transplant alters this. However, the potential risk that this tapeworm poses to immunocompromised patients is reinforced by a patient with AIDS (CD_4 count, 28 cells/mm^3) who developed malignant transformation of *H. nana* infection. Although extra-intestinal infection with *H. nana* is rare, this process involved his lungs, lymph nodes, and other organs and ultimately led to his death [129].

Diphyllobothrium latum

Epidemiology

D. latum (the "fish tapeworm") is the most common species in this genus that infects humans. Humans become infected through the ingestion of undercooked or raw freshwater fish that are infested with this parasite. *D. latum* is most commonly seen in northern Europe, Russia, North America, Chile, and Japan; the estimated worldwide human prevalence is about 10 million. *D. latum* is the largest human tapeworm, reaching sizes of over 10–15 m, and inhabits the ileum and jejunum; the natural lifespan of adult worms can exceed a decade.

Clinical Presentation

Many patients infected with *D. latum* are asymptomatic, but some develop weakness, dizziness, salt craving, and diarrhea. A minority develop abdominal pain or diarrhea. The parasite interferes with vitamin B12 absorption, so megaloblastic anemia may result from long-term infection. Infected patients not uncommonly see large proglottids pass in their stool.

Diagnosis

The diagnosis can be confirmed through the identification of eggs or proglottids on a microscopic stool examination (Fig. 16); oviposition begins about 4–6 weeks after infection. Some patients may develop mild eosinophilia.

Treatment

First-line treatment is with a single dose of praziquantel or, alternatively, niclosamide or nitazoxanide (Table 4).

D. latum in Transplant Recipients

Reports of *D. latum* in transplant recipients have been sparse. One report describes severe infection in an autologous HSCT recipient. In this case, the patient had mild abdominal pain and diarrhea for several months preceding transplant. Three days posttransplant, he developed severe diarrhea which lasted for over a month until stool examination ultimately revealed *D. latum* ova. He was treated with a single dose of praziquantel with improvement of diarrhea, but then had symptomatic and

Fig. 16 Unstained wet mount of a *Diphyllobothrium latum* egg which is characterized by an operculum on one end and a small knob on the other end. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/diphyllobothriasis/index.html)

parasitologic relapse 1 week later, which necessitated a second dose of praziquantel [130]. This case suggests the possibility that transplant recipients may be at higher risk of severe infection from *D. latum* and that longer treatment courses might be necessary for cure.

Dipylidium caninum

Epidemiology

D. caninum (also known as the "dog tapeworm") is the most common intestinal cestode of dogs (and is also found in cats) but occasionally also infects humans as accidental hosts. Part of its life cycle occurs in arthropods, and transmission to mammals (including humans) occurs through the accidental ingestion of infected fleas or lice. Human cases are therefore most commonly seen in young children who have close contact with dogs or cats. *D. caninum* adult worms are usually 15–20 cm in length.

Clinical Presentation

Parasite load is typically low because few infected fleas or lice are typically ingested, and most infected patients are asymptomatic. A minority of infected persons experience mild diarrhea or abdominal discomfort.

Diagnosis

Proglottids are periodically excreted and can occasionally be seen grossly in the diapers or underpants of infected children. Otherwise, the diagnosis is made by identifying ova or proglottids on microscopic stool examination (Fig. 17).

Fig. 17 Adult *Dipylidium caninum* worm made up of proglottid segments, which can break off; if found in a person's underwear, can be mistaken for pinworms. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern. https://www.cdc.gov/dpdx/dipylidium/index.html)

Treatment

Treatment is with single-dose praziquantel; an alternative is niclosamide (Table 4).

D. caninum in Transplant Recipients

There is one case reported of *D. caninum* in a renal transplant recipient who presented with prolonged diarrhea, ultimately diagnosed with *D. caninum* infection by identification of the organism of on stool examination. The patient was treated with niclosamide resulting in symptomatic resolution and clearance of stool [131]. The severity and length of symptoms in this case were unusual for a human infection with *D. caninum*, raising the possibility that this patient's immunocompromised state influenced the course of this infection.

Intestinal Flukes

Flukes (or trematodes) are flatworms that range in size from microscopic to several centimeters in length. There are scores of species of intestinal flukes that infect humans. One of the most common and largest (2–7 cm in length) is *Fasciolopsis buski*, which is endemic mostly to Asia, with highest prevalence in children. Pigs are also hosts of this parasite, and transmission to humans is typically associated with ingestion of contaminated water or aquatic plants (such as watercress or bamboo shoots), especially in areas where pigs are raised. Fasciolopsiasis is usually asymptomatic; when symptoms do occur, they are due to inflammation and ulceration in the intestine. Abdominal pain, diarrhea, eosinophilia, and malabsorption can occur. Diagnosis is made by the examination of microscopic stool examinations. Treatment is with praziquantel (Table 4). While fasciolopsiasis has not been reported in transplant recipients to date, this may become a more common infection in this population and should remain a consideration when risk factors are present.

Conclusion

The differential diagnosis in transplant recipients with a gastrointestinal illness is broad and includes GVHD, adverse effects from medications, bacterial infections, viral infections, and others, in addition to intestinal parasitic infections. Because parasitic infections are less common in the developed nations where transplantation is more common, they are often considered only after initial workup for other etiologies has been undertaken, and even then diagnosis often relies on insensitive stool examinations. Diagnostic delays are therefore common for these otherwise readily treatable infections. There are few reports of infections with intestinal parasites in transplant recipients, but with increasing globalization, these organisms are likely to become increasingly common in this population.

Key Points

- Many intestinal parasites have a worldwide distribution, but most predominate in tropical and subtropical areas where sanitation and hygiene are poor.
- Most intestinal parasites are transmitted by consumption of contaminated food and water; some protozoa such as *Cryptosporidium* spp., *Giardia*, and *E. histolytica* do not require incubation in the environment and can therefore also be transmitted directly from person-to-person.
- There is substantial clinical overlap among the intestinal parasites; most are associated with abdominal pain, diarrhea, or chronic GI symptoms. Some are associated with fulminant infection or extra-intestinal complications, while patients infected with others are often asymptomatic.
- Transplant recipients are at increased risk for severe or recurrent disease from many intestinal protozoal infections and possibly for some intestinal helminths, although data are limited.
- The diagnosis of intestinal parasites is often made through identification on microscopic stool examinations; stool preparations stained with modified acid-fast stains are needed to identify the intestinal coccidia (*Cryptosporidium* spp., *Cystoisospora*, and *Cyclospora*) which are usually missed on standard stool examinations.
- PCR has become increasingly available for the diagnosis of some intestinal protozoa such as *Cryptosporidium* spp., *Cyclospora*, *Giardia*, and *E. histolytica*. PCR testing is much more sensitive and specific than microscopy. However, PCR assays are not commercially available for most other intestinal protozoa and for none of the intestinal helminths, for which diagnosis still relies on insensitive stool examinations.
- Treatment of intestinal parasites in transplant recipients involves antiparasitic medications and in some cases decreasing immunosuppression. Prolonged or combination antiparasitic therapy can also be considered in some cases.

Introduction

Free-living amoebae (FLAs) are protists that are ubiquitous in the environment but rarely cause human infections. Three of these are most often associated with clinical disease: *Naegleria fowleri*, which causes primary amebic meningoencephalitis (PAM); *Acanthamoeba* spp., which can cause granulomatous amebic encephalitis (GAE), *Acanthamoeba* keratitis (AK), and a variety of other forms of disseminated cutaneous, pulmonary, or sinus disease; and *Balamuthia mandrillaris*, which also causes a form of GAE and cutaneous lesions. The pathogenesis and epidemiology of these organisms are varied, with the portal of entry playing an important role in pathogenesis. Strategies for diagnosis and treatment of FLAs are hampered by the rarity of the infections, and it is unknown how many cases are undiagnosed.

FLAs present a twofold challenge to the field of transplantation. First is the consideration of the organ donor potentially infected with an FLA and the need to decide whether to accept or reject the organ in a short time frame, typically based on incomplete information. The second is diagnosis and treatment of FLAs – possibly donor-derived – in a solid organ transplant (SOT) or stem cell transplant recipient already at risk for rare infections that are difficult to diagnose and treat. In addition, a more susceptible host such as a transplant patient often provides greater opportunity for an atypical presentation and disseminated disease.

The transplant clinician needs to maintain a high index of suspicion for FLAs given the appropriate history and epidemiology. An added caution when considering these diagnoses in the transplant population is that recommendations for diagnosis and treatment are based on case reports and series, and best practices are yet to be satisfactorily defined.

The American Society of Transplantation has recently published guidelines for diagnosis and management that briefly address FLAs [1] and donor-derived FLA infections [2]. This chapter will focus on the clinical implications of FLA in the solid organ and bone marrow transplant populations. A reader who is currently caring for a patient with a suspected or confirmed FLA infection may consider going to the Postscript at the end of this chapter for information on obtaining immediate assistance from the Centers for Disease Control and Prevention (CDC).

Disease Epidemiology

Acanthamoeba

Ecology and Pathobiology

Acanthamoeba was first identified in 1930 as a contaminant in a yeast culture. The first description of *Acanthamoeba* associated granulomatous amebic encephalitis (GAE) was reported in 1960, and reports of *Acanthamoeba* keratitis (AK) followed in 1970. Many species of *Acanthamoeba* have caused human infection, including *A. culbertsoni*, *A. polyphaga*, *A. castellanii*, *A. astronyxis*, *A. hatchetti*, *A. rhysodes*, *A. divionensis*, *A. lugdunensis*, and *A. lenticulata*. These protists are found throughout the world and have been identified in soil, water, and air samples. In certain regions of the world, there are reports of 85-100% of healthy populations with evidence of a serologic response to *Acanthamoeba*, suggesting prior exposure [3].

Acanthamoeba spp. grow best at neutral pH and temperatures of approximately 30 °C [3]. However, they are able to survive in a variety of environments, including tissue culture media, salt water, body fluids, and distilled water. Viable amoebae have been recovered from a fresh and salt water sources, water associated with buildings and facilities, and various forms of refuse.

There are two stages to the life cycle of this protist: the active trophozoite stage and the dormant cyst stage. *Acanthamoeba* keratitis is thought to start with trophozoite invasion through a break in the epithelial barrier of the cornea, aided by secreted proteases, followed by a cascade of events to include stromal infiltration, depletion of the keratocytes, and activation of the host inflammatory response, which ultimately leads to photophobia, stromal necrosis, and blindness [4]. In contrast, primary transmission in GAE and disseminated cutaneous disease are thought to occur via inhalation of cysts or cutaneous inoculation. Microscopic findings at autopsy suggest that the amoeba invade the alveolar blood vessels and then spread hematogenously, crossing the blood-brain barrier to infect the CNS [3].

Risk Factors and Incidence

Acanthamoeba keratitis has been associated with contaminated contact lens solution, with a multistate outbreak identified between 2005 and 2007 [5]. The infected patients were otherwise healthy with a median age of 40 years. In contrast, disseminated *Acanthamoeba* infections and GAE occur in immunocompromised patients.

Though historically associated with the AIDS epidemic, transplant recipients are also at risk for invasive disease; infections have been reported in patients with transplants of the heart [6–8], kidney [9–14], and lung [15–18]. In addition, there have been reports of disease in patients with hematologic malignancies [19–21] and in stem cell transplant recipients [22–30]. Immunocompromising conditions with increased risk of infection include diabetes, renal failure, liver cirrhosis, and chronic use of steroids or other immunosuppressive therapies [3]. Due to

the ubiquitous nature of the organism, environmental risk factors have not been definitively identified, although nasal irrigation with contaminated water may have been the source of infection in several cases [31].

Naegleria fowleri

Ecology and Pathobiology

In 1965, an amoeba was identified as the cause of a case of meningitis in Australia [32]. The following year, examination of American cases revealed their cause to be a novel amoeba species distinct from *Acanthamoeba*. The clinical entity was termed primary amebic meningoencephalitis or PAM [33]. *Naegleria fowleri* is the only pathogenic species in the genus *Naegleria*. It exists in three different forms: the trophozoite, which predominates in a warm, high-nutrient aquatic environment; a transient motile flagellate stage, which occurs in a low-nutrient aquatic environment (to allow for movement over long distances in pursuit of nutrients); and a cyst, which forms under adverse conditions. The amoeba grows best at higher temperatures up to 46 °C and is killed by freezing, drying, temperatures over 65 °C, and adequate levels of chlorination; it does not survive in salt water, although it is fairly tolerant of a wide range of temperatures and pH [34]. The trophozoite is the infective form. It enters hosts through the nasal mucosa, translocates across the cribriform plate, and travels via the olfactory neuroepithelia into the central nervous system. It then invades the olfactory bulbs and the base of the brain to cause hemorrhagic and necrotizing meningoencephalitis which results in cerebral edema, herniation, and eventually death [35].

Risk Factors and Incidence

Naegleria fowleri is a thermophilic organism; therefore it has been postulated that the epidemiology of PAM might be an indicator of climate change [36]. Cases have been noted worldwide and are also associated with warm waters, most notably in Pakistan [35]. Association with contaminated tap water has also been observed. Particularly noteworthy as a mode of exposure are practices in which the nasal passages are directly exposed to contaminated water, such as irrigation with a neti pot, or ritual nasal rinsing in Yogic, Ayurvedic, and Islamic traditions [36].

Between 1962 and 2019, 148 cases of PAM were reported to CDC [37, 38] (unpublished data). In the United States, PAM primarily occurs in previously healthy young men exposed to warm, recreational waters, predominantly in lakes, ponds, and reservoirs in southern-tier states during the summer months. Over half the cases occur in Texas and Florida. However, in recent years, cases associated with recreational water exposure in the United States have been seen farther north, including Kansas, Indiana, and even Minnesota [38]. It has been estimated that there may be 16 deaths annually in the United States due to *Naegleria fowleri*, with some cases being undiagnosed [39].

No cases of *Naegleria fowleri* infection have been documented in the transplant population to date, although there is some theoretical risk of transmission from donors [40]. See the *Naegleria fowleri* heading under the "Clinical Impact in Transplant" section below for current practice regarding infected donors.

Balamuthia

Ecology and Pathobiology

Balamuthia mandrillaris was first identified in 1986 from a mandrill (a type of primate) that died of encephalitis [41]. There have been a few reports of isolation from soil, dust, and water; the exact ecologic niche of *Balamuthia* remains unknown. In contrast to other FLAs, this infection is likely associated with exposure to contaminated soil. *Balamuthia* also has two stages to its life cycle, the trophozoite and the cyst stage. It is thought to enter the human body via the lungs by inhalation of cysts or direct inoculation of a break in the skin and then spreading via a hematogenous route.

Risk Factors and Incidence

CDC has identified 109 case reports of *Balamuthia* disease between 1974 and 2016, primarily in the western and southwestern regions of the United States [42]. Patient ages ranged from 4 months to 91 years, with a median age of 36 years, which is different from many etiologies of encephalitis which tend to affect the elderly. A predominance of males and Hispanic ethnicity is proposed to be due to occupations with heavy soil exposure such as landscaping and agriculture.

Approximately 40% of patients had an underlying immunocompromised state (which included diabetes, HIV, SOT, liver or renal failure, use of an immunosuppressive drug, or other hematologic or autoimmune condition). More specifically, 6% of cases were solid organ transplant recipients, and 5% were on an immunosuppressive drug. Alcohol use was reported as a comorbidity in 18% and drug use in 22% of cases.

Clinical Evaluation and Disease Diagnostics

Acanthamoeba

The clinical presentation of *Acanthamoeba* infection varies depending on the host immune system and the portal of entry. *Acanthamoeba* keratitis is characterized by "gray-dirty" epithelial changes, multifocal stromal infiltrates, ring infiltrates, and peripheral perineural infiltrates, with later complications including anterior uveitis, scleritis, synechiae, glaucoma, iris atrophy, cataract chorioretinitis, and retinal vasculitis [4].

Manifestations of disseminated disease include cutaneous lesions, rhinosinusitis, urethritis, and fatal GAE [3] (Figs. 1 and 2). At times the clinical course may be indolent. GAE may present over weeks and months as a progressive disease associated with headache, fever, and subtle neurologic changes [43]. Radiographic findings suggestive of GAE include solitary or multiple space occupying lesions, which may or may not be ring-enhancing. The cerebrospinal fluid (CSF) indices associated with GAE include hypoglycorrachia, elevated protein, and lymphocytic pleocytosis. Skin lesions may be associated with GAE, and biopsy can aid in the diagnosis if present.

(**a**) CT of the head with and without contrast showing an ill-defined hypodensity at the right medial temporal lobe causing mass effect and uncal herniation with surrounding vasogenic edema. (**b**) Coronal section of cerebrum displaying a 6 × 6 × 5 cm area of gelatinous necrosis and hemorrhage. (Reproduced under Creative Commons Attribution-NonCommercial-NoDerivs license)

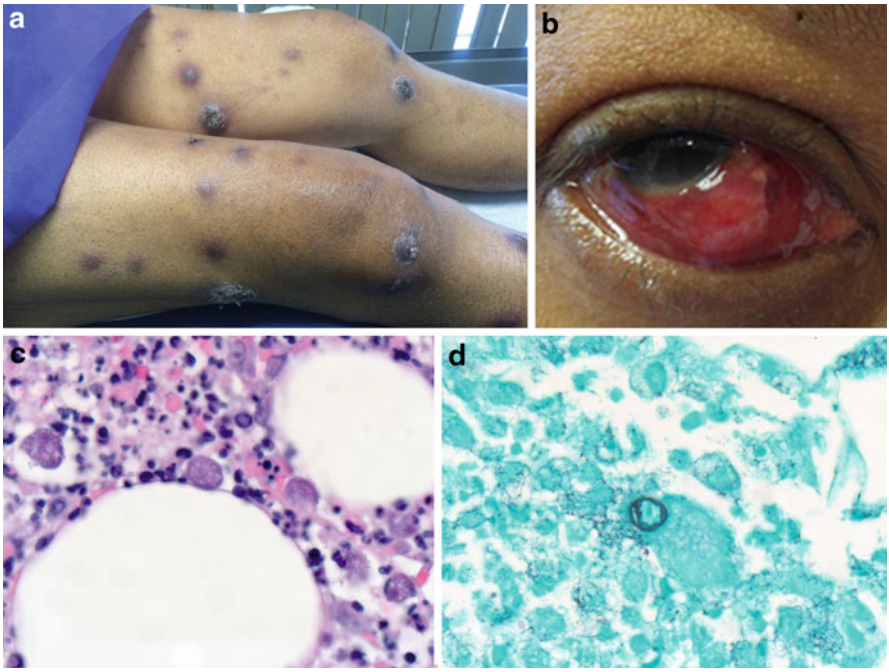

Fig. 2 A renal transplant recipient with disseminated *Acanthamoeba* infection [9] resulting in both (**a**) painful dermal and subcutaneous skin nodules and (**b**) endophthalmitis. Photomicrographs of the skin biopsy demonstrate (**c**) trophozoites stained by hematoxylin and eosin and (**d**) a cyst stained by Gomori methenamine silver. (Reproduced by permission of publisher, John Wiley & Sons, Inc.)

In almost all cases of *Acanthamoeba* infection, tissue diagnosis is required. The diagnosis of cutaneous lesions may be made with tissue biopsy stained for identification of trophozoites or cysts (Fig. 2). Second-level testing may then be pursued to include indirect immunofluorescent antibody (IFA) or immunohistochemical (IHC) staining of tissue and PCR testing (see Postscript).

It is more difficult to make the diagnosis of GAE as *Acanthamoeba* trophozoites are unlikely to be seen in CSF (wet mount or Wright-Giemsa stain), though it is recommended to perform lumbar puncture for CSF analysis and microscopy [1]. Brain biopsy with tissue diagnosis is the standard method to identify *Acanthamoeba* trophozoites and cysts. In many cases the diagnosis is made too late to affect clinical outcome [10, 22, 44] as the mortality associated with GAE is about 90%, with diagnosis often made at autopsy.

Naegleria fowleri

The clinical presentation of PAM due to *Naegleria fowleri* is best described in the most comprehensive review of cases from 1937 to 2013 [38]. In this case series, the median incubation period was 5 days, and the median time from onset of symptoms to death was also 5 days. The clinical presentation of PAM is often indistinguishable from bacterial meningitis with the most common presenting symptoms being headache (92%), fever (75%), and nausea/vomiting (65%). Late symptoms included nuchal rigidity, confusion, and other signs of progressive CNS disease. Only 27% of US cases were diagnosed before death.

CSF studies may be difficult to distinguish from bacterial meningitis. The median opening pressure is elevated at 385 mm H_2O, with a neutrophilic pleocytosis (median WBC count of 2400 with 83% neutrophils). The CSF fluid also has low glucose (median 23 mg/dL) and markedly elevated protein (365 mg/dL). Radiographic studies of the brain often demonstrate generalized edema but are not specific enough to distinguish from other etiologies, although the parasites may favor the frontal lobe and parietal lobes, and some cases have been associated with hydrocephalus [45] (Fig. 3).

A high index of suspicion is required to undertake CSF studies specific to *N. fowleri*. Microscopic examination should be conducted by an expert pathologist or microbiologist [36]. If it cannot be examined immediately, CSF should be stored at approximately 25 °C and handled aseptically before examination. To concentrate the specimen, it may be centrifuged at 5000 × *g* for 5 min and the supernatant removed to leave 200–300 μl. The slide may be incubated at 37 °C to facilitate movement of the amoebae. Wright and Giemsa stains may also be helpful in identifying the trophozoite. If the diagnosis is made in time to affect the clinical outcome, it is most likely to be made based on the presence of trophozoites in the CSF.

N. fowleri-specific PCR [46] can provide diagnosis from CSF or brain biopsy tissue. With proper notification of specimen shipment, the CDC Free-Living and Intestinal Amebas (FLIA) Laboratory can provide same-day PCR results from CSF for clinical decision-making; PCR is available at other reference labs in the United

States as well (see Postscript). Contact the CDC Emergency Operations Center at 770-488-7100 for additional guidance. Culture and antigen detection are also employed but are unlikely to be used in a clinical setting.

Balamuthia

The clinical presentation of *Balamuthia* GAE is nonspecific [42]. When the skin is involved, lesions are often singular and located on the central face but occasionally on the extremities or trunk. They have been described as painless plaques that may progress to central ulceration. The most common general clinical features on presentation are fever (39%), headache (39%), vomiting (30%), and lethargy (28%). The most common neurologic features on presentation are altered mental status (30%), seizures (21%), and weakness (19%). Radiographic findings on brain imaging [42] have included enhancing lesions (29%), multifocal lesions (23%), and edema (27%) (Fig. 4) [45].

CSF studies typically demonstrate elevated protein, low or normal glucose, and a lymphocytic pleocytosis [42], with a median white blood cell count of 106 cells/μL and a median of 57% lymphocytes.

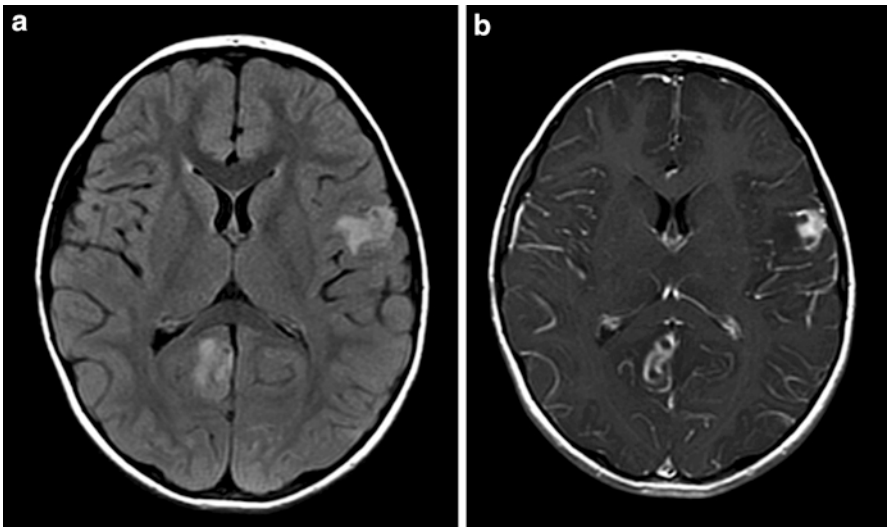

Fig. 4 Brain images showing contrast-enhanced lesions in the right occipital and left parietal lobes of a 4-year-old boy with encephalitis caused by infection with *Balamuthia mandrillaris* amebae [70]. (**a**) T2-weighted fluid-attenuated inversion recovery (FLAIR) image. (**b**) T1-weighted contrasted magnetic resonance image. (Reproduced courtesy of CDC)

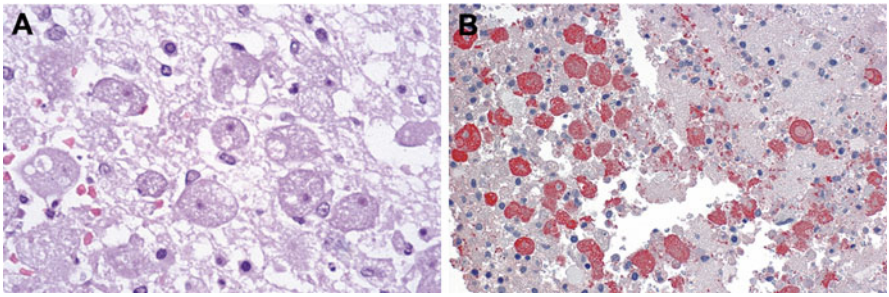

Fig. 5 Photomicrographs showing histopathologic features and immunolocalization of *Balamuthia mandrillaris* antigens in central nervous system tissue from a donor with *B. mandrillaris* infection [70]. (**a**) Typical amebic trophozoites with prominent karyosomes in central nervous system. Hematoxylin and eosin staining. Original magnification, ×158. (**b**) *B. mandrillaris* antigens in amebic trophozoites. Immunoalkaline phosphate staining, naphthol fast red substrate with light hematoxylin counterstain. Original magnification, ×100. (Reproduced courtesy of CDC)

Biopsy results (Fig. 5) may show the trophozoite stage when taken from the skin, while brain biopsy could show both cyst and trophozoite forms. Polymerase chain reaction (PCR) testing of CSF and/or brain tissue is also recommended [1] which is available at CDC and other reference labs (see Postscript).

Clinical Impact in Transplant

Acanthamoeba

While infection with *Acanthamoeba* spp. is rare in transplant patients, it has been associated with severe disease and fatal outcomes. As of the time of this publication, there have been no reports of donor-derived *Acanthamoeba* infection. The etiology of infection in transplant patients seems to be from exposure to contaminated water or soil in the setting of active immunosuppressive drug therapy. Of uncertain clinical significance in the transplant population, in particular, is the ability of *Acanthamoeba* spp. to carry other organisms, known as "endosymbionts," into the human host. Some of these endosymbiont viruses, bacteria, yeasts, and other protists are recognized human pathogens [3].

In a review of 22 cases of *Acanthamoeba* infection in heart, lung, liver, kidney, and multi-organ transplant recipients, the most common immunosuppression regimens included tacrolimus, mycophenolate, cyclosporine, and prednisone. The mean age of the patients identified was 50 years, with mean time to diagnosis after transplant of 18 months (range, 3 months to 6 years) [7]. In the majority of cases reviewed, there was a delay in diagnosis. Multiple case reports suggest that patients are often started on empiric antibacterial and antifungal therapy with little or no improvement, before the diagnosis is made with tissue specimen. The challenge for the frontline clinician is to consider this organism in these immunocompromised patients.

Because these infections are thought to be secondary to inoculation from cysts in the host's environment, there may be an opportunity to counsel the patient on risk reduction after transplant and before the patient is discharged home. The current recommendations from the American Society of Transplantation are "to exercise caution when engaging in occupations or recreational activities that expose them to untreated freshwater," [1] and similar recommendations exist for recipients of stem cell transplants [47]. While there have been studies to evaluate a risk assessment tool for infectious encephalitis in deceased organ donors that might be helpful in preventing *Balamuthia* infections [48], there is no indication that this would be helpful in preventing *Acanthamoeba* infections at this time as there have been no recognized donor-derived infections.

Naegleria fowleri

Organs have been successfully used for transplantation from 5 donors with known PAM due to *Naegleria fowleri* with no evidence of transmission to 21 recipients at follow-up of at least 6 months [40, 49, 50]. In one case [49], the donor had PAM established antemortem by visualization of motile amoebae in the CSF and confirmed by the state parasitology laboratory. Although multiple programs turned down the organ offers, recipients who gave informed consent received the kidneys, liver, right lung, and pancreas.

In four of the cases [40, 50], the diagnosis of PAM in the donor was only identified post-transplant. Five recipients had negative *N. fowleri* serologies 7 weeks to 2 years post-transplant, and one biopsy taken 1 month post-transplant from a donated heart tested negative for *N. fowleri* [40]. However, historical PAM case reports and animal experiments with *N. fowleri*, combined with postmortem findings from PAM patients, suggest that extra-CNS dissemination of *N. fowleri* can occur and might pose a risk for disease transmission via transplantation [40] (Fig. 6).

Given the lack of transmission from infected donors [40, 49, 50], current guidelines from the American Society of Transplantation suggest that "[i]f the donor has proven *N. fowleri*, the organs can be utilized with a low risk of transmission, as long as the recipients are informed of the risk and monitored closely" [2]. However, due to evidence for extra-CNS dissemination in mouse

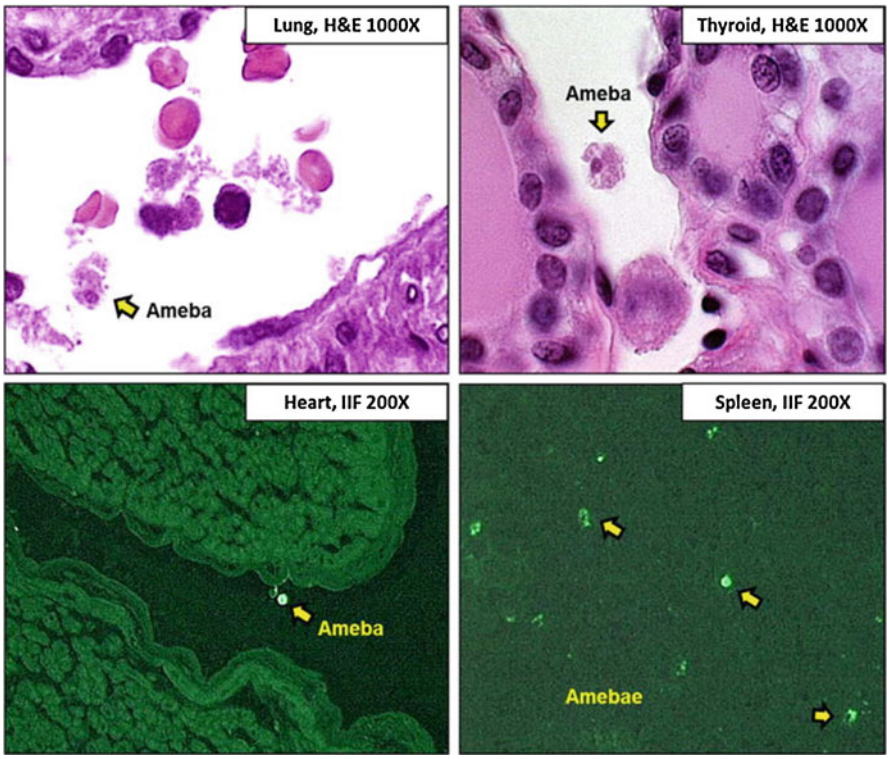

Fig. 6 Postmortem examination of lung, thyroid, heart, and spleen tissue from a 10-year-old male organ donor in Florida who died from primary amebic meningoencephalitis due to *Naegleria fowleri* [40]. *N. fowleri* trophozoites in lung (upper left) and thyroid (upper right) sections by hematoxylin and eosin (H&E) staining at 1000× magnification. *N. fowleri* trophozoites fluorescing in heart (lower left) and spleen (lower right) sections by indirect immunofluorescence (IIF) at 200× magnification. (Reproduced by permission of publisher, John Wiley & Sons, Inc.)

models and in occasional human cases, it has been proposed that a full autopsy of the donor should be performed in the case of a suspected or confirmed case of PAM, to determine the extent of dissemination [40]. If organ biopsies of the recipient are undertaken for other reasons (e.g., to monitor for rejection), it may be prudent to specifically look for *N. fowleri* in the tissue.

The guidelines for safe living after transplantation of solid organs [51] and stem cells [47] recommend that the transplant recipient is counseled to avoid contaminated freshwater, which from a practical perspective is essentially any water source not meant to be potable. This includes consumption or inadvertent swallowing of water from lakes, ponds, rivers, or untreated wells, especially those which may be contaminated (with sewage, human waste, or animal waste). This may also include water rides at amusement parks. The concern is primarily for *Cryptosporidium*, *Giardia*, and coliforms, but in warmer waters, this would also apply to *N. fowleri*.

Directing the recipient to avoid warm ponds altogether is not unreasonable. Water slide use has been associated with PAM as well [36]. Given the known inoculation by nasal irrigation [35, 36], it is reasonable to simply direct transplant recipients to avoid neti pots or nasal ablution entirely. Maintaining adequate levels of chlorine disinfectant in water distribution systems, particularly in those with elevated water temperatures, is thought to be an important strategy in preventing PAM cases related to tap water [36]. Transplant recipients aware of local water quality issues may consider boiled, filtered, or bottled water. Salt water is not known to be a risk factor for *N. fowleri*.

Balamuthia

Clusters of *Balamuthia* transmitted by solid organ transplant were described in 2009, 2010, and 2012 [52]. In the 2009 cluster [53], two kidney recipients were infected, and one died. The asymptomatic heart and liver recipients were treated preemptively, and the liver recipient developed a detectable serology. The donor infection was later confirmed on autopsy.

The 2010 cluster [54] resulted in the death of the recipients of the liver and the kidney-pancreas. The asymptomatic recipients of the heart and other kidney were also treated, with the kidney recipient developing a positive serology which later waned. In 2012, five recipients received *Balamuthia* infected organs, with the liver recipient developing encephalitis 18 days post-transplant and dying, while the remaining recipients had positive *Balamuthia* antibody titers, were treated preemptively, and survived [55].

The implications for screening donors for solid organ transplantation are that all donors with a potential diagnosis of encephalitis should be viewed with caution for infections with free-living amoebae, viruses, and other organisms. A risk calculator for infectious encephalitis has been constructed [48] which can be downloaded at https://chhs.gatech.edu/RiskCalculator.zip

Management

Drug Interactions and Toxicities

Transplant recipients are typically on immunosuppressive agents which are metabolized by the cytochrome P450 (CYP) 3A4 system, most notably the calcineurin inhibitors (CNIs), cyclosporine, and tacrolimus and the mammalian target of rapamycin (mTOR) inhibitors, sirolimus, and everolimus. Azole antifungals generally inhibit CYP 3A4, increasing the area under the curve (AUC) of these agents when coadministered, necessitating a decrease in the dose of CNI or mTOR inhibitors by one-half to two-thirds of the original dose [56]. They may also inhibit uridine diphosphate-glucuronosyltransferases, which may increase exposure to mycophenolate products.

Macrolides in general are CYP3A4 inhibitors. However, the macrolide most used for FLA infections is azithromycin, which has a relatively minor effect on immunosuppressive drug levels [56].

Conversely, the rifamycins are potent inducers of CYP3A4, and coadministration of rifampin may decrease the AUC, requiring an increase in the doses of immunosuppressive agents by two- to tenfold; they may also induce uridine diphosphate-glucuronosyltransferases and decrease mycophenolate levels as well [56]. To further complicate matters, the regimens used to treat FLAs may include both azoles and rifampin. Therefore, transplant patients undergoing therapy for FLAs require careful monitoring of levels of immunosuppressive agents.

In addition, the toxicities of the drugs may affect the organ transplanted, so the risks and benefits will have to be addressed on an individual basis. Since decreasing immunosuppression is a mainstay of the treatment of life-threatening infections in transplant recipients, the decrease in immunosuppression will have to be weighed against the risk of organ rejection.

Acanthamoeba

Therapy for *Acanthamoeba* infection is not standardized in the transplant population, and there are many therapeutic combinations that have been reported in the literature; however, combinations which include miltefosine may have a greater chance of eradicating infection [57, 58]. Miltefosine is an alkylphosphocholine analog and antiprotozoal medication that was recently approved by the US Food and Drug Administration (FDA) for use in treating leishmaniasis. It has also been found to have amebicidal properties, though the mechanism of action is not understood [59].

Prior to the availability of miltefosine, during the AIDS epidemic, there were reports of successful treatment of GAE with surgical resection of the CNS lesion in conjunction with sulfadiazine, pyrimethamine, and fluconazole [60]. Other patients with GAE have previously been treated with combinations of pentamidine, sulfadiazine, flucytosine, and either fluconazole or itraconazole [61]. A 2001 report described three immunocompetent children who developed chronic

Acanthamoeba meningitis, two of whom were successfully treated with a combination of oral trimethoprim/sulfamethoxazole, rifampin, and ketoconazole [62]. More recently, in 2011 a pediatric patient with acute lymphoblastic leukemia (ALL) developed GAE shortly after remission and had curative therapy with prolonged miltefosine, pentamidine, fluconazole, and trimethoprim/sulfamethoxazole in conjunction with hyperbaric oxygen [43]. (See the Postscript for directions on obtaining miltefosine on an urgent/emergent basis.)

Disseminated cutaneous infection in immunocompromised patients may require both systemic therapy and topical treatment. Various reports of successful therapy have included parenteral pentamidine, topical chlorhexidine, and 2% ketoconazole cream, followed by oral itraconazole [63] or voriconazole and amphotericin B lipid complex [16]. In a rare case of disseminated cutaneous disease with concomitant endophthalmitis in a renal transplant patient, bi-weekly intracameral and subconjunctival injections of voriconazole and dexamethasone were used in conjunction with systemic fluconazole, flucytosine, azithromycin, and miltefosine; sulfadiazine had been employed also in this case but was discontinued due to anemia [9].

Expert opinion suggests that a successful regimen involves at least miltefosine and an azole, with adjunctive therapy consisting of a sulfa drug, flucytosine, and/or azithromycin. Treating physicians have typically started with 3–4 drugs and, if the patient improves, scaled back to 2–3 oral drugs with close outpatient follow-up. Table 1 summarizes typical therapies and doses employed.

Table 1 Drugs and typical doses employed in the treatment of *Acanthamoeba* infections, including GAE [61]. When doses are not specified in the case reports, standard doses are recommended

Drug	Dose	Recommended adjustment in immunosuppressive dose for CNI or mTOR inhibitor when starting *Acanthamoeba* treatment
Pentamidine	3–4 mg/kg/day intravenously	–
Sulfadiazine	4–6 g/day orally divided into 4 doses	–
Trimethoprim/ sulfamethoxazole	15–20 mg/kg divided into 3–4 doses	–
Flucytosine	50–150 mg/kg/day oral divided into 4 doses	–
Fluconazole	9–12 mg/kg/day orally or intravenously	↓by 50% then monitor
Itraconazole	10 mg/kg/day orally divided into 2 doses, typically ≤400 mg/daily	↓by 50% then monitor
Voriconazole	8 mg/kg/day divided into 2 doses	↓by 70% then monitor
Azithromycin	10 mg/kg/day orally or intravenously	Monitor
Miltefosine	150 mg/day divided into 3 doses	–

While *Acanthamoeba* keratitis is not associated with the transplant or immunocompromised populations, it may be useful to note that when treatment can be achieved medically, recommended agents are typically a combination of a diamidine (such as propamidine isethionate or hexamidine diisethionate) plus a biguanide (such as polyhexamethylene biguanide or chlorhexidine), possibly with neomycin for both its amebicidal effects and to reduce the load of bacteria which may be a food source for the ameba [4]. Corneal transplant may be required if medical therapy fails.

Susceptibility testing of *Acanthamoeba* isolates have shown differences in drug sensitivity between species and even among strains of a single species, although antimicrobial susceptibility testing is not readily available and is only available in research settings [64].

Naegleria fowleri

In spite of the general approach for employing combination antimicrobial therapy, the case fatality rate for PAM remains high, with only 4 survivors out of 148 documented cases in the United States in the years 1937–2019 [38, 59]. None of these documented cases were transplant recipients, so treatment regimens would likely be extrapolated. Table 2 shows a list of the main therapies employed with typical doses.

Table 2 Drugs and typical doses employed in survivors of *Naegleria* PAM [59]. Posaconazole has been proposed as a replacement for fluconazole (see text) [66]. Note that the recommended formulation of amphotericin is not the liposomal or lipid complex, but conventional amphotericin B deoxycholate

Drug	Dose	Recommended adjustment in immunosuppressive dose for CNI or mTOR inhibitor when starting *Naegleria* treatment
Amphotericin B deoxycholate	1.0–1.5 mg/kg/day intravenously (in one case 0.1 mg intrathecally)	–
Rifampin	10–12 mg/kg/day orally or intravenously	↑twofold then monitor
Miltefosine	150 mg/day divided into 3 doses	–
Fluconazole	9–12 mg/kg/day orally or intravenously	↓by 50% then monitor
Posaconazole		↓by 70% then monitor
Azithromycin	10 mg/kg/day orally or intravenously	Monitor

Intravenous amphotericin B deoxycholate (conventional, not the lipid formulation) remains the backbone of therapy and has been used in all cases who survived; it has been occasionally administered intrathecally as well. Expert opinion suggests employing the deoxycholate formulation [38] for several reasons: all recent survivors received amphotericin B deoxycholate, none of the cases who received non-deoxycholate formulations survived, and in vitro data are conflicting on whether the lipid complex or liposomal formulations are as effective. The toxicities of the deoxycholate formulation (rigors, nephrotoxicity, gastrointestinal side effects) may be outweighed by the benefits in a desperately ill PAM patient.

Rifampin is the most commonly used adjunctive therapy to potentiate the effects of amphotericin B deoxycholate, the rationale based originally on in vitro data. It was also used in all documented survivors in the United States [38].

Miltefosine, discussed above in the treatment of *Acanthamoeba*, has demonstrated good activity in vitro against other amoebae and was used to treat both of the PAM survivors in 2013 as well [38, 59, 65]. Although not all recipients have survived, it is promising and should probably be employed in future cases [59]. (See the Postscript for directions on obtaining miltefosine on an urgent/emergent basis.)

Azoles also have in vitro activity, and miconazole, ketoconazole, and fluconazole have been employed intravenously, orally, and occasionally intrathecally. Posaconazole has been proposed as a superior azole on the basis of in vitro activity and animal models [66].

Azithromycin may be synergistic with amphotericin B and has activity in vitro and in mouse models. It has been employed in a number of cases, most notably in more recent survivors [38].

Aggressive management of elevated intracranial pressure was employed in most survivors [38, 59], including external ventricular or lumbar drain placement, therapeutic hypothermia, and dexamethasone.

Balamuthia

Based on their in vitro activity and successful use in survivor cases, the following drug combination is recommended for treatment of *Balamuthia* infection: pentamidine, sulfadiazine, flucytosine, fluconazole, azithromycin or clarithromycin, and miltefosine [42]. See Table 3 for doses.

Pentamidine may result in nephrotoxicity, hypotension, dysglycemias, pancreatitis, and hepatotoxicity. QT prolongation may be a concern with coadministration with other drugs with a similar effect, such as the azoles.

Sulfadiazine is contraindicated in the case of sulfa drug allergy and may result in blood dyscrasias.

Again, miltefosine may need to be obtained emergently from the manufacturer. See Postscript for directions on obtaining miltefosine on an urgent/emergent basis.

Table 3 Drugs and typical doses employed in survivors of *Balamuthia* GAE [42]

Drug	Dose	Recommended adjustment in immunosuppressive dose for CNI or mTOR inhibitor when starting *Balamuthia* treatment
Pentamidine	3–4 mg/kg/day intravenously	–
Sulfadiazine	4000–6000 g/day orally divided into 4 doses	–
Flucytosine	50–150 mg/kg/day oral divided into 4 doses	–
Fluconazole	9–12 mg/kg/day orally or intravenously	↓by 50% then monitor
Azithromycin	10 mg/kg/day orally or intravenously	Monitor
Miltefosine	150 mg/day divided into 3 doses	–

Nitroxoline, a quinolone antibiotic which has been used to treat urinary tract infections, has recently been identified to have potent in vitro amebicidal activity against *Balamuthia* [67].

Key Points

FLAs are environmental protists which rarely cause infection, but when they do, they can be devastating, particularly in the immunocompromised host. In addition, it may be difficult to determine whether a potential organ donor with encephalitis has an FLA infection, and the diagnosis may not be made until after transplantation.

Acanthamoeba spp. may present as keratitis, GAE, or a variety of disseminated infections in the immunocompromised host. The environmental exposure may be contaminated water or soil. It has not yet been recognized as a cause of donor-derived infection.

Naegleria fowleri is the etiology of PAM and is acquired by exposure of the nasal mucosa with contaminated warm water, from either nasal irrigation or recreational exposure in warm bodies of fresh water. The transplant recipient should avoid these environmental exposures to minimize the risk of PAM. Although transplantation of solid organs from infected donors has not resulted in transmission to recipients, there is evidence of dissemination outside of the central nervous system, so organs should be used with caution.

Balamuthia is another cause of GAE as well as cutaneous disease, likely acquired by inhalation or inoculation. Immunosuppression might be a particular risk factor for infection. Since many of the recognized donor-derived infections

have been fatal in spite of treatment, patients with suspected *Balamuthia* infection should not be considered as organ donors.

FLA infections may be difficult to diagnose and treat, and expert consultation should be sought immediately upon suspicion (see Postscript). Tissue and CSF are crucial in establishing the diagnosis but often require specialized diagnostic modalities, such as those available at CDC. Combination therapy often includes miltefosine, azoles, and macrolides and may include several other drugs, many of which have interactions with transplant medications. Due to the rarity and delayed diagnosis of FLA infections, outcomes are frequently poor.

Postscript: Obtaining Immediate Assistance

A reader in the United States who is considering the diagnosis of FLA infection in an ill patient should consider urgent or emergent consultation with experts at CDC who will facilitate the appropriate diagnostic testing and access the most appropriate therapies. CDC does take consultations from international physicians and will accept international specimens for diagnostic testing as well.

For 24/7 diagnostic assistance, specimen collection guidance, shipping instructions, and treatment recommendations, please contact the CDC Emergency Operations Center at 770-488-7100.

Directions for sending samples for testing for PCR, IFA, and/or IHC are available at https://www.cdc.gov/parasites/naegleria/pdf/Free-Living-Ameba-Testing-Factsheet-508c.pdf. The lab can be contacted by telephone at 404-718-4157, fax at 404-718-4197, and e-mail at CDCFLIALab@cdc.gov.

If submitting formalin-fixed paraffin-embedded specimens, please send your inquiry to pathology@cdc.gov and follow instructions for submission to the Infectious Diseases Pathology Branch.

PCR is also available at other reference labs in the United States:

Mayo Clinic Laboratories, Rochester, MN (800) 533-1710: https://www.mayocliniclabs.com/test-catalog/Overview/64718 (PAM and GAE); https://www.mayocliniclabs.com/test-catalog/Overview/64717 (ocular *Acanthamoeba* infection)

Department of Health, Wadsworth Center, Albany, NY (518) 474-4177: https://www.wadsworth.org/programs/id/idr

California Department of Public Health can also do FLA testing.

Updated information for health professionals is available online:

Acanthamoeba: https://www.cdc.gov/parasites/acanthamoeba/health_professionals/index.html

Naegleria fowleri: https://www.cdc.gov/parasites/naegleria/health_professionals.html

Balamuthia: https://www.cdc.gov/parasites/balamuthia/audience-hcp.html

Since the drug miltefosine plays a role in the treatment of FLAs and is now commercially available (http://www.impavido.com/amoebic-infections), after

discussions with CDC, contact the company directly at 908-635-2326 to expedite delivery of the drug.

Disclaimer The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

Introduction

Over the last decade and a half, left ventricular assist device (LVAD) implantation has emerged as steadfast therapy for patients inflicted with advanced stages of heart failure. Although the continuum of care is more complex than simple dichotomous

designations, currently these mechanical circulatory support (MCS) devices can act as temporary support while a patient awaits heart transplantation (bridge-to-transplant, or BTT), or definitive lifelong therapy (destination therapy, or DT). Large multicenter MCS registries report a progressively increased volume of patients implanted. The International Society for Heart and Lung Transplantation (ISHLT) Registry for Mechanically Assisted Circulatory Support (IMACS) recently reported outcomes from over 14,000 patients from 35 countries between 2013 and 2016 [1]. A recent paper from the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) published outcomes of more than 22,000 LVAD recipients between 2006 and 2016 [2].

The widespread success and generalized acceptance of this therapy have been impacted by the high rates of device-related complications. Although the second and third generations of continuous-flow LVADs (CF-LVAD) have significantly evolved to mitigate complications related to the device, infections continue to be prevalent in this patient population [3, 4].

In this chapter, we will review the patient risk factors, timing and management of infection, and improvements in device design for both durable LVADs (including the HeartMate II, HeartWare HVAD, HeartMate 3, and Jarvik) and temporary LVADs (including the intra-aortic balloon pump, Impella, and extracorporeal membrane oxygenation, ECMO). The latter group has become important in the management of patients with advanced heart failure particularly with the new 2018 United Network for Organ Sharing (UNOS) changes to listing criteria for heart transplant in the United States, in which use of temporary MCS devices is designated with a higher listing status and potentially shorter waitlist time [5].

Types of Mechanical Circulatory Support

Cardiogenic shock affects nearly 50,000 patients annually in the United States and carries more than 40% mortality despite the use of vasopressors, inotropes, and MCS [6, 7]. Temporary cardiac and circulatory support devices are employed to bridge the failing heart toward heart transplantation, durable LVADs, or cardiac recovery. Figure 1 illustrates the different types of temporary (**1a**) and durable (**1b**) MCS.

The intra-aortic balloon pump (IABP) is a catheter-mounted pneumatic pump that can be rapidly inserted at the bedside. Balloon inflation during the diastolic phase displaces blood in the descending aorta thereby proximally augmenting coronary perfusion and distally increasing tissue perfusion. Balloon deflation during systole promotes forward flow and reduces left ventricle (LV) afterload thereby increasing LV stroke volume [8].

The Impella (Abiomed Inc, Danvers, MA) is composed of a set of catheter-mounted axial flow pumps positioned across the aortic valve that continuously displace blood from the LV to the ascending aorta. This family of pumps include the Impella 2.5, CP, and 5.0, roughly providing circulatory support of 2.5 L/min, 3.0–3.5 L/min, and 5.0 L/min, respectively.

The venoarterial extracorporeal membrane oxygenator (VA-ECMO) system consists of a centrifugal pump, a heat exchanger, and a membrane oxygenator. A

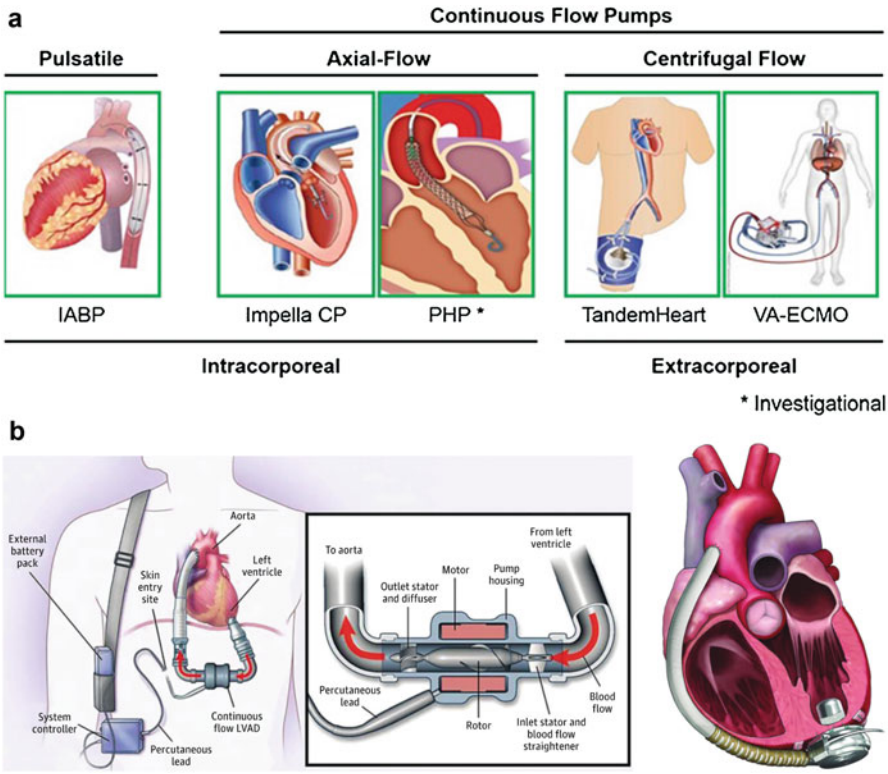

Fig. 1 (**a**) **Types of temporary mechanical circulatory support.** Intra-aortic balloon pump (IABP), Impella axial flow catheter, percutaneous heart pump (investigational axial flow catheter), TandemHeart centrifugal flow pump, and venoarterial extracorporeal membrane oxygenation (VA-ECMO). (Figure adapted with permission from Morine et al. [12]) (**b**) **Types of durable mechanical circulatory support.** (Left) Abbott (Thoratec) HeartMate II axial continuous-flow pump and (right) HeartWare HVAD centrifugal continuous-flow pump. Not pictured, HeartMate XVE and HeartMate 3 devices from Abbott. (Figure adapted with permission from Miller et al. [13])

percutaneous catheter placed in the right atrium or superior vena cava delivers venous blood to the arterial system with a catheter in the descending aorta, using an extracorporeal centrifugal pump. This versatile system provides biventricular circulatory support and provides gas exchange with oxygenation.

The TandemHeart (Cardiac Assist, Inc., Pittsburgh, PA) is an extracorporeal centrifugal pump with inflow cannula placed in the left atrium utilizing a transseptal puncture and an outflow cannula positioned in the femoral artery. This pump reduces LV preload and provides between 3.0 and 5.0 L/min of support.

Durable MCS devices, consisting of ventricular assist devices (VADs), comprise of an inflow cannula surgically implanted in the apex of the LV and pump blood through a motor, either an axial or a centrifugal pump, to the outflow cannula anastomosed to the ascending aorta. There are five main components of a VAD:

the inflow cannula, a pump, an outflow cannula, a percutaneous driveline, and an electrical controller. The pumping chamber is placed within the abdominal wall or intrapericardial space [9, 10]. The percutaneous driveline carries the electrical cable and air vent to the battery packs and electronic control unit, worn either on a shoulder holster or belt. Both second- and third-generation pumps are used today, offering continuous flow for the patient; these have supplanted the first-generation bulky pulsatile pumps (Fig. 1b).

VADs are classified as durable devices because patients can be discharged home on support and can be maintained on these devices for months to years while awaiting transplantation. The second-generation pump, the HeartMate II (Abbott, Pleasanton, CA), has been implanted in over 26,600 heart failure patients [11]. The mechanism of propulsion of blood is based on an axial rotor with a casing unit settling in a surgical pocket underneath the diaphragm. The HeartWare HVAD (Medtronic, Framingham, MA) is the first available third-generation LVAD. This system is directly inserted in the left ventricular apex. The HVAD mechanism of flow is based on a centrifugal system pulling blood from the ventricle and delivering the blood up the outflow cannula. As the newest third-generation device, the HeartMate 3 (Abbott, Pleasanton, CA) has a very similar centrifugal mechanism to the HeartWare HVAD; however HeartMate 3 does have an artificial pulse aimed at washing the housing unit to prevent clot formation.

Current Changes to UNOS Listing Criteria in the United States [14]

The major goal behind the recent changes to the US UNOS listing criteria was to decrease mortality rates for transplant-eligible patients on the waitlist. The previous three-tier system was too narrow to sufficiently prioritize medically urgent cases. The new heart transplant allocation guidelines, introduced October 2018, implemented six tiers with more specific descriptions for each tier. Significantly, LVADs are now seen as viable, long-term alternatives to cardiac transplantation. Advances in LVAD surgical technique, medical management, and patient selection have improved overall patient outcomes [15, 16]. Therefore, stable LVAD patients are listed in Tier 4.

Meanwhile patients on ECMO receive the highest priority, Tier 1. These patients are the sickest and represent the highest mortality on the waitlist. This first tier is followed by patients with a non-dischargeable, surgically implanted device, or the IABP. Consequently, the transplant community is eager to monitor the incidence of usage of the aforementioned temporary MCS devices [5].

There are concerns with the implementation of the new cardiac allograft allocation system, as many believe that prioritizing ECMO patients will result in worse post-transplant outcomes or are concerned with the possibility that hearts will be given to patients who will experience a smaller marginal benefit when compared to other patients. In particular, infectious complications are a concern that potentially could impact post-transplant as well as waitlist mortality. Therefore, centers are urged to be highly selective in listing patients with ECMO or temporary MCS for transplant, even though these patients have the highest priority in the allocation process [5].

Definitions of VAD Infections

With growth in the emerging MCS field, standardization of infection definitions and diagnostic criteria has become paramount. In 2011, the ISHLT commissioned a consensus paper detailing standard definitions to improve clinical communication and facilitate comparison between practices and centers [17]. These definitions – based on the pathophysiology of equivalent infectious processes (e.g., indwelling prosthetic devices and catheter-related infections) – have been divided into three categories as noted in Fig. 2:

VAD-specific infections are directly related to the device hardware such as pump and/or cannula infections, pocket infections, and percutaneous driveline infections (superficial or deep).

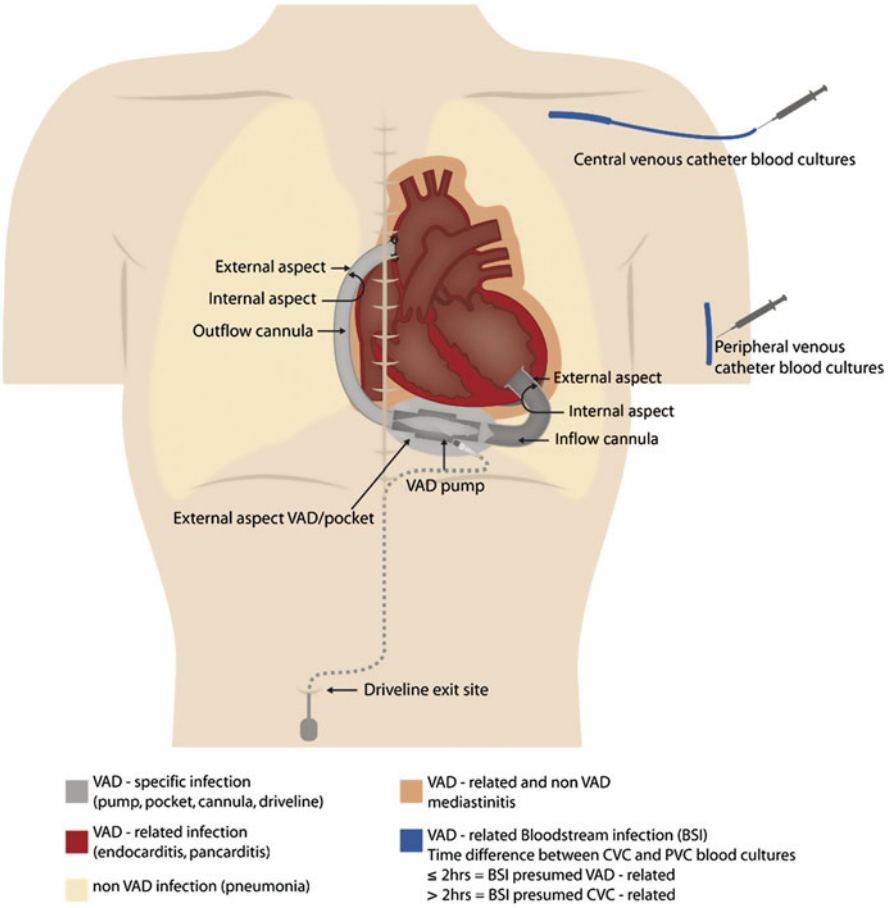

Fig. 2 Categories of LVAD infections. (Figure adapted with permission from Hannan et al. [17])

VAD-related infections warrant special considerations due to the presence of the LVAD, such as infective endocarditis, bloodstream infections, and mediastinitis.

Non-VAD infections are unrelated to the indwelling device and consist of lower respiratory tract infections, cholecystitis, *Clostridiodes difficile* infection, urinary tract infections, and others.

Epidemiology of VAD Infections

The incidence of VAD infections varies depending on the device used and subsequent management. Of the >15,000 patients in the most recent seventh INTERMACS report, infection was the fourth most common cause of death within 1 year after implantation (8.8%), following multisystem organ failure (MSOF, 15.6%), neurologic complications (15.6%), and withdrawal of support (10.4%) [18]. As the incidence of MSOF or withdrawal of support caused by severe infection cannot be delineated in the report, the true incidence of infection leading to death may be underestimated. In the European Registry for Patients with Mechanical Circulatory Support (EUROMACS) inaugural report, infection was the most common major adverse event occurring in 153 of 741 patients (35.3%) and accounted for 23% of the total reported cases of mortality [19].

Of potential device-related complications, infection is a common reason for readmission [20, 21]. Table 1 lists several of the recent studies that report the incidence of infection after VAD implantation. The true incidence of VAD-associated infection is difficult to ascertain, in part due to a relative lack of infectious disease-related variables in larger databases.

As detailed later in this chapter, the transition from pulsatile-flow to continuous-flow devices was associated with a decline in infection rates.

In a global analysis between 2013 and 2015, non-VAD infections were the leading category of infection and the most common within 3 months of implantation [28]. Of 10,171 patients, 4,501 individuals had a non-VAD infection, while 1,756 and 501 patients had VAD-specific infections and VAD-related infections, respectively. Pneumonia, non-VAD-related bloodstream infection, and urinary tract infection were the most common non-VAD infections. It appears the more invasive the pump and power mechanism, the higher the risk of adverse events overall. A meta-analysis comparing IABP to percutaneous VAD (pVAD) noted that although survival benefit was similar with either device strategy, pVADs were associated with more adverse events including infection, acute kidney injury, major bleeding, and vascular injury [29]. ECMO-supported patients harbor the greatest risk of bleeding, cerebrovascular events, and infection. In a Korean study, 23% of ECMO patients were recorded to have nosocomial infections including respiratory tract and bloodstream infections. Independent predictors of infection during ECMO were preoperative creatinine and duration of ECMO support [30]. Similarly, a Chinese study reported a nosocomial infection rate of 25.7% in their cohort of ECMO patients. The majority of cases involved Gram-negative bacterial infections (74.1%) [31]. Finally, in a recent meta-analysis of 2,986 post-cardiotomy ECMO patients, 14.7% of patients were recorded to have deep

Table 1 Recent studies involving LVAD patients with incidence of infection

Study	Number of patients (timeframe)	Device(s) used (no of patients)	Patients in the study with infection (%)
Schaffer et al. [22]	133 patients (Jun 2000–May 2009)	HeartMate XVE (47) HeartMate II [85]	DLI: XVE 19 patients (40%), HMII 28 patients (30%)
Nienaber et al. [22]	247 patients (Jan 2005–Dec 2011)	HeartMate II HeartWare	Total: 78 patients (32.3%) DLI: 37 patients (14.9%)
Hasin et al. [23]	115 patients (Jan 2008–July 2011)	HeartMate II	Total: 25 patients (21.7%)
Slaughter et al. [4]	332 patients (Aug 2008–Dec 2011)	HeartWare	DLI: 56 patients (16.9%)
Simeon et al. [24]	159 patients (2007–2012)	HeartMate II [33], HeartWare [2], Ventracor [1]	Total: 36 patients (22.6%) DLI: 17 patients (10.6%)
Mehra et al. [3]	366 patients (Sep 2014–Nov 2015)	HeartMate II (176), HeartMate 3 (190)	DLI: 79 patients (21.8%) Non-LVAD: 130 patients (36%)
Gustafsson et al. [25]	482 patients (Jan 2015–current)	HeartMate 3	Total: 163 patients (35.2%) DLI: 54 patients (11.7%)
Hanke et al. [26]	27 patients (Jun 2014–Apr 2017)	HeartMate 3	Total 13 patients (48.1%); VAD related 6 patients (24%)
Olmsted et al. [27]	437 patients (May 2009–Mar 2016)	HeartMate II (314), HeartWare (123)	Total: 244 patients (55.8%) DLI: 69 patients (15.8%)

Abbreviations: *DLI* driveline infections

sternal wound infection/mediastinitis [32]. The studies concluded that in order to reduce the incidence of ECMO-associated infections, preventative strategies should be employed to shorten the duration of ECMO support.

Microbiology

Despite the evolution of VAD management and device design, pathogens implicated in infections have not changed over time. The percutaneous driveline is a common portal of entry for these organisms. The most common organisms, *Staphylococcus aureus* and *Staphylococcus epidermidis*, are responsible for more than 50% of MCS infections. These pathogens are present on the skin and adhere to indwelling devices creating a biofilm [33–35]. *Enterococcus* species are the next most common Gram-positive organism [23]. The most common Gram-negative bacteria are *Pseudomonas aeruginosa* (22–28%), followed by *Enterobacteriaceae* such as *Klebsiella* species (2–4%) and *Enterobacter* species (2%) [23].

While the prevalence of fungal infection is low, high morbidity and mortality are associated with this type of organisms due to the difficulty in achieving eradication. Candidemia has been reported in 1.3–9.7% of VAD recipients; fungal VAD infections carry an overall mortality of up to 90% [36, 37]. The most common fungal pathogen is *Candida albicans* (70%), followed by *C. glabrata* (10%) [23].

Pathogenesis

Bacterial and fungal organisms infecting cardiac devices rapidly form biofilms which are difficult to eradicate with antimicrobial therapy alone. A biofilm consists of microbial cells that are adherent to the underlying device surface and encased within an extracellular polysaccharide matrix [38, 39]. This protective mechanism of growth allows survival in otherwise hostile environments; thereby organisms within a biofilm behave in a fundamentally different manner than their free-floating (planktonic) counterparts [34]. In fact, gene expression profiling and proteomic techniques, used to compare organisms in a biofilm and planktonic organisms, have revealed significant differences in gene and protein expression [40, 41]. The extracellular polysaccharide matrix offers a distinct advantage by preventing the penetration of opsonizing antibodies and mitigating the phagocytic ability of macrophages. Additionally, organisms in a mature biofilm diminish the efficacy of antibiotics due to (1) slower rate of division, (2) centralized density of pathogens within the biofilm, (3) changes in bacterial metabolism, and (4) antimicrobial resistance due to proximity-facilitated bacterial conjugation [42, 43]. These mechanisms lead to increased difficulty in organism eradication, often necessitating prolonged courses of antibiotic administration or, ultimately, device removal. Moreover, the minimal inhibitory concentrations for organisms within a biofilm can be approximately 1,000-fold higher than the planktonic counterparts [34]. A recent study evaluated biofilm formation and migration using a drip-flow reactor assay. This study revealed that *P. aeruginosa* and *C. albicans* have the greatest biomass compared to other organisms, highlighting that different pathogens appear to have a propensity to different components of the driveline. Finally, as these protective properties of mature biofilm deem these organisms extremely difficult to eradicate, patients with infected devices may experience prolonged bridge-to-transplant VAD waiting period and worse post-transplant outcomes [44].

Risk Factors for Infections

The body of literature describing risk factors for VAD-related infections is based on limited retrospective analyses. A recent systematic review and meta-analysis of studies revealed younger age and higher body mass index (BMI) were associated with higher rates of VAD infections [45, 46]. Diabetes mellitus (DM) is often a comorbidity with advanced heart failure. Sepsis was found to be higher in diabetics based on retrospective studies of patients undergoing LVAD implantation [46, 47]. The Ventricular Assist Device Infection Study Group prospectively evaluated preoperative indices and noted both depression and elevated baseline serum creatinine were independent predictors of VAD infection [48].

Malnutrition is a significant comorbidity in advanced heart failure patients. Comprehensive preoperative evaluation of nutritional status, including measurements of albumin and BMI, has been shown to be essential in managing heart failure patients [49, 50]. The immune system is attenuated in patients on VAD support and

Table 2 Risk factors for infection in patients with VAD

Extremes of age	Intravascular lines	Organisms capable of biofilm formation
Diabetes mellitus	Delayed sternal closure	T-cell dysfunction associated with the device
Renal failure, hemodialysis	Longer ICU stay	Hypogammaglobulinemia
Malnutrition	Prolonged duration of device support	Trauma to the driveline
Obesity	Concomitant surgery at the time of VAD placement	Severity of heart failure (i.e., cardiogenic shock)
Depression	Frailty	

therefore plays an even more important role in infection risk. This occurs primarily due to cytokine downregulation and emergence of suppressive T-regulatory cells regardless of the age of the patient [51]. Quantitative immunoglobulin G (IgG) levels were evaluated in a bridge-to-transplant cohort, and it was found that hypogammaglobulinemia (HGG) is associated with an increased risk of infection [52]. Table 2 summarizes risk factors for infection in patients with VAD.

Perioperative technique has a significant influence on the risk of infection. Registry analysis was performed comparing outcomes in patients with the HeartMate II device placed utilizing a surgical tunneling technique to keep the entire driveline (DL) velour portion in the subcutaneous tunnel, resulting in a silicone-skin interface (SSI) at the exit site, as opposed to patients with device placement via the velour-to-skin method used in the HMII DT trial [53]. The results demonstrated that leaving the entire DL velour portion below the skin was associated with at least a 50% reduction in DL infection compared to the standard procedure. In a related study, patients implanted with HMII at a single institution were divided between two eras: the externalized velour era (2008–2009) and the externalized silicone era (2010–2011) [54]. Externalization of only the silicone portion of the DL led to a significant reduction in infections, 44% in the externalized velour group vs 8.8% in the externalized silicone group ($p<0.05$). Delayed sternal closure in patients with coagulopathy, hemodynamic instability, or isolated right ventricular dysfunction has been associated with longer ICU stays but does not significantly increase the risk of infection or death [55]. Other studies have shown prolonged ICU stay after implantation, and longer duration of VAD support is associated with an increased risk of infection [56, 57].

Evolutions in design and device selection play a role in the risk of infection as well. The early-generation pulsatile-flow LVAD (PF-LVAD), HeartMate XVE pump, was crippled by infection among other complications. In retrospective analyses of the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial and HeartMate XVE registry, sepsis was the leading cause of death in patients with PF-LVAD, accounting for 29.5–41% of deaths [58, 59]. Although the study was based on patients not eligible for transplant, the data reveal how infections plagued the earlier devices.

New-generation continuous-flow LVADs (the axial pump HeartMate II and the continuous-flow pumps HeartWare HVAD and HeartMate 3) have been the most widely available devices in the last decade owing to the enhanced design, smaller device pocket, and lower complication profiles. In the HeartMate II BTT study, sepsis accounted for 20% of deaths at 6 months, while retrospective analyses illustrate lower incidences of infection in both newer-generation devices compared to the predecessor device [60–62].

As noted earlier, the percutaneous driveline is a common portal of entry for microbial pathogens. Many VAD-related infections occur early after implantation before the driveline site has fully healed and integrated into the host tissue. Factors that impair healing, such as excessive movement or trauma at the exit site, poor nutritional or overall status of the patient at the time of implantation, and diabetes mellitus, can all increase the likelihood of driveline infections.

Finally, the daily care provided by patients and their caregivers is crucial in attenuating infection risk. Disruption of the seal between the driveline and adjacent skin, primarily through pulling of the driveline, has been reported as a common cause of infection [63].

Strategies for Prevention

The prevention strategies involved in curbing VAD infection rates are multifaceted but can be divided into four targeted categories [64]:

1. *Preoperative risk factor modification*: Management of modifiable risk factors include weight loss in obese patients, nutritional optimization in malnourished patients (e.g., enteral feeding tube), euglycemia in patients with diabetes mellitus, complete treatment of open wounds, minimizing the use of urinary and vascular catheters, and using tunneled catheters when vascular access is needed for more than 14 days. A full screening of active infections along with a full dental evaluation in those with poor dentition is also recommended.
2. *Antibiotic prophylaxis at time of surgery*: Although no randomized trials exist to guide the use of antibiotics and antifungals, in VAD recipients, an ISHLT consensus recommendation included anti-staphylococcal agents (e.g., vancomycin or cefazolin) as prophylaxis for a maximum period of 48 h postoperatively [64]. This was based on studies of prophylaxis in cardiac surgery patients in general.
3. *Surgical techniques*: Driveline tunneling technique has evolved with subsequent LVAD generations. The new standard of care involves tunneling of the velour portion of the DL into the subcutaneous tissue. As noted earlier, this technique is associated with a substantial reduction in DL infection [54]. A minimally invasive, lateral thoracotomy approach to spare the sternum has shown

to decrease infection risks when compared to the median sternotomy, albeit without significant impact on survival, though this remains investigational at present [65, 66].

4. *Long-term driveline management strategies*: Current recommendations include extensive patient and caregiver education to prevent VAD driveline-related trauma (e.g., dropping the battery), DL immobilization using a binder or anchoring device immediately postoperatively, aseptic dressing change techniques (in accordance with institutional policies) using sterile gloves and mask, and the use of chlorhexidine as a cleaning agent at the DL exit site [64].

Clinical Outcomes

Survival after heart transplant is similar for patients with or without VADs leading up to the transplant [67]. Other studies note that patients with VAD infection can be transplanted successfully as well [46, 56, 68].

Infection is the fourth most common cause of death in patients with durable VADs within 1 year and steadily rises over a 4-year follow-up period [18]. Device infection often presents as a spectrum of disease progression. Superficial DLI may evolve over time to become deep tissue infection, and those with deep tissue infection are more likely to develop bacteremia [69, 70]. DLIs are the most common VAD-specific infection. Superficial DLIs may be treated with a 2-week course of antibiotics. However, deep DLIs generally require prolonged intravenous antibiotics as well as suppressive therapy as they are difficult to eradicate. Suppressive therapy is generally continued until transplantation. Intraoperative cultures at the time of transplant surgery may be used to guide the selection and duration of post-transplant antibiotics. Bloodstream infections are less frequent but are associated with increased incidence of cerebrovascular events and mortality [71]. Deep DLIs can be associated with BSIs as well.

The timing of infection after LVAD implantation influences the type of infection. Initial infections within the first 3 months of device implant tend to be nosocomial infections that are common in a critical care setting [28]. Among nosocomial infections, pneumonia was the leading cause, followed by bloodstream infection (BSI), urinary tract infection (UTI), and gastrointestinal (GI) infection. Early DL infection within 3 months of implant may be directly related to the implant surgery. Generally, outside of this time period, device-specific and related infections tend to be more prevalent. The risk of infection increases as a function of time on device support, and this is particularly true of DL infection [28].

The infecting organism also may differ depending on duration of time elapsed after LVAD implantation [72]. In one study, patients were divided into two groups: early ($<$180 days) and late ($\geq$180 days). Superficial driveline-related infection was the most common type of infection in both groups, whereas driveline drainage

was more prevalent in the late group. *S. aureus* was the most commonly isolated organism in early VAD infection (69% vs 33%, p = 0.049), while *P. aeruginosa* was the most prevalent bacteria in late VAD infection (25% vs 57%, p = 0.045). And as expected, deeper infections were associated with worse outcomes, but the overall mortality in this study was extremely high (13% vs 46%, p 0.046).

In a Taiwanese study of all infected ECMO patients in the national hospital system, pneumonia accounted for 50%, while primary bloodstream infection accounted for 15%. The primary pathogens were evenly attributed to Gram-negative bacteria, *Enterobacteriaceae*, and Gram-positive cocci [73].

Management of Infection

Without randomized, controlled studies, the principles governing guideline-based therapies are limited to observational data and expert opinion. In a consensus document, a formal infectious disease consultation is recommended in VAD patients with proven or suspected infection. The overall management goals should include evaluation of the extent of infection as well as microbiologic identification of the causative organism [65]. The general approach to infection management is detailed in Table 3.

Basic laboratory testing, microbiologic cultures, and imaging studies are recommended. Computed tomography (CT) and ultrasonography (US) of the chest and abdomen, although lacking in specificity, are endorsed as initial imaging modalities to assist in identifying deep DLI as well as abscess. Single-photon emission computed tomography scans (SPECT) with radiolabeled leukocytes can improve both sensitivity and specificity and therefore can be considered as additional diagnostic modalities [74–77]. A recent paper demonstrated the feasibility of [18] F-fluorodeoxyglucose positron emission tomography/computed tomography (FDG PET/CT) for the diagnosis of left ventricular assist device (LVAD) infection as well [78].

Once an infection is suspected, empiric antimicrobial therapy against *Staphylococcus* species and *P. aeruginosa* should be started promptly. As illustrated in Table 3, in patients with infection limited to the superficial plane without systemic signs of sepsis, cultures of the DL should be collected followed by antibiotic therapy for 2 weeks. Patients with deeper infection (e.g., driveline, pocket infection, pump, cannula infection, systemic illness, or sepsis) should be hospitalized and prompt a procedure of surgical drainage with consideration for wound vacuum-assisted closure (VAC) system [79, 80]. In patients with pump and cannula infections, persistent bloodstream infection, septic emboli, or sepsis despite adequate antimicrobial or drainage therapy, device explant may be considered. Device removal/heart transplant remains the definitive cure of a VAD-specific infection [81–83].

Procalcitonin (PCT) has been widely used to assist in antibiotic stewardship in bacterial infection. However, a study in VAD patients noted that PCT levels in this population were not correlated with infection but serial changes may have been related to postoperative inflammation [84].

Table 3 Management of VAD-specific and VAD-related bacterial infections [64]

Infection types	Medical management	Surgical management
VAD-specific		
Superficial DLI	Treat with IV or PO antibiotics for a minimum of 2 weeks or until infection has resolved (drainage, redness, tenderness, etc.)	None
Deep DLI/pocket infection	Treat with IV antibiotics until clinical stabilization and improvement of infection (usually 6 to 8 weeks), followed by long-term PO suppression therapy	Surgical debridement and/or abscess drainage and wound VAC as necessary. New drive-line exit site from previous infected tract may be required
VAD pump and/or cannula	Treat with IV antibiotics for at least 6–8 weeks. If bacteremia resolves, recommend PO suppression until transplantation in BTT patients. Check intraoperative cultures: If positive, recommend 4–6 weeks of IV antibiotics following transplantation If negative, recommend 2 weeks of PO antibiotics following transplantation	Surgical drainage and debridement may be required to control infection. Source control: BTT: explant the device for HT DT: explant/exchange device for control of infection
Persistent bacteremia, relapsing infection, septic emboli, sepsis despite adequate antimicrobial/ surgical therapy	BTT: IV antibiotics should continue until after HT. Base duration and route of antibiotics on intraoperative cultures DT: IV antibiotic treatment is followed by long-term PO antibiotic suppression; if at times PO options are not available, IV therapy is continued beyond 8 weeks. Duration of antibiotic treatment after device exchange depends on the clinical course and pathogen. A longer course (4–6 weeks) should be offered with positive intraoperative cultures or recent preoperative bacteremia, and a shorter course (14 days) may be offered in the absence of such conditions	Strong consideration for device explant/exchange. One could consider bridging patients with a percutaneous device to achieve infection control prior to VAD exchange

(continued)

Table 3 (continued)

Infection types	Medical management	Surgical management
VAD-related		
Bacteremia	Duration of antibiotics depends on the source, organism, and clearance of bacteremia *S. aureus*: treat for 4–6 weeks and remove catheter *S. aureus* negative, blood cultures negative within 24–48 hrs without signs of metastatic infection: 2 weeks from first negative blood culture may be adequate (e.g., urinary tract source) No identifiable source: treatment may be considered as with VAD pump and cannula infection	
Bacterial mediastinitis	Duration of antibacterial therapy is at least 6 to 8 weeks after last surgical debridement	Surgical debridement is often indicated. Open chest and VAC wound closure may be required
Infective endocarditis	Duration of antibacterial therapy is the same as for MCS pump and cannula infection	Surgical intervention may be required

Significant Circumstances

Multidrug resistant (MDR) bacteria. MDR bacterial infections lead to longer intensive care unit stay ($p < 0.0001$) and longer cumulative hospital stay ($p = 0.04$) in patients with VADs. Colonization with MDR bacteria leads to a higher risk of infection-associated death as well [85].

Fungal infection. Although fungal infection such as fungemia, necrotizing pulmonary aspergillosis, and *Aspergillus* device infection are rare, the potential devastating and fatal complications after VAD implantation warrant some attention. A retrospective review of 292 patients receiving VAD support between 1996 and 2009 revealed only seven cases of VAD-associated fungemia: five patients with *Candida* species and two with *Aspergillus* species [86]. The latter two succumbed to multiorgan failure and sepsis, while all five patients with *Candida* infections were successfully treated with systemic antifungal therapy leading to transplantation in four of the five. The last patient remained on DT support at the publication of the review. In a separate case report, a patient with necrotizing pulmonary aspergillosis and device involvement was successfully treated by segmentectomy and prolonged antifungal treatment without device exchange or removal [87].

Post-heart Transplant Outcomes in VAD Infection

Patients with a history of device infection are at increased risk of infectious complications following heart transplantation. Studies have shown patients with pre-transplant DLI predict post-transplant infection and increased overall post-transplantation hospital length of stay; however, post-transplant survival risks may vary [70, 73, 74, 88].

Two large recent analyses report a decrease in survival in VAD patients with pre-transplant infections. A retrospective analysis of UNOS database involving 15,253 patients listed as status 1A (the highest status in the previous listing algorithm) noted that patients with pre-transplant device infection had increased mortality compared to those without complications [89]. A recent meta-analysis including 6,067 LVAD patients demonstrated increased post-transplant mortality in patients with a VAD infection (hazard ratio [HR] 1.30, 95% CI: 1.16–1.46, $p < 0.001$) [90].

Cerebrovascular Risk in VAD Infection

Cerebrovascular accident (CVA) remains one of the most devastating complications in VAD patients, with high associated morbidity and mortality. Bloodstream infections (BSI) have been shown to be associated with CVA in recent reports. This was first described in the continuous axial pump population (HeartMate II) in which patients with VAD and bacteremia were found to have a much greater incidence of CVA compared to those without BSI (43.3% vs 10.0%, $p < 0.0001$), carrying an eightfold increase in risk (OR 7.9, [CI] = 2.4–25.5; p 0.001], compared to VAD patients without BSI [91]. In particular, *P. aeruginosa* BSI are associated with hemorrhagic CVA [92–94]. A recent INTERMACS analysis of 16,597 CF-LVAD recipients reported that infected VAD patients had a significantly higher prevalence of CVA compared to patients without an infection (18% vs 11%, $p < 0.001$). Of the three ISHLT categories of infection, VAD-related infections were associated with the highest risk for CVA, followed by non-VAD related and then VAD-specific infections.

Conclusions

We reviewed current MCS devices used as a bridge to transplant in patients with heart failure including VADs, percutaneous cardiac support devices, and ECMO. Most of the current literature regarding infection in MCS is in patients with VADs; definitions, microbiology, prevention, and management strategies specific to VADs are discussed in this chapter. Given an increase in the use of percutaneous devices and ECMO as a bridge to transplant, there is a need to study infections in this population and in particular a need to study post-transplantation outcomes.

Key Points

1. Infections in patients with ventricular assist devices (VADs) are categorized as VAD-specific (driveline, pump, pocket), VAD-related (bacteremia, mediastinitis, infective endocarditis), and non-VAD–related infections (urinary tract infections, *Clostridioides difficile*, among others).
2. Patients with temporary mechanical circulatory support devices, such as intra-aortic balloon pump, percutaneous VAD, and extra-corporeal membrane oxygenation (ECMO), have high rates of infection.
3. *Staphylococcus aureus* and *Pseudomonas aeruginosa* are key pathogens that cause VAD infections, and initial empiric therapy should include agents active against both.
4. Strategies to prevent VAD infections are modification of pre-operative risk factors, antibiotic prophylaxis at the time of surgery, change in surgical practices (such as externalization of the silicone portion of the driveline, modification in thoracotomy approaches), and driveline exit site management.
5. Management of deep driveline, pump, pocket, and other complicated VAD-related and VAD-specific infections consists of prolonged courses of intravenous antibiotics followed by suppressive therapy till transplant.
6. Bloodstream infections in VAD recipients are associated with cerebrovascular complications.

Introduction

Cystic fibrosis (CF) is an autosomal recessive genetic disorder of salt and water transport stemming from a defect in the cystic fibrosis transmembrane conductance regulator (CFTR) chloride channel. It is a multisystem disease due to the near-ubiquitous expression of the *cftr* gene, though the pulmonary manifestations tend to be the main driver of survival. As of 2018, the predicted median survival for individuals with CF was 47.4 years [1].

Lung transplantation remains an integral therapy in the spectrum of CF disease management with about 16% of all lung transplants being performed for CF[2]. CF-related liver disease, while prevalent, progresses to end-stage liver disease requiring liver transplantation at lower rates compared to the lung disease. Only 52 simultaneous lung-liver transplantations were performed in the United States between 2005 and 2016; internationally that number was 108 in a similar time period (2004 to June 2017) [2, 3].

The changes in airway surface liquid hydration, defective mucociliary clearance, and altered airway inflammatory responses in CF result in airway colonization with a plethora of microorganisms, most characteristic of which is *Pseudomonas aeruginosa*, especially of the mucoid phenotype [4]. Other bacterial pathogens such as *Staphylococcus aureus*, *Burkholderia* spp., and Stenotrophomonas, fungal pathogens such as *Aspergillus* spp. and *Scedosporium* spp., as well as non-tuberculous mycobacteria comprise the rich microbiome of CF airways [5]. When combined with the immunosuppression needed for management of transplant allograft survival, unique infectious challenges arise in for CF patients. Furthermore, these issues require thoughtful, multidisciplinary approaches to transplant candidate selection, pretransplant CF disease management, perioperative antimicrobial selection, and posttransplant surveillance.

While the full spectrum of infections in CF transplant recipients is beyond the scope of this chapter, we will focus on particularly challenging infections and their management from a transplant perspective, novel approaches to widely drug-resistant species, and CF-specific considerations.

For a more detailed discussion on antimicrobial resistance, please refer to ► Chap. 14, "Multidrug-Resistant Organisms: Posttransplant Management for Extended-Spectrum Beta-Lactamase Producers and Carbapenem-Resistant Enterobacterales."

MDR/XDR Organisms

Before we discuss specific pathogens of interest in the CF transplant population, it is worth noting that while often considered a relative contraindication to lung transplantation, the presence of multidrug-resistant bacterial pathogens is generally not deemed a contraindication at larger or more experienced transplant centers, as long as a suitable antimicrobial plan can be devised that is both active against the pathogen in question and tolerable by the patient.

There is a lot of heterogeneity in how terms relating to degree of resistance are used. However, we suggest adhering to standardized nomenclature [6, 7]: Multidrug-

resistant (MDR) pathogens are thus those with non-susceptibility to at least one agent in three or more antimicrobial categories, extensively drug-resistant (XDR) pathogens are those with non-susceptibility to at least one agent in all but two or fewer antimicrobial categories, and pan drug-resistant (PDR) pathogens are those with non-susceptibility to at least one antimicrobial in all categories.

With this distinction in mind, several studies have failed to show a significant deleterious impact of pan-resistant organisms on long-term survival after lung transplantation. For instance, while CF lung transplant recipients with PDR *Pseudomonas aeruginosa* had worse overall survival compared to those with sensitive organisms in a two-center study, the survival of the PDR group was no different from that of non-CF lung transplant recipients in the United Network of Organ Sharing (UNOS) registry [9]. Death was attributable to the PDR Pseudomonas only in 3 out of 45 patients in the study group in that study. A large single-center study assessing the same question found similar outcomes between CF patients with PDR Pseudomonas and those with sensitive pathogens [8]. Using data from the CFF and UNOS registries, Pseudomonas infection was not found to be an independent predictor of mortality post-lung transplant [10]. Similar results were found when analyzing outcomes in CF patients infected with *Achromobacter xylosoxidans* and *Stenotrophomonas maltophilia*; their outcomes were similar to non-cepacia CF lung transplant recipients [11].

This is not to say that non-cepacia PDR organisms are necessarily safe. Growing evidence suggests that chronic lung allograft dysfunction (CLAD), an umbrella term describing chronic rejection and graft loss post-lung transplant, is linked to airway colonization with Pseudomonas posttransplant, especially in patients with CF [12].

Burkholderia

Epidemiology

Burkholderia cepacia complex (Bcc) was named after a plant pathologist at Cornell University, Burkholder, who discovered the organism in 1949 [12]. It was first described as pathogenic in humans in the 1950s. Bcc is a ubiquitous aerobic Gram-negative bacillus commonly found in water, soil, and moist environments and is composed of up to 20 closely related bacterial subspecies also referred to by genomovars [13–15]. Bcc is a common colonizer of the upper and lower respiratory tract in CF patients and frequently carries multidrug resistance. The most common causes of Bcc colonization and infection in CF patients are *B. cenocepacia* (genomovar III) and *B. multivorans* (genomovar II) [14].

For a more detailed discussion on Burkholderia, please refer to ▶ Chap. 17, "*Burkholderia* in Transplant: Important to Speciate and Important to Treat."

It is important to recognize that horizontal transmission of Bcc can occur directly via person to person contact or indirectly through droplet or fomite transmission. Several Bcc outbreaks have been described due to contaminated medications,

medical products, and equipment [15]. However, due to stringent contact precautions and infection prevention strategies the Cystic Fibrosis Foundation has actually reported a decrease in the prevalence of Bcc respiratory infections in CF patients in the United States from 3.6% in 2006 to 2.6% in 2018, suggesting that local level controls can be impactful [16, 17].

Clinical Impact in Transplant

Early studies of CF patients colonized with Bcc demonstrated increased morbidity and mortality in the posttransplant period. However, additional studies and identification of specific Burkholderia genomovars suggest that the increased posttransplant mortality is associated primarily with *B. cenocepacia* (genomovar II) and not *B. multivorans* (genomovar II) or other subspecies [18]. *B. cenocepacia* is associated with accelerated decline in lung function in CF patients prior to transplant, early recurrence in the allograft leading to declining lung function, as well as significant antimicrobial resistance patterns all contributing to increased morbidity and mortality [15]. In one study, *B. cenocepacia* colonization in the pretransplant period led to 1-year and 5-year survival of 68% and 48%, respectively, versus 94 and 74%, respectively, for *B. cepacia* negative CF patients [19].

Patients with CF who are colonized with Bukholderia other than subspecies cenocepacia have rates of survival, rejection, and bronchiolitis obliterans syndrome (BOS) similar to the general CF population. As a result of better understanding and identifying the *B. cepacia* genomovars, only *B. cenocepacia* continues to be regarded as a relative contraindication to lung transplant due to the associated early mortality [14].

Diagnostics and Clinical Evaluation

All CF patients who are undergoing lung transplant evaluation should have sputum samples obtained in the pretransplant period to identify colonization and guide antimicrobial therapy in the perioperative period. As with all organisms with the potential for multidrug resistance, antibiotic susceptibility testing should be completed ahead of transplant to guide perioperative antibiotics.

Management

Once Bcc is established in the airways of a patient with CF for more than several months, the organisms persist despite aggressive attempts at eradication [20]. Removal of any indwelling intravenous catheters as is common in the CF population is generally recommended at the time of transplant. If a patient has concomitant sinus disease with known colonization of the lower respiratory tract, consideration for early sinus surgery and intervention is recommended, in order to minimize the

burden of bacteria before the introduction of immunosuppression. Although this is our specific practice, granular data to support the advantage of sinus debridement ahead of transplant for Burkholderia specifically is lacking.

In general, parenteral trimethoprim-sulfamethoxazole has been the drug of choice against Bcc in combination with additional intravenous therapy [21]. Synergistic effects as well as the potential for emerging resistance with monotherapy suggest that treatment should include at least two parenteral antimicrobial agents. Two-drug combinations of parenteral trimethoprim-sulfamethoxazole plus a β-lactam (ceftazidime, piperacillin, meropenem) or a fluoroquinolone should be considered [21].

Early review of susceptibility testing as well as drug allergies in the pretransplant evaluation process should be completed in order to devise a patient-specific treatment plan prior to listing for transplantation. The optimal duration of therapy is not known; however, extended therapy for 4–6 weeks in the perioperative period depending on additional patient-specific factors is generally recommended.

It is for these reasons that CF patients who are found to be colonized with Bcc prior to transplant should be evaluated at transplant centers with experience in managing such patients with a multidisciplinary approach including a specialized transplant infectious disease physician.

Scedosporium

Epidemiology

Scedosporium species are ubiquitous, filamentous fungi found in soil and water sources with a global distribution and are the second most common cause of fungal infection in organ transplant recipients; Aspergillus species being the most common [22]. Infections in humans are primarily acquired by direct inhalation to the sinuses and respiratory tract or direct inoculation by skin puncture. The majority of infections are due to two species: *Scedosporium apiospermum* and *Lomentospora prolificans* formerly *Scedosporium prolificans* [23, 24]. For the purpose of this chapter we will consider both together. *S. apiospermum* complex has greater response to azole therapy as compared to *L. prolificans* which has significant resistance to antifungal therapies.

The role and pathogenicity of Scedosporium are controversial. Immunocompetent patients colonized with Scedosporium may not manifest true infection, although allergic bronchopulmonary disease and rare infections have been described [22]. However, patients with underlying sinus disease, bronchiectasis, viscous secretions, and impaired mucociliary clearance as is common in cystic fibrosis (CF) are especially at risk for colonization and infection.

Clinical Impact in Transplant

Scedosporium in immunocompromised patients after lung transplantation has a variety of clinical presentations ranging from asymptomatic colonization of the

respiratory tract to life threatening infections if unrecognized and without appropriate timely therapy. The presence of Scedosporium species found in bronchoalveolar lavage has been associated with bronchiolitis obliterans and airway stenosis, especially if anatomical issues support its growth. A bronchial anastomosis that becomes telescoped in on itself, for example, is at high risk for the development of fungal infection due to the poor delivery of systemic antifungal agents [25]. Other infections associated with Scedosporium include pneumonia, disseminated blood stream infection, endophthalmitis, keratitis, central nervous system infections, skin and soft tissue infections, as well as osteomyelitis [26].

For a more detailed discussion on skin manifestations in transplant patients, please refer to ▶ Chap. 63, "Rashes to Recognize in the Immunocompromised Transplant Patient: Focus on the Solid Organ Transplant Recipient."

Due to the association with increased morbidity and mortality, some centers consider Scedosporium colonization a contraindication to lung transplant, even though patients have been transplanted with reported successful outcomes. This is especially true for *L. prolificans* where 31% of respondents to a multicenter survey said this would be a contraindication at their center [27]. Despite being recognized as an emerging opportunistic pathogen, the reported data on management and outcomes of scedosporial disease in the CF population after lung transplantation remain scarce.

In a single-center 15-year experience published in 2017 [22], the clinical outcomes of 14 patients with CF colonized by Scedosporium species following lung transplantation were described. Nine patients were colonized prior to transplantation, five were colonized in the posttransplant period, and only two were colonized with *L. prolificans*. The patients were all treated with an azole, either voriconazole or posaconazole. Only one patient who was colonized prior to transplantation developed significant scedosporial disease. Among the remaining eight patients colonized prior to transplantation, the median survival was 1.92 years (range 0.21–12.5 years) and death was due to unrelated causes. All but one became free of fungal colonization with treatment. For the five patients colonized in the posttransplant period, the median survival was 1.75 years (range 0.1–13 years).

This highlights the importance of early recognition of Scedosporium as well as initiation of azole therapy in the pre- and post-lung transplantation period, thereby decreasing the progression from colonization to Scedosporial disease and achieving fungal clearance. It is important to observe that pretransplant colonization was not a risk factor for increased morbidity and mortality in this series.

Diagnostics and Clinical Evaluation

The diagnosis and clinical evaluation for Scedosporium species is patient specific. Proven invasive mold infection is defined as histopathology consistent with tissue invasion and a culture result positive for mold or clinical or radiographic findings consistent with infection and a positive culture for mold obtained using sterile technique from a normally sterile site [28]. Additional pieces of softer supportive evidence can be obtained by looking at whether KOH staining is positive

on bronchoscopic sampling of the lower respiratory tree, and whether the fungal culture represents a single isolate or multiple isolates found repeatedly on multiple days.

Specimens including transbronchial biopsies and bronchoalveolar lavage as well as radiographic evidence for fungal disease should be routinely obtained whenever a clinical suspicion for infection exists. They are also variably obtained in centers where scheduled bronchoscopies occur post lung transplant, in which case preemptive therapy can sometimes be initiated. It is important to note that positive cultures may represent colonization rather than true disease, though both may warrant initiation of therapy in the context of enhanced immunosuppression. Additionally, in patients with identified Scedosporium in the lower respiratory tract, a thorough investigation of the sinuses and upper respiratory tract is again warranted to identify the extent of involvement. In the CF population, radiographic evidence of sinus disease combined with a positive Scedosporium sinus culture is diagnostic.

Fungal blood cultures are used in identification of disseminated disease in the appropriate clinical context post-transplant. Noninvasive tests include beta-D-glucan, which is a cell wall constituent of many fungi including Scedosporium. However, the diagnostic accuracy of this test for Scedosporium infections is not yet known, nor is it validated in CF or solid organ transplant recipients.

Management

Susceptibility testing from isolates should be used in guiding therapy in addition to regular therapeutic drug monitoring. The optimal choice and duration of therapy is unknown. In patients who are receiving immunosuppressive therapy, we recommend reducing the immunosuppressive therapy when feasible and clinically appropriate.

Scedosporium Apiospermum

Voriconazole is a broad spectrum triazole agent that is fungicidal for the majority of *Scedosporium apiospermum* isolates. Posaconazole also shows activity against *Scedosporium apiospermum*; however, voriconazole has demonstrated greater in vitro activity [29]. Originally, the food-dependent absorption of posaconazole, particularly in CF patients with pancreatic insufficiency, limited its activity, with drug levels demonstrating unreliable bioavailability [26]. However, newer formulations of posaconazole have made this less of an issue, and for now, voriconazole remains an ideal first-line agent in the CF population due to lower MIC's. It should be noted that isavuconazole has shown in vitro activity against some isolates of *S. apiospermum* and could also be considered in the treatment based on susceptibility testing [30]. Echinocandins have variable activity depending on the species and are generally not used as first-line treatments [31]. Perhaps most importantly, *S. apiospermum* is essentially always resistant to amphotericin B products.

Lomentospora (formerly Scedosporium) Prolificans

L. prolificans presents greater challenges to treatment, as it is resistant to most antifungal agents. As a result, combination antifungal therapy is often used. Although studies have shown poor in vitro potency of terbinafine monotherapy against Scedosporium species, the combination of terbinafine with voriconazole or itraconazole when used against *L. prolificans* in vitro has demonstrated synergistic activity [26]. Synergy has also been described with the combination of voriconazole plus terbinafine with the addition of micafungin although all these approaches should be considered salvage [32].

Given the potential for increased risk and complications associated with delayed identification and treatment of Scedosporium, the rarity of these infections, as well as the resistance associated with *L. prolificans*, a skilled multidisciplinary team approach involving an infectious disease specialist is recommended. Therapy should be tailored to the individual patient including surgical debridement when indicated as well as optimization of the patient's immunosuppression in order to achieve the best clinical response to treatment. Antifungal sensitivity patterns should also be sought, although these will often require subspecialty mycology laboratory services, and may not be available to all centers.

Mycobacterium Abscessus

Non-tuberculous mycobacteria (NTM) are particularly challenging in the CF population, especially in the context of immunosuppression posttransplant [33]. They appear to be on the rise nationally, with regional variation. Almost 20% of all CF patients with end-stage lung disease referred for transplant evaluation will have NTM-positive sputum cultures [34]. The combination of difficult-to-eradicate NTM from advanced bronchiectatic airways, high toxicity and side effect burden of available antimicrobial agents, and potentially serious morbidity and mortality of untreated NTM requires a thoughtful, multidisciplinary approach to NTM. Here we will focus on *M. abscessus* infections, as they remain controversial in the management of patients with CF peri-transplant. This is perhaps best highlighted by the fact that the reported prevalence of *M. abscessus* among lung transplant recipients tends to hover around only 1–2%.

Historically, *M. abscessus* infections have been considered to be relative contraindications to lung transplantation due to the risk of dissemination and poor outcomes posttransplant [35]. Indeed, several instances of fatal and nonfatal disease disseminations following lung transplantation have been reported in the older literature. In an international survey of 31 transplant centers, for instance, 17 patients with *M. abscessus* infections were identified. Seven mortalities were reported, only two of which were attributable to *M. abscessus* [36].

More recent literature, however, shines a more optimistic light on transplantation outcomes with *M. abscessus* infections. It should be noted that most of the available data are in the form of single-center retrospective analyses. In a review of 13 lung

transplant recipients with at least one positive respiratory sample for *M. abscessus* at one center, there were no deaths in the 20-year period analyzed and no statistically significant difference in survival when compared to contemporaneous CF recipients without *M. abscessus* [37]. A similar experience was reported more recently at another lung transplant center at which seven cases were identified in an 18-year period whose survival and time to development of chronic lung allograft dysfunction (CLAD) were similar to the comparator group of CF lung transplant recipients [38]. The single mortality in that study was unrelated to *M. abscessus*. Of note, all seven patients were smear-negative at the time of listing, while five remained culture-positive.

Not all transplant centers reported a neutral effect of *M. abscessus* on survival after lung transplantation, though. Twenty-four cases of *M. abscessus* infection were identified in what is likely the biggest series to date [39]; 22 of which were pulmonary isolates. Mortality among the subset with pulmonary disease was significantly higher than those merely colonized based on the American Thoracic Society/Infectious Diseases Society of America guidelines: 1-year all-cause mortality was reported at 50% versus 0% for the pulmonary disease versus colonization groups, respectively. Differences in methodology and definitions notwithstanding, this center's finding that 73% of patients required changes or interruptions in therapy due to toxicity and/or intolerance is noteworthy [40].

It is therefore not surprising that despite the increasing experience with transplantation in the setting of *M. abscessus* colonization and infection, there remains a great deal of controversy regarding the optimal approach. In a survey of 37 transplant centers in Europe, North America, and Australia, only 29% of centers were found to have a clear written policy on NTM [41]. While only four centers considered NTM isolation to be an absolute contraindication, the majority of respondents (76%) continued to count it as a relative contraindication to listing. While the requirement for treatment pretransplant is near-universal, practices differ regarding listing when patients are smear-negative only or culture-negative as well. In one case, a favorable outcome was reported in a CF patient who was smear- and culture-positive for *M abscessus* at the time of transplant, though thankfully such reports are insufficient to call into question the prevailing strategy of suppression pretransplant [42]. Our strategy is to evaluate the extent of disease and at a minimum, commence 3–4 drug therapy ahead of transplant. Optimally the patient would convert their AFB stain from positive to negative, or even become culture negative. However, bronchiectatic patients pretransplant often have cavitary disease making airway sterilization impossible. In that case, 4–6 weeks of pretransplant *M. abscessus* therapy is used principally to test tolerance, recognizing the drugs may well be needed for more than 6 months posttransplant.

As far as treatment is concerned, surgical source control is crucial in the cases of surgical site infections, empyema, or other discrete skin and soft tissue infections. Antimicrobial susceptibility testing remains the cornerstone of guiding medical therapy, which is almost always parenteral combination therapy. Macrolide resistance can be assumed to be less likely in patients infected with the *M. abscessus ss massiliense* subspecies compared to those with the *M. abscessus ss bolletii* and

abscessus subspecies, as the latter two demonstrate inducible macrolide resistance as a result of the presence of the erm(41) gene [43, 44]. Up to 80% of *M. abscessus* isolates may be macrolide-resistant, especially since chronic azithromycin use for its anti-inflammatory effects in those CF patients colonized with Pseudomonas is common practice [45].

As such, common antimicrobial regimens tend to be centered on a combination of intravenous, inhaled, and oral agents. Common intravenous antimicrobials include imipenem and cefoxitin. The aminoglycoside amikacin is preferentially administered in inhaled form in cases of pulmonary infection without extrapulmonary involvement, especially in light of the frequent changes in renal function in the early posttransplant phase. Macrolides such as azithromycin may or may not be included in the regimen depending on subspecies and susceptibility; clarithromycin tends to be avoided given its potential for drug–drug interactions with immunosuppressants, for example, via inhibition of P-glycoprotein. Oral clofazamine and bedaquiline are becoming more widely used as we encounter more patients with unfavorable *M. abscessus* susceptibility patterns. Frequent monitoring and adjustments in the *M. abscessus* regimen based on intolerances and side effects are necessary, especially given the protracted duration that comes with NTM treatment.

The CF Foundation guidelines suggest that for patients with CF, treatment of *M. abscessus* should be 3–12 weeks of IV amikacin with at least one additional drug, guided by sensitivity profile. In our experience, once a patient approaches their transplant window, treatment should be longer, often at least a month pretransplant, and 3–6 months after transplant at a minimum, sometimes even a whole year posttransplant depending on institutional practices. When the patient's lung disease has progressed closer to their transplant window, we advocate for multidisciplinary management by transplant pulmonologists and transplant infectious disease physicians with an eye on consistency and suitability of the peri-transplant regimen.

For a more detailed discussion on *M. abscessus* in transplant patients, please refer to ▶ Chap. 19, "Rapidly Growing Mycobacterial Infections in Transplant: Evolving Epidemiology and Treatment Options."

Bacteriophage Therapy

Given the complexity and pitfalls inherent in treating drug-resistant infections and given the increasing development of resistance by the time a patient with cystic fibrosis typically gets referred for transplantation, alternative options are needed. Specifically, there is a growing interest in the transplant community for alternative, or at least adjunctive, therapies to antibiotics. Bacteriophages are naturally occurring viruses with bacterium-specific cell killing capabilities. They are in their nascent stages of development as potential therapeutic agents in select cases.

Bacteriophages are particularly attractive in the CF patient population due to their ability to break down biofilms, a common adaptive defense mechanism of pathogens colonizing CF airways or recolonizing lung allograft airways posttransplant from their sinus reservoir. In addition, while data are limited, there is some evidence that

treatment with bacteriophages may overcome antibiotic resistance patterns and confer susceptibility to antibiotics previously inactive against the target bacterium in question [46].

Currently, data are limited to case reports of successful eradication of difficult-to-treat bacterial and mycobacterial infections, but even in the limited time since the availability of bacteriophage libraries at select institutions in the United States came to light, clinicians are increasingly attempting to pursue bacteriophage therapy for their patients with untreatable infections pre- or posttransplant. Typically, the process of acquiring a phage involves an effort to match a particular bacterial strain of interest with a specific phage from an institutional library. This is laborious and slow, often taking weeks. An early example in the literature demonstrated safety and tolerability of a *Pseudomonas aeruginosa* bacteriophage in conjunction with systemic antibiotics for a woman with advanced CF awaiting lung transplant [47].

Of course, the excitement should be tempered given the limitations of bacteriophage therapy. Notably, there are no well-designed randomized trials supporting their use, and existing literature is scarce. In addition, beyond the labor and time-intensive bioengineering often required to target an individual patient's specific pathogens, the concern for lysogenic insertion and possibility of resultant mutations, including those conferring more antimicrobial resistance, should give us pause. Of note, the significance of bacterial evolution against the phage and host immune responses against the virus are two open questions that remain unanswered. Whether the patient's immune response against the phage has any subsequent impact on lung allograft function is unknown as well. Finally, dosing and route of administration remain unresolved questions. Studies so far have combined both inhaled and intravenous routes.

CFTR Modulators

The advent of CFTR modulators in the last decade has been an exciting expansion to the CF therapeutic armamentarium. Having an understanding of the way they interact with multiple other medications, including anti-infectives and immunosuppressives, is crucial. Ivacaftor (trade name Kalydeco), a CFTR potentiator that targets the so-called 'gating' mutation G551D, showed multiple benefits in terms of improvement in lung function, reduction in pulmonary exacerbations, and weight gain [48]. Subsequent studies based on several years of ivacaftor use have also shown a reduction in the rate of lung function decline by about 50% [49]. Ivacaftor use has been expanded to 37 additional mutations since its initial approval and now affords access to modulator therapy to about 5% of all individuals with CF.

Lumacaftor/ivacaftor (trade name Orkambi) is a combination modulator that was introduced for patients homozygous for F508del, the most common CFTR mutation and accounting for about 45% of all individuals with CF. It is a combination of a folding corrector (lumacaftor) addressing the main folding defect of

F508del with ivacaftor addressing the pleiotropic gating defect seen in F508del CFTR once folding is corrected. Its effect on lung function improvement was more modest than that of ivacaftor in its eligible patients and was limited by airway side effects [49]. Tezacaftor/ivacaftor (trade name Symdeko) is a corrector-potentiator combination that exhibits benefit in patients homozygous for F508del and those heterozygous with a second residual-function mutation and does not have the same limiting side effects as Orkambi [50, 51]. More recent studies combining Symdeko with an additional second-generation corrector called elexacaftor have been concluded and show great promise with a bigger impact on lung function and a potential to cover over 90% of all individuals with CF [52, 53]. They have led to FDA approval of the combination elexacaftor/tezacaftor/ivacaftor (trade name Trikafta).

The use of CFTR modulators is limited in the transplant setting owing to the multitude of drug–drug interactions, especially with calcineurin inhibitors, a mainstay of immunosuppression, and azoles, which are often needed for prophylaxis or treatment of invasive fungal infections. In particular, ivacaftor is a weak inhibitor of CYP3A4 and P-glycoprotein (P-gp), the latter interaction would be of additional interest when concomitantly used with tacrolimus. Lumacaftor, on the other hand, is a potent CYP3A4 inducer, and the net effect of lumacaftor/ivacaftor use is strong CYP3A4 induction. Tezacaftor is a CYP3A4 substrate, and as such dose reduction is necessary when used concomitantly with strong CYP3A4 inhibitors such as voriconazole and posaconazole or moderate inhibitors such as fluconazole.

In the lung transplant community, ongoing CFTR modulation following transplantation is generally considered unnecessary thanks to the replacement of the disease- and prognosis-defining organ. An argument can be made that the quality of life and weight gain benefits of CFTR modulators are now provided by the lung transplant and the resolution of chronic airway inflammation. In addition, the risks of subtherapeutic calcineurin inhibitor levels and the potential for higher rates of both acute cellular rejection and chronic lung allograft dysfunction do not justify continuing CFTR modulator therapy.

However, there are other extrapulmonary benefits to modulators, for example, improvements in exocrine pancreatic function, glycemic control, and sinus disease, which have emerged from clinical use. Depending on the disease phenotype of each particular patient, those may tip the risk-benefit balance toward continuing modulators post-lung transplant. As modulators gain widespread use earlier in the course of the disease, it is conceivable that more patients would maintain lung function longer and potentially need other organ transplants prior to the progression of their lung disease. In such instances, the need for lung function-preserving modulator therapy will need to be thoughtfully weighed against the drug–drug interactions between modulators and immunosuppressants or azoles. Recent case reports of CFTR modulators being continued after liver transplantation have highlighted exactly that conundrum and provide an early blueprint for dose adjustment and monitoring to allow for concomitant use of all necessary medications [54, 55]. What impact modulator therapy will have on the heretofore progressive colonization of airways with multidrug-resistant microorganisms remains to be seen.

Emerging Considerations in the Patient with Cystic Fibrosis

Many other considerations play into a patient with cystic fibrosis being an acceptable candidate for lung transplant. Many vary according to center preference and center experience. Anatomical considerations should be considered. Patients with considerable bronchiectatic change or bullous disease often have such significant burden of bacteria and/or fungi such that sterilization of the airway becomes impossible. Furthermore, bullae near the surface of the lung, or especially those that have burst resulting in a pneumothorax or pleurodesis, require special consideration. Our approach is to still take those patients to transplant, but to have frank discussions with surgical colleagues ahead of time, with regard to cautious extensive debridement to dissect the lung away from the thoracic wall, followed by aggressive washing out of the chest cavity, with either bacitracin or even Dakin's solution if frank empyema is noted.

The other reason to consider the anatomical differences in patients with CF is the impact on drug absorption. Generally speaking, the more bronchiectasis noted on chest imaging, the less likely sterilization is possible, and the more drug penetrance becomes variable.

When considering the CF patient with known liver disease, multidisciplinary management is often easiest. Combined liver/lung transplant is done at a limited number of centers and is felt best when a patient has underlying moderate to severe fibrotic function. Understanding how antibiotics and other medications are metabolized through the cirrhotic pretransplant liver is important. For example, to avoid decompensated liver failure, clinicians at our center tend to try an IV echinocandin instead of a triazole to reduce the fungal burden associated with pulmonary Aspergillus colonization ahead of transplant.

In very rare situations, pretransplant control of infection can be achieved by complete double pneumonectomy, using extracorporeal membrane oxygenation (ECMO) as a bridge to buy time for antibiotics to clear bacteremia where the lungs are felt to be the source, thereby facilitating transplant [56, 57]. An example (Fig. 1) was used to clear recurrent episodic *Burkholderia* bacteremia in a patient with terminal cystic fibrosis. This should be considered largely experimental at this time, although as advancing surgical techniques and ECMO support continue to grow, more significant surgical solutions to complicated pretransplant cystic infections may become possible [58].

Conclusion

Cystic fibrosis transplant recipients tend to enjoy better survival outcomes compared to non-CF recipients. While likely due to their younger age and fewer comorbidities on average, advances in CF care, availability of effect CFTR modulators to attenuate disease progression, and the resultant changes in airway microbiota are likely to change the landscape of transplant in CF toward older patients and those with more

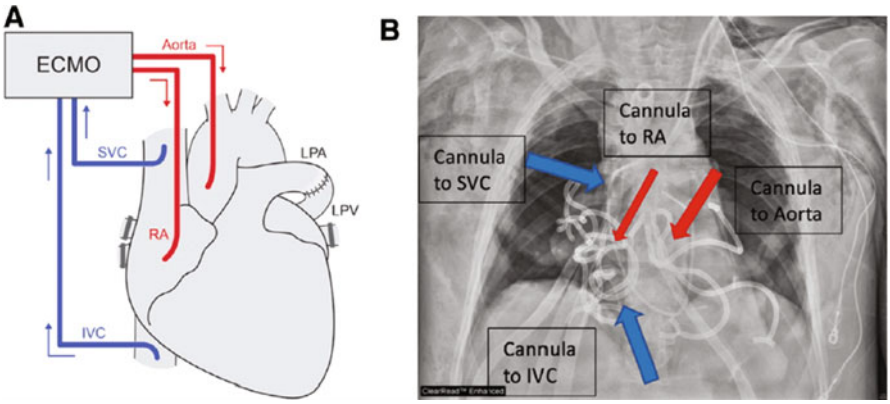

Fig. 1 (**a**) Schematic diagram of the VAC ECMO support configuration after bilateral pneumonectomy. The LPA is connected to the LPV (this is a side-to-side, functional end-to-end anastomosis). This allows for blood flow from the right heart to the left heart. In blue are the venous limb cannulas of the ECMO circuit and in red are the arterial limbs. (**b**) Post-operative chest X-ray demonstrating the support ECMO apparatus and the absence of lungs. complex microbial pathogens. Novel therapeutic approaches and more elaborate multidisciplinary management will thus become increasingly crucial for the effective management of future challenges.

Key Points

- Cystic fibrosis care has improved significantly pretransplant, leading to a much slower progression to end-stage pulmonary failure. Transplant remains the only option for those with end-stage disease.
- CFTR modulators have shown a lot of promise in further controlling the progression of CF, although they have significant drug interactions.
- Protracted antibiotic courses can be necessary for those patients with multi-drug resistant organisms. This is especially true for *Burkholderia* species and non-tuberculous mycobacteria.
- Bacteriophage therapy provides a potentially novel and targeted treatment that can be used in conjunction with an optimized antibiotic regimen. Currently, it should be reserved to use in more critical situations.
- Multidisciplinary discussions between pulmonologists, infectious disease physicians, and thoracic surgeons are crucial, especially where bullous disease has ruptured into the thoracic cavity or pleurodesis has been previously performed.

Background

Introduction

A vascularized composite allograft (VCA) is a quality of life transplant that encompasses the transplantation of multiple tissues as a functional unit [1]. Indications for transplantation vary based on the tissue defect and the type of transplant being performed. Due to their unique nature and wide variability, VCAs come with their own distinctive challenges and infectious threats. As a field in development compared to most other solid organ transplants (SOT), much of what is known about overall outcomes and infectious complications is based on small-number reviews and case reports or extrapolated from SOT data. This chapter will specifically address abdominal wall graft, face, hand, trachea/larynx, penile, and uterine transplantation. However, based on the definition of VCA, other types can also be included, and the same considerations of infection risks in different tissues can be therefore applied to any theoretical allograft.

Introduction to Immunosuppression and Infection Risk

Induction Immunosuppression

A large contributor to the infectious risk of any transplant population is the duration and intensity of immunosuppression the patient receives. A unique aspect and a challenge of VCA is that different tissue layers have varying levels of immunogenicity, with skin often considered the most immunogenic [2, 3]. Nonetheless, much of the information that guides VCA immunosuppression recommendations comes from the SOT literature.

Current experience shows that VCA recipients require similar immunosuppression regimens and doses to those used for other SOTs [4–9]. Specifically, hand and face transplants most commonly receive induction immunosuppression with monoclonal or polyclonal antibodies [10–12] such as antithymocyte globulin (ATG) or basiliximab [13], often along with mycophenolic mofetil [14] and steroids.

Maintenance Immunosuppression

Following induction, maintenance regimens vary from monotherapy to triple or quadruple drug regimens [11, 14–16]. For the most part, these include a combination of calcineurin inhibitors, mycophenolic mofetil, and steroids, with target drug levels akin to regimens used for renal transplantation; thus systemic infection risk with VCA appears consistent with renal transplantation. Treatment duration may be shorter for uterine transplant than for other grafts due to the decreased planned time of organ retention – currently about 5 years, up to two pregnancies [17]. Most

other VCA transplants will require indefinite immunosuppression for the life of the allograft. The average graft survival for other VCAs has not been defined and is likely different for each VCA type. However, if similar to all other organs, the average graft survival would be 15 years [1].

Rejection

One of the benefits of skin-containing VCAs is that initial evidence of rejection may be seen on external exam and can be readily biopsied [18]. Initial acute rejection is usually treated with intravenous steroid burst and oral taper [11, 14]. Though topical agents including steroids and tacrolimus have been used in the past [10], it is not recommended to use these agents in the absence of augmented systemic immunosuppression, as skin manifestations are often an indication of deeper rejection, which topical agents cannot penetrate [19]. However, it is important to remember that increased doses of systemic corticosteroids and other immunosuppressive agents can have widespread effects on the immune system and significantly increase the risk for infection, as discussed in other chapters [20].

Perioperative Antibiotics

Perioperative antibiotic regimens have increased in spectrum of coverage over time. Initial face transplants used antibacterial agents such as third-generation cephalosporins with metronidazole or amoxicillin-clavulanate monotherapy, with gram-negative, anaerobic activity, and streptococcal coverage specifically targeting bacterial flora of the oral cavity and sinuses, which were felt likely to cross-contaminate the graft site [12, 21, 22]. Presently, agents with a broader antibacterial spectrum, including MRSA coverage, are now being utilized – primarily vancomycin and a third- or fourth-generation cephalosporin, with antibiotics tailored to donor and recipient culture results as well as taking into consideration the microbiome of the transplanting hospital [14, 23–25]. The specific VCA type also impacts choice of perioperative antibiotics – while face transplants require a focus on upper respiratory tract flora, uterine and potentially penile transplants need consideration of genitourinary flora, which includes more anaerobes, *Enterobacteriaceae*, and *Candida*.

Typically antiviral prophylaxis with ganciclovir or valganciclovir is added for cytomegalovirus (CMV) prevention, along with trimethoprim-sulfamethoxazole for *Pneumocystis* (PCP) prophylaxis and dosing is the same as SOT. For a detailed discussion of the preventative and treatment strategies for CMV and PCP, please refer to the corresponding chapters in this book.

Furthermore, some centers add antifungal prophylaxis, particularly if there are concerns for *Candida* colonization [14, 26]. It should be noted that there is a lack of data to support this approach. In comparison to the SOT population, antifungal prophylaxis would not normally be required in most abdominal organ transplantation – such as the kidney or liver – based solely on the level of immunosuppression.

Graft Preparation

Preparation of VCA grafts is not a standardized process. Typical methods arose out of traditional plastic surgery techniques and include flushing the graft

post-procurement with University of Wisconsin (UW) solution, followed by wrapping in moist gauze and transferring on ice [27, 28]. This does carry the risk of exposing the graft to potential UW contamination issues; however, there is a lack of data describing alternative methods of graft preparation. Furthermore, prospective data tracking potential for skin and tissue contamination using this approach is lacking. Thus, this will require continued research and investigation to consider its potential implications and complications.

Tissue-Specific Risk of Infection

VCAs differ significantly by the type of tissue transplanted. Therefore, this chapter will approach the infectious risks in this population per tissue and structures involved. As a result, a clinician faced with a VCA need only understand the type of tissues involved in order to better understand the infectious implications for the recipient. Examples of the kinds of tissues transplanted during face, hand, uterine, and abdominal wall transplants are included; see Figs. 1, 2, 3, and 4. Other systemic infections that are not tissue specific will be covered elsewhere in their respective chapters.

Mucosa

1. **Mouth, nose, sinus, upper airways**
   This is often the first portal of entry for many inhaled environmental pathogens and can carry a number of colonizing pathogens that are predisposing factors for

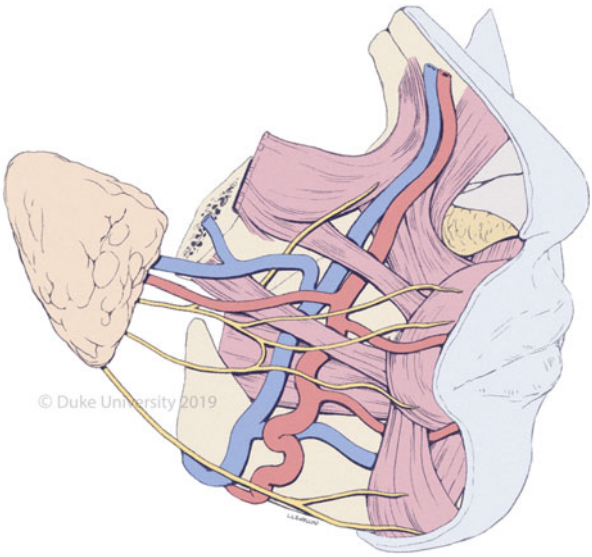

Fig. 1 Face transplant allograft

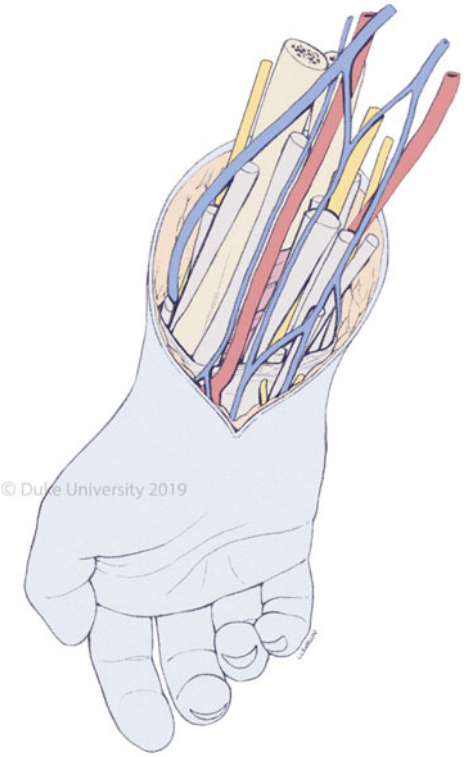

Fig. 2 Hand transplant allograft

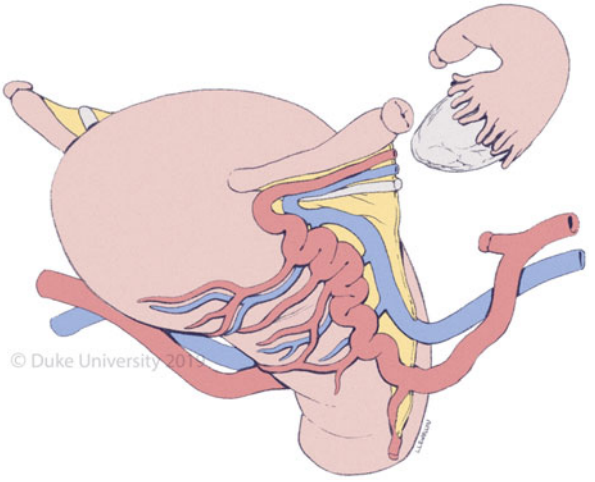

Fig. 3 Uterine transplant allograft

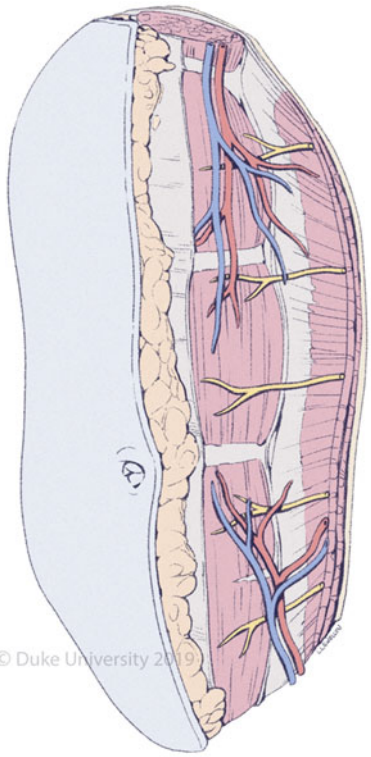

Fig. 4 Abdominal wall transplant allograft

future infection [25]. Thus, it is prudent to obtain mucosal bacterial, mycobacterial, and fungal cultures of the recipient pretransplant and of the donor during transplant evaluation. Recipient cultures are best done weeks in advance, to facilitate preparation. For the donor, in the United States, many of the bacterial lower respiratory tract cultures are routinely collected by the organ procurement organization (OPO), in accordance with national policy. However, sinus or oropharyngeal cultures are not typically collected, so close working relationships – often in real time during donor evaluations – with the OPO are imperative to ensure appropriate tissue cultures are obtained. Similarly, given the length of time taken to finalize fungal and mycobacterial cultures, care must be taken to ensure ongoing post-procurement communication to ensure timely communication of results. Empiric antimicrobial coverage may wish to cover *streptococcal* species, *Staphylococcus aureus*, *Candida*, and anaerobes but should be tailored based on culture results.

2. **Vaginal**
   Candida colonization or infection may be present in the genitourinary tract, which can pose a significant risk factor for infection. The first uterine transplant in the United States succumbed to a severe *Candida* infection ultimately requiring organ removal [29]. Additionally, it is important to consider screening for other

genitourinary infections including sexually transmitted infections. Donor and recipient screening tests should include vaginal wet mount to assess for various causes of vaginitis, *Chlamydia trachomatis* and *Neisseria gonorrhoeae* PCR, herpes simplex virus (HSV), human papillomavirus (HPV), and syphilis serologies. Other colonizing bacteria vary by the age of the donor patient (affected by major life episodes such as puberty, pregnancy, and menopause) and include *Lactobacillus* and anaerobes [30].

Skin

The skin carries its own unique reasons for potential complications. While its external location makes it easy to visualize any areas of concern for rejection and readily biopsy, this same location also can intensify its infectious risk. This site is in continuous exposure to the surrounding environment, which can increase the risk of surgical site infections and mechanical trauma [25, 31]. Skin is also colonized by normal flora such as *Streptococcus*, coagulase-negative *Staphylococcus*, and *Staphylococcus aureus*, which by itself may not be pathogenic but when introduced into a surgical site, can cause both local and invasive diseases. Additionally, many potential donors during their terminal hospitalization will have peripheral and central intravenous lines that cause further breaks in the skin and portals for future infection [32]. Minimizing such interventions once the move toward VCA transplant is recognized becomes crucially important to maintain healthy skin viability and reduce infection risk. Other systemic bacterial infections such as *Nocardia* and non-tuberculous mycobacteria can cause cutaneous lesions in the donor graft, especially if the donor cause of death involved trauma and skin penetration. Such atypical bacteria have a high predilection to disseminate in the immunosuppressed transplanted recipient; however, generally they are rare in the donor pre-procurement [33, 34].

Nonbacterial infections should also be taken into consideration. Topical viral infections such as HPV have been reported on bilateral hand transplants, either latent in the donor at the time of procurement or acquired posttransplant, and have been treated with topical cidofovir [35, 36]. Topical cidofovir has also proven to be useful in cutaneous HSV cases in VCA transplant patients that, under the influence of immunosuppression and repeated treatment, have become drug-resistant or particularly refractory to treatment [37, 38].

Fungal skin infections can also be present, as in the reported case of *Alternaria alternata* in a forearm transplant that was treated with amphotericin and itraconazole [36, 39] or *Candida* surgical site infection in a face transplant recipient, requiring echinocandin therapy [16]. Additional fungi have also been documented in the skin leading to superficial infections of SOTs. For example, in addition to *Alternaria*, other dematiaceous molds can cause nail or skin lesions, particularly in areas that have had minor trauma [40]. These are often treated with surgical removal and azole therapy. The dermatophytic fungus *Trichophyton rubrum* was also identified in the feet of a face transplant recipient and treated with 3 months of terbinafine [14].

Although the cutaneous manifestations of fungal infections usually represent complications of primary direct inoculation, care should be taken to consider the risk of disseminated disease in any VCA recipient. For example, the cutaneous nodules frequently seen with *Cryptococcus*, *Coccidioides*, or *Mucorales* may reflect cutaneous presentation of widely disseminated disease. With the exception of *Candida,* we recommend evaluating any recipient for other sites of infection with targeted history, exam, and chest imaging at a minimum.

It is also important to note that some skin infections or common skin conditions can appear clinically similar to acute rejection on visual examination. One example is a bilateral hand transplant patient who developed an erythematous maculopapular rash along the allografts over 16 years after transplantation. While initial presentation was felt to be most consistent with acute rejection, the rash also seemed to involve additional non-transplanted areas of the skin, including the abdomen. Skin biopsy was obtained and was ultimately consistent with scabies infection [41]. This case highlights the importance of having a low threshold to obtain skin biopsy for abnormal cutaneous lesions to ensure appropriate treatment is pursued [42]. Other noninfectious inflammatory skin conditions such as rosacea or coloring changes due to prolonged sun exposure can also manifest similarly and be difficult to diagnose both clinically and even on histopathology, particularly in face transplants [43].

Muscle

Particular pathogens prefer to primarily affect muscle tissue. *Toxoplasma* tachyzoites tend to target muscle and the central nervous system and cause both myositis and myocarditis [44, 45]. Thus, *Toxoplasma* has already been shown to cause significant morbidity in the transplant population, particularly in heart transplants [46, 47]. Although there has not yet been a case reported of *Toxoplasma* transmission from skeletal muscle transplantation alone, we recommend *Toxoplasma* serology be performed in both donor and recipient pretransplant. Transplant recipients whose serology does not demonstrate prior *Toxoplasma* exposure (IgG negative) should be advised to avoid possible risk factors for acquisition, including undercooked meat and close proximity to feline feces. Fortunately, trimethoprim-sulfamethoxazole (TMP-SMX), typically administered in posttransplant cases for *Pneumocystis* prophylaxis, is also effective against *Toxoplasma* [48]. Consideration should be given for extended prophylaxis in transplants where skeletal muscle is used and the donor antibodies are positive but recipient antibodies are negative, although precise duration is unknown for non-cardiac transplantation. Typically, in non-heart SOT populations, we recommend TMP-SMX or atovaquone prophylaxis for 3–6 months. Notably dapsone or inhaled pentamidine has no activity against toxoplasmosis.

In the setting of immunosuppression and recent surgery after transplantation, there can also be a risk of bacterial pyomyositis. Often this is caused by hematogenous spread, with a partiality to the muscle due to minor muscle injury and inflammation from surgery or trauma. In community-acquired cases, the most common pathogen is *Staphylococcus aureus* [49]. However other pathogens

including *Streptococcus* and gram-negative organisms have also been reported, including polymicrobial infections [50]. There have been multiple reports of bacterial infections transmitted from tissue allografts of deceased donors [51–54]. This risk can be augmented if appropriate donor screening is not performed, or if sterility is not maintained during tissue processing and transplantation.

Bone

Some of the risks of bone transplantation in the face or arms can be extrapolated from known history of bone graft transplantation [54, 55]. Certain infections can be transmitted via bone specifically. Up to 40 possible cases of bacteria transmission of various species have been reported in bone graft transplantation, including tuberculosis [54, 56]. These also include both gram-negative and gram-positive pathogens such as *Citrobacter*, *Streptococcus*, *Staphylococcus aureus*, and *Pseudomonas*.

Other types of infections reflect blood-borne transmission of systemic illnesses due to the vascular nature of the bone marrow. However, advancements in laboratory screening for many communicable diseases have significantly decreased the infection transmission rate. The rate of HIV transmission dropped significantly after nucleic acid testing (NAT) and p24 antigen testing of the donor were initiated, provided this testing is done within close timing to organ donation, preferably within 7 days of organ recovery [1, 57–61]. Hepatitis C and HTLV transmission events have been reported, although again, with appropriate donor screening, the risk for a VCA recipient should be no different than any other SOT [62–65]. (It is important to keep in mind however that the overall rise of hepatitis C donors is increasing in contemporary periods, particularly with the rise of fatalities due to the opioid epidemic. Transplantation of these organs has been demonstrated to be safe, and the virus can be cured with direct-acting antiviral agents within an appropriate time window without sacrificing patient welfare or graft function. At the time of publication, there have been no documented cases of intentional D+/R- HCV transplants within the VCA field) [66–68].

Nerve

Herpesviruses such as HSV and varicella zoster virus (VZV) have been known to lie latent in the nerve root ganglia and can reactivate under circumstances of significant stress or immunosuppression [31, 69]. For HSV, this typically causes painful oral or genital blisters [70]. However it can progress to disseminated disease with multi-organ involvement [71]. Donors and recipients should be tested for HSV IgG prior to transplant. It is important to recognize that HSV testing is not presently routine for solid organ donors, and this would need to be requested at the time of procurement. Acyclovir can be used for prophylaxis if the patient also does not have risk factors for CMV. Ganciclovir and valganciclovir, used for CMV prophylaxis, also have activity against HSV and are protective. Topical cidofovir is also available for reactivated or primary cutaneous cases that become drug-resistant or particularly refractory to treatment [37, 38].

VZV also remains latent in nerves and can be reactive years later as herpes zoster in both immunocompetent and immunocompromised patients, particularly in times of physiological stress. This typically manifests with a painful blistering rash but also can lead to disseminated infection. Varicella serology should be tested in all recipients pretransplant and appropriate pretransplant vaccination can be pursued [72, 73]. The treatment for both disseminated HSV and VZV is high-dose intravenous acyclovir. For a more detailed discussion of herpesvirus in transplant, please refer to ▶ Chap. 26, "Herpes Simplex and Varicella Zoster in Transplant Candidates and Recipients."

Lymphoid Tissue

Because many VCA transplants involve the transplantation of multiple lymph nodes, special consideration should be given to risks associated with these tissues. It should be noted that documented cases of lymph node associated transmission events are not present in the literature, but the passenger lymphocyte syndrome and graft versus host disease (GVHD), as described in ▶ Chap. 68, "Transplant Infectious Disease Evaluation of Cytopenias," may be more likely than in other transplant recipients.

Blood Vessel

There have been reports of HCV transmission by saphenous vein transplant [62] as well as rabies by iliac artery segment [74]. Additionally bacterial and fungal anastomotic mycotic aneurysms have been commonly associated with allografts, especially in the first few months after transplant. VCA transplants would be expected to carry a similar risk to SOT, proportional to the number of vessels used, and anastomoses formed.

Salivary Glands

Multiple episodes of infectious parotitis have been reported in one patient after face transplantation, all treated with cephalosporins [14]. The patient ultimately underwent dilation of a stenotic left parotid duct and ductoplasty 3 years after transplantation with resolution of symptoms. An additional patient with an sialocele infected with *C. albicans* and *Peptostreptococcus saccharolyticus* within the first month after face transplantation was treated with fluconazole and amoxicillin-clavulanate [16].

Organ-Specific Infections Particular to VCA

For systemic bacterial, fungal, mycobacterial, and viral pathogens transmissible by SOT, refer to the chapter on donor-derived infections.

General History

It is important to take a thorough medical and social/occupational history of the donor prior to transplantation. Some potential exposures that can lead to recipient infection have been discussed in other sections of this chapter but include HSV or HPV (verruca vulgaris risk) and occupational history (particularly fungal exposures). It is also important to be aware of health maintenance and preventative measures of the donor. Particularly for genitourinary transplantation, this can include including papanicolaou smear history, vaccine history (including HPV vaccination), previous multi-parity/uniparity, miscarriages, and sexually transmitted infection history.

Abdominal Wall Graft

Normal skin flora of the donor can potentially lead to surgical site or other wound infection. Recognizing that the abdominal wall flap typically includes fat, muscle, and neuronal tissue as well as the skin, apart from standard skin flora, little additional risk is acquired through abdominal wall transplants.

Face

Empiric antibiotic coverage should be based on pretransplant donor and recipient antimicrobial colonization. These include organisms found in the sinuses, nasal passages, and oropharynx. Face transplant recipients have had documented eye infections including palpebral conjunctivitis and bacterial blepharitis – treated with topical antibacterial ointment [16].

Hand

Fungal infections, particularly tinea infections, have been reported in hand transplantation, including the nail [70]:

1. **Occupational/activity-related or mortality-related infections** [75]. Thorough social history of donors and recipients should be obtained to assess for potential risk factors based on occupation/hobbies/endemic region or the circumstances leading up to the acute period before donor death:
   (i) *Donor who was a farmer/gardener or with motor vehicle accident as the cause of death*: Consider soil exposure pathogens, including *Nocardia*, endemic fungi*, Aspergillus, Mycobacterium*, and *Sporotrichoid*.
   (ii) *Donor with aquatic exposure during life or with drowning as the cause of death*: Differences in pathogens to consider can depend on whether the donor was exposed to salt water, fresh water, brackish water, or aquarium water. These organisms can include *Vibrio* species, *Aeromonas* species, and *Mycobacterium marinum*.
   (iii) *Donor who was an animal farmer, sheep handler*: Consider potential infections that can be transmitted from animals to humans, such as Orf virus, poxvirus, brucellosis, and *Coxiella*.

Larynx

Routine bacterial infections should be considered. One of the first laryngeal transplants (laryngopharyngeal complex, including thyroid, parathyroid, and five rings of trachea) in 1998 developed three separate episodes of tracheobronchitis within the first 15 months, one with *Pneumocystis* [76, 77]. Additionally, it would be important to also consider respiratory viruses, which can primarily affect this anatomic region and are not typically screened for in organ donation.

Penile

Screening for sexually transmitted infections should be done prior to transplantation. These include HSV, HPV, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Trichomonas*, and syphilis. Special preparatory discussion should occur between penile VCA programs and their associated organ procurement organizations, in order to facilitate such testing. There have also been documented fungal infections, such as one report of cutaneous infection with *Alternaria alternata*, treated with topical antifungals [78–80].

Uterine

Screening for sexually transmitted infections (as discussed in the above "Penile" section, but also including vaginal wet mount) should be done prior to transplantation. Genital HSV has been documented in a uterine transplant recipient within the first month posttransplant who subsequently developed postinfectious cervical stenosis [81]. Donors should also be tested for HPV, including but not limited to high-risk types (such as 16 and 18) associated with cervical cancer [82]. Additionally, common organisms found in the genitourinary tract can cause severe infection if they become more widespread. For example, the first uterine transplant in the United States succumbed to a severe *Candida* infection resulting in loss of the graft [29].

Furthermore, uterine transplants carry a similar ischemia-reperfusion risk to other SOT recipients. This can be of particular concern during transplantation when the uterus is exposed to vaginal flora, increasing the risk of graft infection. One uterine transplantation in a Swedish cohort of nine patients resulted in graft loss and ultimately graft removal due to *E. faecalis* abscess formation that was not responsive to antibiotics and surgical evacuation [81, 83].

With uterine transplant, it is also important to consider not only infectious risks associated with the graft itself but also potential risks that can arise for any future fetuses that may develop from that uterus. Specific considerations should be taken for cytomegalovirus, syphilis, and *toxoplasma*, specially D+/R- cases where control of infections may be more difficult because of immunosuppression. Active maternal infections during pregnancy can cause congenital infections with high morbidity in a fetus and are discussed later in this chapter, as are unique considerations for pretransplant vaccination in the uterine transplant population.

Systemic Infections that Can Be Predicted from Donor Testing

Cytomegalovirus

Cytomegalovirus (CMV) is a very common infectious complication of all types of transplantation, including VCA. CMV seroprevalence in the general population (including both adult and pediatric patients) has been widely variable in reports, referenced between 30% and 97% [84–86]. As with other SOTs, the greatest risk of disease occurs when a recipient is seronegative and is transplanted from a donor who is CMV IgG positive [26, 31, 36, 70, 87–96]. However, this discordance of serologies is of even higher concern when considering VCA transplantation, particularly uterine transplantation. In this situation, primary CMV in utero could have devastating congenital effects on the fetus. Therefore, uterine transplant programs should strongly consider CMV seromatching their donors and recipients or at the very least continuing antiviral prophylaxis for the duration of the graft until pregnancy is complete. CMV infection is typically treated with intravenous ganciclovir or oral valganciclovir. For a more extensive discussion on CMV disease and management, refer to ▶ Chap. 24, "Cytomegalovirus in Solid Organ Transplant Recipients: Prevention, Diagnosis, and Treatment."

Epstein-Barr Virus

Epstein-Barr virus (EBV) is another frequently seen complication in posttransplant patients, particularly in transplant recipients with negative EBV serology but a donor with positive serology. This can lead to a spectrum of both infection and malignancy including primary viremia and posttransplant lymphoproliferative disorder (PTLD). There are no dedicated antiviral agents for EBV infection, and treatment is typically focused on reducing immunosuppression. Ganciclovir, foscarnet, or cidofovir can be used for treatment of severe infection. For a more extensive discussion on EBV and PTLD, refer to ▶ Chap. 27, "Epstein-Barr Virus and Posttransplant Lymphoproliferative Disorders."

Toxoplasma

As with CMV, the serologies of *Toxoplasma* are particularly important in the situation of uterine transplantation. A donor positive/recipient negative serology could potentially lead to primary infection in utero, which would carry high infant morbidity and mortality. *Toxoplasma* mismatch, where a recipient is seronegative and a donor is seropositive, should probably be avoided altogether in the setting of uterine transplant, although to date, *Toxoplasma* in a subsequent fetus has not been documented. Clinicians should consider prophylaxis with TMP-SMX for at least the first 3–6 months posttransplant if a mismatch occurs.

Syphilis

Syphilis is a sexually transmitted infection that can cause both a local chancre and disseminated infection including neurologic and cardiac involvement. Care should be taken to perform syphilis serologies on all recipients and donors prior to receiving a VCA transplant, particularly those that involve genitourinary organs. Detecting and treating syphilis infection is particularly a concern in the setting of uterine transplantation, as congenital syphilis can lead to significant fetal impairment.

Additional Considerations

Vaccinations

VCA transplants should follow the same vaccination schedule and recommendations as those for SOT, at a minimum [97]. Every effort should be made to administer all vaccinations pretransplant, particularly live vaccinations, as investigations are still ongoing as to live vaccination safety posttransplant (e.g., measles-mumps-rubella, varicella). As with other SOT, live vaccines should be administered at least 4 weeks prior to transplantation to allow for appropriate host response before starting systemic immunosuppression. If vaccinations are administered posttransplant, care should be taken to wait at least three to six months after transplantation, ensure the recipient is on stable immunosuppression, and that it is an inactivated vaccine.

Additionally, given many VCA transplants involve skin, HPV vaccination should be considered ahead of transplant for all recipients under the FDA-approved age of 45 years. Data is not available for older recipients, although vaccination is likely to be safe. HPV infection appears to have an accelerated course with increased severity and complications in the transplant population. It is unknown how vaccination impacts cases where the donor already has documented HPV, though it is possible it may still have a partial protective effect.

There are some unique immunization recommendations for VCA cases, predominantly for the pre-uterine transplant population, where the ultimate goal of transplantation is to produce a viable pregnancy. In this group, specific recommended live pre-pregnancy vaccinations (particularly measles-mumps-rubella and varicella) should be administered pretransplantation [98]. There are high maternal and fetal morbidity concerns for measles, rubella, and varicella infections during pregnancy. Serologies should be tested in the recipient pretransplant, and if they are found to not have documented evidence of immunity, then vaccination should be pursued according to routine guidelines. All live vaccines should be completed at least 4 weeks prior to transplantation. Additional routine inactivated prenatal vaccinations should also be considered pretransplant, including tetanus-diphtheria-pertussis (TDAP) vaccines and seasonal flu vaccines, as well as additional routine pre-transplant vaccines such as pneumococcal and hepatitis A and B.

Safe Living Practices Posttransplant

The majority of safe living practices that are recommended after solid organ transplantation are also recommended after VCA transplantation [99]. For more extensive discussion on safe living after tranpslant, refer to ▶ Chap. 11, "Preventative Health in Solid Organ Transplant: Safe Living Post-transplant."

Environmental Exposures

After VCA transplant, patients should avoid sick contacts and encourage appropriate hand hygiene, both for themselves and those with whom they are in contact. Care should be taken to use facemask protection if they may be exposed to any sick contacts or if they are working outdoors to reduce the risk of respiratory inhalation of pathogens. Particular care should be taken to avoid trauma to the VCA skin. Other recommendations vary based on the potential posttransplant exposures of the recipient based on their home or work environment and hobbies.

Future Directions

Surgical advances and transplant techniques are continuing to evolve, and throughout this process, SOT and VCA transplantation practices continue to influence each other. Currently, different VCA types include vascularized, upper and lower limb, head and neck, abdominal wall, genitourinary organs, adrenal gland, spleen, and musculoskeletal composite graft segments. In addition, current and future considerations include progression toward a VCA type concomitant with various organ transplantations, akin to abdominal wall transplantation currently pursued with intestinal transplant. However, even in this ever-evolving field, if infection risk is considered in terms of the tissue layers transplanted, as described throughout this chapter, potential complications can be predicted and managed accordingly.

Conclusion

VCA transplantation is a novel, exciting, and continuously evolving field. Due to similarities in immunosuppression, much of the guidance designed to prevent and treat infections can be extrapolated from solid organ transplant experience. However, VCAs also have their own unique risks and considerations that must be taken into consideration. This is a new field without significant historical context and a body of literature that remains somewhat sparse. Consequently, a systematic approach to infection management is most beneficial. As multidisciplinary transplant providers, we need to publish and share information together to continue to grow this field.

Key Points

- Many different types of vascularized composite allografts (VCA) exist, although the most common are hands, face, and uterine transplants.

- The goals of VCA transplant differ depending on the tissue type but are typically quality of life affirming, rather than necessarily life-saving. Donor-recipient matching factors in many unique features such as size, gender, skin tone, etc.
- Immunosuppressive regimens are generally on par with deceased donor kidney transplants in terms of intensity and therefore infection risk.
- By better understanding the individual risk associated with any one tissue, infectious disease physicians can learn to appreciate the risk that any unique VCA may pose to the recipient.
- Advice regarding safe living, and strategies for risk and infection mitigation should be tailored to match the individual allograft type.

Introduction

Following solid organ and hematopoietic stem cell transplantation, innate and adaptive immune responses are significantly impaired, placing patients at high risk for infections with both community-acquired and opportunistic pathogens. In contrast to the general population, immunocompromised hosts often develop infections with multiple pathogens at once or with uncommon pathogens for which currently available conventional diagnostics are suboptimal. Owing to prolonged hospitalizations and greater exposure to antimicrobials, transplant recipients patients are also at higher risk for acquisition of multidrug-resistant (MDR) organisms. In light of the increased vulnerability to infection, diagnostics applicable to the practice of transplant infectious diseases are essential. Though culture and histopathology remain a bedrock of diagnosis, diagnostic microbiology has witnessed immense progress in the last decade, including a shift toward culture-independent methods such as molecular testing, mass spectrometry, and magnetic resonance-based technologies. Such methods have greatly expanded the array of organisms identified, enhanced the detection of resistance determinants, significantly shortened the time to diagnosis, and positively impacted the care of transplant patients with infections. On the horizon is another wave of diagnostic modalities with immense potential to enhance our diagnostic capabilities for transplant infectious diseases including highly multiplexed polymerase chain reaction (PCR) panels directly applicable to clinical specimens and with the potential for resistance detection, metagenomic next-generation sequencing (mNGS), and breath-based diagnosis of volatile metabolites among others. In this review, we examine emerging diagnostic methods for infectious diseases with a focus on the application to transplant patients.

Epidemiology and Impact of Antimicrobial Resistance in Transplant Populations

The emergence and spread of MDR organisms in the last decade have imposed an enormous clinical burden on patient populations worldwide. Partially a result of systematic misuse and overuse of available antibiotics, the crisis of antimicrobial resistance has been compounded by diminished antibiotic drug development, leading to a severely restricted antimicrobial armamentarium to treat MDR organisms. At the turn of the twenty-first century, infections with resistant Gram-positive organisms including methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE) predominated as the foremost causes of nosocomial infections, with strains of vancomycin-intermediate *S. aureus* (VISA) now encountered worldwide [1]. In the last decade, however, MDR Gram-negative infections, driven by extended-spectrum beta-lactamase (ESBL) producing and carbapenem-resistant *Enterobacteriaceae* (CRE), have emerged as a serious threat to hospitalized patients. The negative impact of increasing multidrug resistance has been most pronounced among certain subsets of patients, including the critically ill and immunosuppressed, for whom ineffective empiric antibiotic therapy is strongly

correlated with increased mortality [2]. Recipients of solid organ transplantation (SOT) and hematopoietic stem cell transplantation (HSCT) are particularly vulnerable to MDR infections due to underlying chronic disease, extended and recurrent hospitalizations, use of immunosuppressive modalities, ubiquity of intravascular catheters, risk of surgical site infections, repeated exposure to antimicrobials, and, in some cases, acquisition of donor-derived pathogens [3, 4]. Within transplant populations, allogeneic HSCT and heart and lung transplantation are associated with higher rates of resistance in Gram-negative bacteria, likely as a result of the aforementioned factors, including more intense immunosuppression [5, 6]. Resistance presents challenges to the selection of antibacterial prophylaxis and both empiric and targeted treatment modalities in any setting. Yet these are significantly amplified in the context of transplantation due to drug-drug interactions and poor baseline vital organ function which further limit antibiotic choices. Indeed, infections with drug-resistant organisms including MRSA, ESBL, CRE, *Pseudomonas*, *Burkholderia*, *Stenotrophomonas*, and *Acinetobacter* species have been associated with increased mortality for kidney, liver, and lung SOT and HSCT [5–9]. In parallel with the continued threat of bacterial resistance, drug-resistant fungi have become an important public health concern. *Candida* species are now the fifth most common nosocomial pathogen and a leading cause of mortality for transplant patients, especially in liver transplantation [10]. Recent years have seen the emergence of *C. auris*, an organism with the potential for resistance to all three major classes of antifungals (azoles, echinocandins, polyenes), and a proclivity for environmental persistence and nosocomial transmission including the possibility of donor-derived acquisition [11–13].

Since transplant patients with bacteremia or fungemia are at significantly higher risk for mortality than other populations, with a risk of death of up to 60% by some assessments, prompt identification of bloodstream pathogens is crucial in timely administration of effective antimicrobial therapy [24, 14].

Emerging Diagnostics for Bloodstream Infections

In the last decade, molecular-based diagnostics that rapidly identify bloodstream pathogens and their resistance determinants directly from positive blood cultures and on blood samples have been developed. These assays, along with non-PCR-based methods such as magnetic resonance and metagenomics, hold significant promise for improving diagnostic yield and ultimately outcomes of transplant patients.

Molecular Methods Performed on Positive Blood Culture Bottles

Rapid identification and antimicrobial susceptibility testing (AST) for bloodstream pathogens are critical in transitioning empiric to directed antimicrobial therapy, a key step in optimizing patient outcomes in the setting of sepsis. In traditional laboratory schemes, organism identification takes 48 hours or longer, and results of AST require

an additional 24 hours at least [15]. Such delays in the identification of bloodstream pathogens prompt treating clinicians to select empiric antimicrobial therapy for anticipated infecting pathogens based on the clinical syndrome and host, as well as local or facility-specific antimicrobial resistance patterns for selected pathogens. However, empiric therapy based on estimation of pretest probability is very often incorrect, with up to 50% of patients with bacteremia and up to 70% of patients with fungemia receiving inadequate empiric treatment prior to resulting of culture data [16, 24]. To circumvent the inherent delays associated with this testing paradigm, several molecular-based rapid diagnostic tests have been developed in an attempt to directly identify organisms from positive blood culture broth and provide resistance information without the need for culture. These techniques have the capacity to identify specific organisms (to the species or genus level) or groups of organisms. Importantly, many methods provide additional direct genotypic resistance information by identifying specific genetic determinants associated with phenotypic resistance, such as the *mecA* gene that confers methicillin resistance in *S. aureus* or direct phenotypic resistance data by providing extrapolated minimal inhibitory concentration (MIC) for specific antimicrobials. These molecular assays are considered moderate in terms of user complexity but benefit from minimal sample processing and hands-on time as well as automated test interpretation. Though little data exists in the context of transplant patients, these assays hold significant promise to accelerate diagnosis and resistance detection for this vulnerable population.

Several FDA-cleared rapid molecular tests for direct organism and resistant detection from blood culture are currently commercially available in the United States (Table 1). The *Quick*FISH and PNA FISH BC assays (OpGen, Maryland, USA, previously AdvanDx) for *Staphylococcus*, *Enterococcus,* Gram-negative, and *Candida* (*Candida Quick*FISH not FDA cleared at time of this writing) employ fluorescence in situ hybridization (FISH) using nucleic acid probes to identify organism-specific ribosomal RNA sequences, followed by automated examination and quantification under fluorescence microscopy, within a turnaround time of 2.5 hours and 20–30 minutes, respectively. The Gram-negative organisms identified are limited to *Escherichia coli, P. aeruginosa*, and *Klebsiella pneumoniae*, and *Candida* species are categorized into groups (*C. albicans/C. parapsilosis*, *C. glabrata/C. krusei*, and *C. tropicalis*). No AST information is provided using this assay; importantly the method does not differentiate between MRSA and methicillin-sensitive *S. aureus* (MSSA). Other limitations include the high limit of detection of 10^5 CFU/mL and the possibility of false negatives with prolonged times between specimen collection and processing. With the PNA FISH assay, *Micrococcus* may be misidentified as *Staphylococcus*, and *S. anginosus* may be misidentified as *Enterococcus.*

The Xpert MRSA/SA blood culture assay by Cepheid (Carlsbad, USA) identifies *S. aureus* from positive blood cultures within a 50-minute time frame. Using PCR, the assay detects DNA sequences for staphylococcal protein A (SpA) as well as staphylococcal chromosomal cassette (SCC*mec*) and *mecA*, genes specific to MRSA. This assay therefore provides some resistance information to guide directed treatment of *S. aureus* bacteremia. Test sensitivity in FDA trial data was reported at

Table 1 Direct organism identification and detection of resistance from positive blood culture

Manufacturer, assay	Methodology	Organisms identified	Direct genotypic resistance detection	Direct phenotypic resistance detection	Turnaround time	FDA Performance Data (in comparison with culture)	Caveats

100%, but real-world incidence of false negatives (~0.5–1%) can be significant in a high-volume center and has the potential to lead to inappropriate narrowing of empiric antibiotics, so internal verification of the assay and ongoing surveillance for false negatives should be performed [17]. False negatives may occur with novel or rare MRSA strains whose resistance is based on variant resistance genes (such as *mecC*) and in cases of coinfection with MSSA and MRSA.

The FilmArray (bioMerieux, France, Biofire Diagnostics, USA) blood culture identification panel utilizes multiplex PCR to detect bacterial and yeast nucleic acids specific to *S. aureus*, Streptococci, *Enterococcus*, *Listeria*, Enterobacteriales, *Acinetobacter*, *Pseudomonas*, *Hemophilus influenzae*, and *Candida* species in a turnaround time of 1 hour . In previous iterations, only one sample could be processed at a time, but a new version of the instrument (FilmArray Torch) allows for much greater throughput. Select genetic determinants of antimicrobial resistance are provided including methicillin (*mecA*), vancomycin (*vanA/B*), and carbapenems (KPC). The assay delivers species identification for the five most clinically important *Candida* species. Species level identification for *Enterococcus* is not provided, and this genus may be misidentified as *Staphylococcus*. False-positive detection of the *mecA* gene in Staphylococci can occur.

The Verigene GP and GN assays (Luminex Corporation, USA) employ a microarray-based detection of specific nucleic acid targets whereby specific target sequences within the clinical sample bind to capture probes in defined spots on a microarray plate. Probe-target hybridization is detected and quantified by detection of gold-labeled targets to determine relative abundance of nucleic acid sequences in the target. The GP and GN assays are associated with turnaround times of 2.5 and 2 hours, respectively. Gram-positive organisms identified include *S. aureus* and coagulase-negative Staphylococci (including *S. lugdunensis*), Streptococci including *S. pneumonia*, *E. faecalis*, and *E. faecium*, and *Listeria* species. The GP assay also detects genetic markers of resistance including *mecA, vanA,* and *vanB*. Gram-negative organisms include several species of Enterobacteriacae, *P. aeruginosa*, and *Acinetobacter* species. The GN assay further detects genes associated with ESBL (CTX-M) and carbapenemase production (KPC, IMP, NDM, OXA, VIM). Notably, the assay does not distinguish *E.* coli from *Shigella* species.

The recently FDA-approved ePlex (GenMarkDx., Carlsbad, USA) blood culture identification (BCID) panels by GenMark Diagnostics provides a more expansive coverage of infecting pathogens than other commercial tests, with a similar turnaround time (90 min) and a considerable throughout capacity of 244 patient samples in a 24-hour period. The assay is based on nucleic acid amplification followed by competitive DNA hybridization and electrochemical detection. In addition to common Gram-positive pathogens, the BCID-GP panel includes *Bacillus*, *Lactobacillus*, *Cutibacterium acnes* (formerly *Propionibacterium acnes*), and *Corynebacterium* species. The Gram-negative panel (BCID-GN), which is undergoing FDA review at the time of this writing, includes an expanded array of organisms including anaerobes (*Fusobacterium*, *Bacteroides*), *Cronobacter*, and *Stenotrophomonas maltophilia*. The fungal pathogen panel (BCID-FP) includes an array of clinically important *Candida* species. This includes *C. auris*, as well as other clinically

important yeast (*Cryptococcus*, *Rhodotorula*) and molds (*Fusarium*) that are significant causes of disease in transplant populations. In addition to common resistance determinants, ePlex BCID-GP detects *mecC*, a novel *mecA* homologue encoding for a variant penicillin-binding protein (PBP2a). Real-world experience using the ePlex assays will be important in defining its utility and identifying potential caveats.

The Accelerate PhenoTest BC kit (Accelerate Diagnostics, Arizona, USA) represents the first FDA-approved rapid molecular test on blood that provides phenotypic resistance information in addition to organism identification directly from blood culture. The assay employs FISH-based technology for identification, which is obtained within 90 minutes. While FISH identification is underway, remaining clinical sample is combined with growth media in individual flow cells containing single concentrations of each test antibiotic. The cell morphology and light intensity of growing bacteria in each flow cell are imaged every 10 minutes for up to 4.5 hours, creating a time-lapse record of bacterial growth. Software algorithms then derive MIC values and apply appropriate interpretive criteria, delivering AST information approximately 5 hours after identifying the infecting pathogens. The array of organisms identified is comparable to some of the other genotypic methods, including the Verigene. The assay does not differentiate *S. pneumoniae* from other *Streptococcus* species. No AST is provided for *Streptococcus* or *Candida* species, and resistance to ceftazidime and cefepime may be overestimated. The assay achieved essential and categorical agreements of >95% in comparison with Vitek 2 (bioMerieux), a routine identification and AST method used in clinical laboratories in the United States [18].

For all the aforementioned assays, false negatives may occur in the setting of polymicrobial bacteremia, though the FilmArray and ePlex assays perform better in this setting, a Gram stain of blood culture broth must be used for confirmation.

Molecular Methods Performed on Blood Specimens

Molecular methods performed directly on whole blood specimens rather than on positive blood culture broth have several potential advantages. By eliminating the need for a growth phase, they allow for more rapid identification of bloodstream pathogens and are less susceptible to poor organism growth as with fastidious or unculturable organisms or growth inhibition from antimicrobials. Such methods also require lower volumes of blood compared to assays based on blood culture collection [19]. There are currently no FDA-approved molecular methods for direct BSI identification in the United States, but several are available in Europe and Asia. Among these, the LightCycler SeptiFast (Roche Molecular System, Basel, Switzerland) identifies 19 bacterial and 6 fungal pathogens directly from whole blood (1.5 mL sample) with a turnaround time of 6 hours. The assay is based on detection of ITS regions within ribosomal DNA via fluorescence resonance energy transfer probes. This method demonstrated higher positivity rates than blood culture in immunocompromised patients including organ transplant recipients but lower rates in normal hosts with endocarditis [20]. The SepsiTest (Molzym, Bremen, Germany)

identifies a vast array of pathogens including bacteria, fungi (including molds and yeast), and parasites (*Plasmodium* spp.) within 8–12 hours via broad range PCR of ribosomal DNA followed by sequencing. The assay achieved a sensitivity and specificity of 87.0 and 85.8%, respectively, in comparison to blood cultures in a multicenter study [21]. The Magicplex™ Sepsis Real-time Test (Seegene, Seoul, Korea) similarly targets a wide panel of pathogens as well as three resistance determinants (*vanA, vanB*, and *mecA*) and is applied directly to 1 mL of whole blood. The assay has not been well evaluated in transplant population but was poorly sensitive in comparison to blood culture in one study [22].

Methods that are directly applied to whole blood have several inherent disadvantages. First, diagnostic sensitivity is often suboptimal due to low bacterial concentration in whole blood and the low specimen volumes (~1 mL) processed by these assays as compared to blood culture (~10 mL). Second, high concentrations of human DNA and other blood constituents can act as interfering factors for PCR-based amplification, yielding false-negative results. Third, in the absence of growth amplification of live organisms, contaminating DNA or residual DNA from killed organisms may be preferentially amplified leading to false-positive results [19].

Impact of Rapid Molecular Diagnostics on Clinical Outcomes in Transplant Populations

For patients with bloodstream infections, the implementation of rapid molecular diagnostics on positive blood culture into standard microbiology practices reduces the time to targeted therapy as compared to routine microbiology techniques [23]. When combined with direct communication of results to treating clinicians and pharmacists, these assays are also associated with a significant reduction in mortality [24, 25]. Implementing rapid testing in conjunction with antimicrobial stewardship programs further reduces time to antimicrobial de-escalation, decreasing exposure to unnecessarily broad antibiotics [26]. This results in decreased selective pressure, a key driver of antimicrobial resistance, and reduces cost associated with antimicrobial treatment, lengths of hospitalization, and overall healthcare expenses [27]. Evidence for improved outcomes among transplant patients is limited as most studies either include this subpopulation as part of broader analyses or exclude them from stewardship interventions [23, 28]. However, since transplant patients are at increased risk for developing infections with MDR organisms as compared to other patient populations, they are at higher risk of receiving empiric therapy that does not have activity against highly resistant organisms. Transplant patients are also at higher risk for morbidity and mortality resulting from inadequate empiric therapy for bloodstream infections. Therefore, this population is conceivably more likely to benefit from the use of rapid molecular diagnostics than other groups [29]. Immunosuppressed patients are also more likely to develop infections with opportunistic pathogens encompassed within testing panels but for which traditional microbiologic identification is slow or suboptimal. This is particularly true for

bloodstream infections due to fungi, especially *Candida* species, which are more common in SOT and HSCT populations. Since conventional blood culture methods for candidemia are only 50% sensitive and *Candida* species often require an additional 24–48 hours to grow, the diagnosis is very often missed or delayed, with expected negative effects on clinical outcomes [30]. Several assays encompass targets for the most common clinically important *Candida* species, including *C. albicans* and *C. glabrata*, while newer assays now include *C. auris*, an emerging pathogen associated with high mortality in immunocompromised patients and for which microbial identification with traditional diagnostic methods is challenging [12, 31]. Rapid molecular tests on blood or positive blood culture bottles carry the potential to revolutionize the management of candidemia in transplant populations by improving the sensitivity of detection, reducing time to diagnosis and ultimately leveraging results to guide initiation and selection of appropriate antifungal therapy. Since rapid molecular tests were validated against blood cultures in FDA trial data, additional studies will be needed to determine if they can surpass the sensitivity of this "gold standard" and uncover the "missing 50% of invasive candidiasis" [30].

Magnetic Resonance-Based Methods

The T2MR platform (T2 Biosystems, Lexington, MA) detects genetic material directly from blood samples using PCR amplification of fungal and bacterial nucleic acid followed by measurement of T2 magnetic resonance emanating from DNA probe complexes [32]. The platform is a non-culture-based stand-alone device, validated for whole blood specimens, and provides results within a 4-hour time frame. At present, two panels (T2Candida and T2Bacteria) are commercially available for clinical use, while a T2Candida auris panel is currently designated as research use only (RUO). T2 assays represent significant progress in the ability to directly detect pathogens from blood without the need for culture and carry the potential to reduce the time to diagnosis of bloodstream infections, an important cause of morbidity and mortality in the transplant population.

The T2Candida panel detects five clinically significant *Candida* species, including *C. albicans*, *C. glabrata*, *C. krusei*, *C. parapsilosis*, and *C. tropicalis* with the amplification step targeting internal transcribed spacer 2 (ITS2) rDNA. The assay does not provide resistance information other than susceptibility patterns inferred from species level identification. In a multicenter trial comparing detection of candidemia both from patients (including transplant recipients) with suspected candidemia as well as spiked samples, T2Candida achieved overall sensitivity and specificity of 91.1% and 99.4%, as well as a significantly reduced turnaround time for the final assay result compared to conventional blood cultures [33]. Discordant results included two samples identified by blood culture that were missed by the T2Candida panel as well as 29 samples labeled positive by the T2Candida assay which were not identified by conventional methods. Some of these cases were later shown to represent *Candida* infections through other methods of detection.

A subsequent study that included transplant recipients detected more episodes of candidemia as compared to conventional culture methods in patients on antifungals [34]. This system may have utility for early diagnosis, management, and antifungal stewardship in transplant populations at risk for *Candida* bloodstream infections, but prospective trials are needed to determine if rapid and enhanced diagnosis translates to reduced morbidity, mortality, or cost savings. The primary utility and cost savings of the T2MR platform may be related to antimicrobial stewardship.

Despite the significant theoretical advantages of the T2Candida assay, particularly in a transplant population with higher risk for candidemia, translating the reported diagnostic performance into real-world utility may be problematic for several reasons. First, though the initial validation study reported a sensitivity exceeding 90%, the true sensitivity is likely to be lower as a majority of samples included in the study (44%) were nonclinical, contrived specimens which contained a yeast concentration significantly higher than the mean concentration in initial blood cultures of candidemic patients (11–100 Candida CFU/mL vs. 1 CFU/mL) [33]. Even a small decrease in sensitivity and therefore in negative predictive value reduces the utility of the assay in guiding initiation or continuation of antifungals in transplant patients with a high-pretest probability for candidemia, rendering such an assay much less useful diagnostically. Second, in its current iteration, T2Candida does not detect several clinically important *Candida* species (such as *C. kefyr*, *C. lusitaniae*, *C. guilliermondii*, and *C. auris*), which comprise up to 10% of *Candida* infections in SOT patients [35]. Finally, in both clinical trials and real-world settings, the T2Candida has been susceptible to a high frequency of technical errors as well as indeterminate or invalid readings that require repeat testing and are disruptive to workflow.

T2Candida auris is currently a research-use-only assay that detects the emerging and potentially MDR organism, *Candida auris*. A validation study investigating the ability to detect *C. auris* from cutaneous sites demonstrated a sensitivity of 89% and a specificity of 98% in comparison to CDC methods [36]. Given the propensity of *C. auris* to persist on environmental surfaces, to lead to hospital-based outbreaks, and potentially to donor-derived transplant infections, this assay has significant implications for hospital epidemiology of transplant patients [11, 13].

The more recently FDA-approved assay for the T2MR system, T2Bacteria, can detect *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Escherichia coli.* No resistance information is provided. This assay was validated in a single-center study in comparison with conventional methods of bacterial identification from blood, achieving an overall sensitivity of 83.3% and specificity of 97.6%. Notably, the sensitivity and specificity varied by the pathogen detected, ranging from 50% with *K. pneumoniae* to 100% with *E. faecalis*, *P. aeruginosa*, and *S. aureus* [37]. As with molecular methods applied to whole blood and blood culture, the T2Bacteria panel carries the potential to shorten time to diagnosis of BSI and may prove highly useful in transplant populations, but data will be needed to determine if theoretical advantages translate into real-world benefit.

Metagenomic Sequencing

Metagenomic next-generation sequencing is an unbiased, hypothesis-independent approach to pathogen detection that is directly applicable to clinical samples. In contrast with PCR-based and 16S ribosomal RNA gene-based sequencing which target specific primers, mNGS is capable of sequencing all the nucleic acids in a clinical specimen and entire pathogen genomes. The majority of mNGS-based assays sequence only DNA, excluding organisms with RNA genomes. To address this, complementary DNA can be synthesized from total RNA. In addition to pathogen identification, mNGS has the potential to identify genetic determinants associated with phenotypic resistance [38–40]. Due to its capacity to identifying a multitude of pathogens in clinical samples, careful interpretation of data and clinical correlation is needed. Current mNGS platforms may vary with regard to sequencing technologies and software packages required for data analyses [41]. Metagenomic methods have been applied to blood samples in transplant patients. A prospective study of allogeneic HSCT recipients evaluated the value of a commercially available mNGS assay on plasma (Karius**,** Karius Inc., Menlo Park, California) obtained prior to conditioning, at time of graft infusion, weekly intervals after transplant, and at time of acute illness [42]. Plasma mNGS added diagnostic value in 3 of 20 cases, including the identification of uncommon presentation of *Chlamydia trachomatis* and of MRSA infection prior to diagnosis by blood cultures. In addition to bacterial pathogens, plasma mNGS detected CMV and EBV in concordance with standard PCRs. In a multicenter blinded prospective study of 101 immunocompromised patients including 22 SOT and 18 HSCT, blood samples tested within 30 days of enrollment by an mNGS assay identified more clinically relevant viruses and bacteria than standard testing (36/101 vs. 11/101) [43]. In this study, mNGS was associated with a high negative predictive value compared with conventional diagnostics (64/65, 95% CI 0.95-1). These findings suggest that negative mNGS results may have a role in antimicrobial and diagnostic stewardship.

Emerging Diagnostics for Respiratory Infections

In the evaluation of community-acquired pneumonia, 40–60% of cases remain undiagnosed despite extensive testing with traditional microbiologic tests [44]. Sputum cultures and blood cultures provide diagnostic information in only 15% of cases of community-acquired pneumonia, while bronchoscopy provides additive diagnostic value in 50% of cases. The diagnostic yield of microscopy with staining of induced sputum for *Pneumocystis jirovecii* pneumonia is around 50%, while that of serum galactomannan for *Aspergillus* infection can be as low as 30%, depending on the population. *Aspergillus* PCR assays, gas chromatography-mass spectrometry of exhaled metabolites, multiplex PCR, and mNGS have the potential to significantly improve diagnostic sensitivity for respiratory pathogens.

Aspergillus PCR

Aspergillus PCR for Diagnosis of Invasive Pulmonary Aspergillosis

Invasive pulmonary aspergillosis (IPA) is the most common fungal infection among HSCT recipients and one of the most common among SOT patients, particularly lung transplant recipients. Conventional methods for diagnosis of IPA include histopathology demonstrating septated hyphae and growth on culture followed by species identification. However, the diagnosis of aspergillosis can sometimes be challenging using these methods alone. Indeed, barriers to biopsy, such as severe thrombocytopenia, are common in this population. Additionally, culture yield is variable, especially with antecedent antifungals, and histopathological findings cannot reliably distinguish *Aspergillus* species from other hyaline molds. Galactomannan antigen testing on serum and bronchoalveolar lavage (BAL) fluid serves as an additional diagnostic tool and an important adjunct for diagnosis, but the sensitivity is suboptimal and significantly impacted by treatment with triazoles.

Molecular testing with PCR on blood or respiratory specimens is an emerging method to diagnose IPA. Multiple genetic targets have been investigated, including 18 s rRNA, 18 s rDNA, 5.8S rDNA, 28 s rRNA, mitochondrial DNA, and internal transcribed spacer (ITS) regions [45]. Use of PCR for routine diagnosis of IPA has not been uniformly accepted by society guidelines. Whereas guidelines proposed by the European Organization for Research and Treatment of Cancer/Invasive Fungal Infections Cooperative Group in collaboration with the National Institute for Allergy and Infectious Diseases Mycosis Study Group (EORTC/MSG) advocate against PCR-based diagnosis given the lack of standardized testing procedures, more recent ESCMID-ECMM-ERS guidelines indicate that PCR should be considered in conjunction with other diagnostic testing [46, 47]. The 2016 Infectious Disease Society of America (IDSA) guidelines caution against the routine use of PCR without utilizing other standardized methods of diagnosis, but committee members differed in opinions regarding the utility of this platform with one group favoring use of PCR in conjunction with other standard methods and the other group indicating that lack of standardization among heterogeneous PCR methods needed to be addressed prior to being implemented for routine use [48].

Indeed, the primary challenge facing acceptance of PCR for the identification of *Aspergillus* species genetic material is assay standardization, which allows for uniform test performance and interpretation across institutions and in clinical trials. A Cochrane review of PCR methods for diagnosing *Aspergillus* species infection from blood demonstrated a mean sensitivity and specificity of 80.5% and 78.5%, respectively, when compared to EORTC/MSG recommendations for diagnosis as a reference standard [49]. Following publication of the initial EORTC/MSG guidelines, the European Aspergillus PCR Initiative (EAPCRI) was formed in an effort to progress toward increased standardization. Comparison of protocols from involved centers yielded specific recommendations for processing serum and whole blood samples [50, 51]. Notably, the DNA extraction protocol was identified as the most significant component of standardization. Utilizing standardized protocols, the

sensitivity and specificity of diagnosing invasive aspergillosis by PCR were found to be similar to that of *Aspergillus* galactomannan and beta-D-glucan assays at the time these assays were included in guideline recommendations [52]. Accordingly, future guidelines are likely to incorporate *Aspergillus* PCR as a routine tool for the diagnosis of invasive disease.

Though several reference laboratories in the United States offer *Aspergillus* PCR testing in the form of laboratory-developed tests (LDT), there are currently no FDA-approved assays. In recent years, several commercially available PCR assays for identification of *Aspergillus* species in blood or bronchoalveolar lavage have become available in Europe, including the MycAssay Aspergillus assay (Microgen Bioproducts Ltd., Cambridge, United Kingdom), the AsperGenius assay (PathoNostics, Maastricht, Netherlands), the MycoGENIE assay (Ademtech, Pessac, France), the SeptiFast assay (Roche Molecular System, Basel, Switzerland), and the RenDx Fungiplex assay (Renishaw Diagnostics Ltd., Glasgow, United Kingdom) (Table 2). These PCR assays incorporate internal standardization protocols validated by the manufacturer, allowing a degree of reproducibility across institutions. Many kits are validated on multiple real-time PCR-capable instruments, permitting a given laboratory to utilize the assay on existing devices.

The AsperGenius assay, a real-time PCR targeting the 18S rDNA, detects *A. fumigatus* complex, *A. terreus*, and other *Aspergillus* species (*A. flavus* and *A. niger*). The assay was initially evaluated on BAL samples in comparison with positive galactomannan samples in patients with suspected invasive aspergillosis. The sensitivity and specificity ranged from 80% to 88.9% and 89.3% to 93.3%, respectively, depending on the patient population studied, with a higher sensitivity in leukemic and HSCT patients [53]. A larger retrospective study involving five European hospitals evaluated the performance of the AsperGenius assay on BAL in comparison with galactomannan and culture data in patients primarily with hematologic malignancies and HSCT and found a sensitivity and specificity of 80% and 84%, respectively [54]. This assay has also been applied to serum, suggesting broader potential application [55, 56].

The MycoGENIE assay (Ademtech, France) identifies presence of *Aspergillus fumigatus* by targeting 28 s rRNA in clinical samples. This assay was validated using culture-positive bronchoalveolar lavage samples with a sensitivity of 92.9% and a specificity of 90.1% [57]. However, the sensitivity on BAL was only 40% for proven or probable IPA in a retrospective study from a majority of patients status-post HSCT. An increase in sensitivity and specificity was observed when the assay was combined with galactomannan antigen testing [58].

The MycAssay (Myconostica, Lab21, Manchester, UK), an early commercial kit detecting 15 *Aspergillus* species, targets 18 s rRNA. Validation studies used samples from patients primarily with hematologic malignancies and compared the assay to galactomannan and institution-derived PCR testing. Initial evaluation using samples spiked with *Aspergillus fumigatus* and samples from patients with possible/probable IPA demonstrated similar performance to an institutionally developed PCR panel [59]. However, subsequent investigations found a lower sensitivity and specificity for diagnosis of invasive aspergillosis as compared to galactomannan antigen testing

Table 2 Commercially available PCR assays and platforms for *Aspergillus* species identification

Assay and manufacturer	Methodology	Target	Species identified/ readout	Resistance mutations identified	Tested specimens and performance
AsperGenius (PathoNostics)	Real-time multiplex PCR kit	28 s rDNA; CYP51A	*A. fumigatus*, *A. terreus*, *Aspergillus* spp.	*CYP51A* mutations: 1) L98H 2) Tandem repeat 34 3) T289A 4) Y121F	BAL 80.0–88.9% sensitive, 84.0–93.3% specific per patient population; compared against BAL galactomannan and/or culture [53, 54] Serum 78.6% sensitive, 100% specific for serum samples of patients with proven/probable/ possible disease [55] Plasma 80% sensitive, 77.8% specific for plasma samples of patients with proven/probable/ possible disease [56]
A. fumigatus Bio-Evolution (Bio-Evolution)	Real time PCR kit	ITS1 rDNA	*A. fumigatus*	None	BAL 100% sensitive, 81% specific for BAL samples of patients with probable/possible disease [62]
MycoGENIE (Ademtech)	Real-time multiplex PCR kit	28 s rRNA; CYP51A	*A. fumigatus*, *Aspergillus* sp.	CYP51A mutations 1) Tandem repeat 34 2) L98H	BAL 100% sensitive, 71% specific for BAL samples of patients with probable/possible disease [62] 40% sensitive, 69% specific for BAL samples of patients with proven/probable disease [58]

Assay and manufacturer	Methodology	Target	Species identified/ readout	Resistance mutations identified	Tested specimens and performance
					82–90% sensitive, 64–79% specific for biopsy specimens as compared to microscopy and culture based diagnosis [101]
PLEX-ID Broad Fungal (Abbott)	PCR with electrospray ionization mass spectrometry; PLEX-ID platform	mtSSU rRNA, proprietary primers	*A. fumigatus, A. flavus, A. nidulans, A. niger, A. terreus* Other non-*Aspergillus* species detected as well	None	Respiratory samples Correctly identified of 11 of 12 standard samples and 6 of 8 samples from respiratory samples [102] No studies conducted to evaluating sensitivity and specificity
RenDx Fungiplex (Renishaw)	PCR with surface enhanced resonance Raman scattering spectroscopy	18 s rRNA, 28 s rRNA	*A. fumigatus A. terreus, A. niger, A. flavus* Other non-*Aspergillus* species detected as well	None	Serum/plasma 81.3% sensitive, 87.5% specific for serum/plasma specimens of patients with proven/probable/ possible disease [66]
SeptiFast (Roche)	Real-time multiplex PCR; Roche LightCycler platform	ITS rDNA	*A. fumigatus* Other non-*Aspergillus* species detected as well	None	No studies conducted to evaluating sensitivity and specificity for detection of *A. fumigatus*. Variability is reported between detection *A. fumigatus* with SeptiFast and comparative assays

Abbreviations: *BAL* bronchoalveolar lavage; *mtSSU rRNA* mitochondrial short subunit ribosomal ribonucleic acid; *ITS* internal transcribed spacer; *PCR* polymerase chain reaction; *rDNA* ribosomal deoxyribonucleic acid; *rRNA* ribosomal ribonucleic acid

[60, 61]. The MycoGENIE assay demonstrated similar performance to the *A. fumigatus* Bio-Evolution assay (Bio-Evolution, France) in a retrospective analysis using BAL samples [62].

The Roche SeptiFast assay is based on real-time multiplex PCR using the Roche LightCycler platform and is capable of detecting multiple bacterial and fungal pathogens, including *A. fumigatus.* This assay has been investigated against blood culture, individual laboratory-developed PCR assays, and galactomannan testing in patients with hematologic malignancy and neutropenic fever, some of whom were recipients of or being conditioned for HSCT [63, 64]. Positive results for *A. fumigatus* were reported in these studies, but positive results were rarer than for bacterial pathogens or *Candida* species, reflecting either lower prevalence or lower sensitivity for aspergillosis. Notably, this platform was also found to support the diagnosis of invasive aspergillosis in two patients with hepatic transplantation [65]. A primary limitation is the ability to only detect *A. fumigatus*, whereas patients with SOT or HSCT are at an increased risk for other *Aspergillus* species as well.

The RenDx Fungiplex assay (Renishaw, United Kingdom) utilizes PCR and surface-enhanced resonance Raman scattering spectroscopy to detect amplified DNA. The assay was developed to detect ten fungal organisms, including *A. fumigatus* and *A. terreus*, and demonstrated a sensitivity of 85.7% when detecting *Aspergillus* species from blood in a group of patients including recipients of HSCT [66].

In a review of published literature, the sensitivities and specificities of aforementioned *Aspergillus* PCR assays were overall comparable but consistently higher in BAL than in serum and likely lower sensitivity in non-hematologic patients as well as in those on antifungal treatment or prophylaxis [67]. Active investigation is ongoing to determine the feasibility of incorporating these and other developing platforms into the difficult process of diagnosing invasive aspergillosis. At present they do not represent stand-alone diagnostic methods, and results must be evaluated in the context of the clinical presentation and all other available data.

Aspergillus PCR for Diagnosis of Resistance in *Aspergillus* Species

The need for improved diagnostics is further highlighted by the increasing prevalence of azole-resistant *Aspergillus* species worldwide [68]. The first azole-resistant *Aspergillus fumigatus* clinical isolates were reported in the United States and the Netherlands in 1997 and 1998 [69, 70]. Since then, the prevalence of resistance has risen to 10–15% in some areas of Europe. At this time, resistance appears to be uncommon in the United States, with surveys of clinical isolates reporting a resistance prevalence of less than 1.8% [58, 71]. Mutations in the CYP51A (ERG11) gene encoding sterol demethylase are primarily responsible for resistance seen in clinical *A. fumigatus* isolates. Resistance develops in the setting of selective pressure from long-term and widespread azole use such as with environmental application of triazoles as fungicides in mass agriculture and less commonly with conditions favoring active reproduction in vivo such as with long-term treatment of patients

with aspergilloma. Some CYP51A mutations are associated with minimal inhibitory concentrations (MIC) that exceed the epidemiologic cutoff value (ECV) of ≤ 1 μg/mL for azoles established by the Clinical & Laboratory Standards Institute (CLSI) and the European Committee on Antimicrobial Susceptibility Testing (EUCAST) by multiple dilutions. The presence of such mutations has been linked to treatment failure and increased mortality in patients with IPA [15].

Among the aforementioned *Aspergillus* PCR assays, the AsperGenius and the MycoGENIE assays have the added capability of detecting azole resistance based on the presence of *CYP51A* mutations. The MycoGENIE assay detects two resistance-associated mutations in *CYP51A*, whereas the AsperGenius assay identifies four *CYP51A* point mutations representing prevalent mutation types. In a retrospective study, samples with positive results for resistance-associated mutations using this assay were associated with significantly poorer patient outcomes [54].

Given the low prevalence of azole-resistant *Aspergillus* isolates in the United States, current IDSA guidelines do not recommend routine susceptibility testing. Susceptibility testing was suggested in cases of suspected azole resistance (without further specifications on when to suspect), lack of response to normally effective antifungals, or for epidemiologic purposes. With ongoing widespread clinical and industry use of triazoles in the United States, the prevalence of azole resistance is likely to increase, leading to a greater need for resistance detection.

Gas Chromatography-Mass Spectrometry of Exhaled Metabolites

Molds produce organic compounds during routine metabolism, many of which are released as volatile metabolites during exhalation. Monoterpenes and sesquiterpenes, the primary metabolites produced by *Aspergillus* species, can be detected using breath-based diagnostics to establish a diagnosis of invasive aspergillosis. The first report of this method involved recipients of SOT and HSCT with proven or suspected IPA [72]. The study compared volatile organic compounds produced in vitro with those detected from patient breath samples using gas chromatography-mass spectrometry. Sesquiterpene compounds were detected from varying in vitro culture conditions as well as in breath samples. Breath-based detection of volatile organic compounds achieved a sensitivity of 94% and specificity of 93% for identifying patients with IPA as compared to clinical diagnosis by EORTC/MSG criteria. Some sesquiterpene metabolites were only identified in the in vivo breath samples corresponding to activation of alternate metabolic pathways in the context of an immune response and lung microbiome [73]. Notably, sesquiterpenes are produced in a species-specific manner by *Aspergillus* species, potentially allowing diagnostic discrimination beyond the genus level. Development of this method for clinical diagnosis has many challenges involving consistent breath collection, which can be affected by multiple factors including age, race, respiratory rate, and tidal volumes among others, and standardization of analysis methods used to identify the volatile organic compounds [73]. However, this platform has the potential to significantly improve the diagnostic yield for IPA and could be expanded to other invasive

fungal infections, particularly those due to Mucorales species for which few targeted diagnostics are available.

Multiplex PCR

Respiratory multiplex PCR can be performed on nasopharyngeal swab samples, nasal washes/aspirates, and BAL specimens. There are currently five FDA-approved respiratory multiplex assays, including NxTAG Respiratory Pathogen Panel (RPP) (Luminex, TX, USA), Verigene Respiratory (RP) Flex (Nanosphere, IL, USA), FilmArray Respiratory Panel (RP) (BioFire Diagnostics, UT, USA), eSensor Respiratory Viral Panel (RVP) (Genmark, CA, USA), and, the recently approved, Unyvero Lower Respiratory (Curetis, CA, USA) (Table 3). The former four panels include predominantly viral targets, while Unyvero also detects bacterial pathogens and genes associated with antimicrobial resistance (Table 4) [74]. Such assays have the advantage of providing earlier diagnoses than culture- or immunofluorescence-based methods, as well as the potential to detect multiple coinfecting pathogens with early institution of appropriate therapy and enforcement of isolation practices, measures that are especially critical for the care of immunocompromised hosts. However, studies of these assays among immunocompromised patients are limited. The FilmArray RP was evaluated in 87 immunocompromised patients (48% HSCT, 37% SOT and 18% with hematologic malignancies) using either BAL or nasopharyngeal samples [75]. In this cohort, only viral pathogens were detected. The positive and negative predictive values were 86% and 100%, respectively. Unyvero was evaluated in BAL samples of 522 immunocompromised patients with suspected lower respiratory tract infections [76]. Compared to conventional methods, the assay result was more expedient (available within 5 hours), but sensitivity was poor at 68.4% (specificity was 86%), notably failing to identify cases of *Streptococcus pneumoniae* infection.

Metagenomic Sequencing

In patients without a microbiologic diagnosis using conventional testing, mNGS may have a role in providing an early and definitive diagnosis, which is especially important in lung transplant recipients for whom respiratory infection is associated with allograft dysfunction and mortality. Using a laboratory-developed mNGS assay in a cohort of lung transplant recipients with suspected respiratory infection, Lewdowonska et al. [77] identified respiratory viral pathogens in only 5 of 29 cases (Table 5). Langelier et al. [78] enrolled 22 HSCT recipients with respiratory illness whose BAL was tested by standard microbiologic testing and mNGS. Standard microbiologic testing identified clinically relevant pathogens (as determined by the treating physician) in six cases, all of which were concordant with mNGS. Conversely, six other cases identified by mNGS were missed by conventional testing. Studies of mNGS for the diagnosis of fungal infections in transplant recipients are limited. Li et al. evaluated 20 patients by lung biopsy, 5 of which were

allogeneic HSCT recipients [79]. Histopathology demonstrated fungal elements in 5/5, while fungal culture was only positive in 2/5. mNGS identified fungal species as follows: *Rhizopus microsporus* (2), *Mucor racemosus* (2), and *Rhizopus oryzae* (1). Although available studies are small and require validation in larger cohort, they emphasize the diagnostic potential of mNGS in comparison with standard diagnostics. In addition to pathogen identification, one study stressed the potential role of mNGS in the identification of genetic determinants related to host immune response of immunocompromised patients with confirmed lower respiratory infection [78].

Table 5 Utility of metagenomic next-generation sequencing (mNGS) on respiratory specimens for diagnosis of pneumonia in SOT and HSCT recipients

BAL bronchoalveolar lavage; *HSCT* hematopoietic stem cell transplantation; *SOT* solid organ transplantation

Explify™ Respiratory (IDbyDNA, San Francisco, USA) is a commercially available mNGS assay validated for BAL and detects hundreds of bacterial, fungal, and viral respiratory pathogens in a single run with result turnaround time of 2–3 days. In a study among immunocompromised children with suspected pneumonia (42% of which had underlying hematologic malignancies), mNGS testing demonstrated high agreement with conventional microbiologic tests (90.2% for bacterial, 94.1% for virus, 66.7% for fungal detection). The assay also identified putative and possible infectious causes in 44% of children with suspected respiratory infections whose conventional testing was negative [80].

Emerging Diagnostics for CNS Infections

Identification of the causative agent of encephalitis and differentiation between infectious and noninfectious processes are critical in delineating the treatment approach for transplant recipients and potential deceased donors with encephalitis/meningitis syndromes. The conventional diagnostic approach to encephalitis consists of testing

tailored to a patient's clinical presentation and epidemiologic exposures including targeted antigen-based, PCR, and serologic assays. Despite extensive concurrent and sequential testing, the underlying pathogen remains unclear in up to 60% of encephalitis cases [81]. Novel diagnostics for CNS infections, on the other hand, have the capacity to test for dozens or even hundreds of pathogens simultaneously. These include targeted multiplexed PCR assays and mNGS.

Multiplex PCR

Multiplex PCR assays that include several viral, bacterial, and fungal targets are now available. The FilmArray meningitis/encephalitis (ME) panel (Biofire Diagnostics) tests for six bacterial (*E. coli K1*, *H. influenzae*, *L. monocytogenes*, *N. meningitides*, *S. pneumoniae*, *S. agalactiae*), seven viral (HSV1-2, VZV, CMV, HHV6, *Enterovirus*, human parechovirus), and two fungal pathogens (*C. neoformans* and *C. gattii*) on cerebrospinal fluid (CSF) with a turnaround time of 1 h. In a multicenter study of 1560 prospectively collected CSF samples utilizing FilmArray ME panel versus conventional techniques (i.e., culture for bacteria and monoplex PCR for other agents [82], the FilmArray ME panel had a sensitivity of 100% for 9/14 pathogens (*E. coli* K1, *H. influenzae*, *S. pneumoniae*, CMV, HSV-1, HSV-2, human parechovirus, VZV, *Cryptococcus neoformans/gattii*). Enterovirus and HHV-6 had an agreement of 95.7% and 85.7%, respectively. The specificity was $\geq$99.2% for all 14 pathogens. This study did not include immunocompromised hosts, but other studies include limited data for this population. Chang et al. evaluated the ME panel in hospitalized patients, which included eight immunocompromised patients (HIV/AIDS, steroid use, active chemotherapy, transplant). The ME panel detected HHV-6 in an HSCT recipient with symptoms of encephalitis, while the concurrent HHV-6 PCR was negative [83]. There are emerging data that the sensitivity of ME panel for *Cryptococcus* is relatively poor compared to conventional testing. The ME panel failed to detect *Cryptococcus* in CSF twice, resulting in delayed diagnosis in a kidney transplant recipient [84]. The diagnosis was later confirmed by the conventional cryptococcal antigen lateral flow assay. Another study retrospectively evaluated patients who underwent CSF or serum testing for *Cryptococcus* with ME panel CSF culture and antigen testing [85]. Twelve of the 14 cases who met inclusion criteria were HIV-positive. Of the 14 cases with positive CSF cryptococcal antigens, 5 had positive ME and culture. Among the nine cases with negative ME, two had positive culture, and seven had negative culture. The sensitivity was calculated at 71.4% while specificity was 100%. Based on these two reports, a negative ME result for *Cryptococcus* does not rule out cryptococcal meningitis, especially in at-risk patients.

Metagenomic Sequencing

mNGS carries the potential for hypothesis-independent testing of hundreds of pathogens simultaneously and may be particularly useful when applied to normally

sterile specimens such as CSF. The value of mNGS in the diagnosis of encephalitis in SOT and HSCT recipients has already been demonstrated (Table 6). In a review of the current literature, 8 of 17 cases diagnosed with mNGS involved novel pathogens including arenavirus [3/17], astrovirus [4/17], and human betacoronavirus [1/17]. Unexpected etiologies such as *Candida* and Hepatitis E encephalitis were found in two cases. Donor-derived transmission of tick-borne virus encephalitis [86] and possibly due to arenavirus [87] was also reported. These cases illustrate the potential use of mNGS in diagnosing meningoencephalitis of unclear etiology in potential organ donors, a high-risk category that normally precludes utilization of organs due to concern for transmission of life-threatening infectious pathogens not detected by conventional testing.

Emerging Diagnostics for Gastrointestinal Infections

Diarrheal disease is associated with significant morbidity and mortality for immunocompromised hosts. In SOT recipients, diarrhea is associated with poorer graft survival and increased risk for death [88]. Establishing a diagnosis early and accurately allows providers to distinguish infectious from noninfectious causes including immunosuppressive drug-related (e.g., mycophenolate) or graft-versus-host disease-related diarrhea, which require special intervention. In comparison with conventional testing, which includes stool culture, microscopy, and antigen testing, molecular assays can identify multiple pathogens simultaneously with shorter turnaround times.

Multiplex PCR

There are currently three FDA-approved multiplex tests for gastrointestinal pathogens: FilmArray Gastrointestinal Panel (Biofire Diagnostics, Utah, USA), xTag Gastrointestinal Pathogens Panel (GPP) (Luminex, Texas, USA), and Verigene Enteric Pathogens (Nanosphere, Illinois, USA) (Table 7). Studies in immunocompromised patients with gastrointestinal illness are limited. Mengelle et al. evaluated xTag GPP in 102 adult organ transplant recipients with diarrhea [89]. Twenty-five of 147 samples (17%) collected were positive for at least one pathogen. Toxigenic *C. difficile*, norovirus, and *Salmonella* spp. were detected in 7.5%, 4.1%, and 2.7%, respectively. Coste et al. evaluated xTAG GPP in 49 adult kidney transplant recipients with 54 severe diarrhea events [90]. Among 39 positive samples, multiplex PCR identified multiple infections in 15 (38%), providing additional diagnoses compared to traditional tests. The most common pathogens identified by multiple PCR were enteropathogenic *E. coli* (15/39, 38%), *Campylobacter* spp. (15/39, 38%), and norovirus (14/39, 36%). Despite the potential for additional diagnoses, there are drawbacks to increased sensitivity. Since nucleic acids of viable and nonviable pathogens including free DNA/RNA is not distinguished [91], disease, asymptomatic carriage, or shedding (particularly with certain viruses) can be confounded. This

Cyclospora cayetanensis	X		
Entamoeba histolytica	X	X	
Giardia lamblia	X	X	

includes detection of *C. difficile* [92–94] which may represent colonization rather than infection. Detection of more than one pathogen [95], though sometimes useful, may render result interpretation difficult. As opposed to culture techniques, multiplex PCR assays do not provide antimicrobial susceptibility, information that is essential for antimicrobial stewardship and epidemiologic monitoring. Notably, GI panels that include adenovirus such as GPP and FilmArray assays only target adenovirus types F40/41. However, other adenovirus types especially within subgroup C cause most infections among transplant patients, so these assays do not rule out adenovirus gastroenteritis [96].

Conclusion

In the past decade, several novel diagnostic modalities have emerged with the potential to revolutionize the diagnosis of infectious diseases in transplant patients in a way comparable to the effect of MALDI-TOF MS on general microbiological diagnostics. Though significant strides have been made, most modalities continue

to have certain drawbacks that limit their applicability. Molecular methods applicable directly to blood samples for the diagnosis of BSI benefit from very short processing times but suffer from lower sensitivity due to circumvention of a growth phase, while assays performed on positive blood cultures are generally more sensitive except for fastidious or unculturable organisms. T2 magnetic resonance-based testing is rapid and highly sensitive, but translating the reported diagnostic performance into real-world utility has been problematic. mNGS has significant potential for rapid and broad detection of pathogens in multiple specimen types, but current methods remain less sensitive than targeted PCR tests that are based on amplification [97], and cost of commercial mNGS assays is prohibitive. Breath-based diagnosis has been shown to improve the diagnosis of invasive aspergillosis, yet there remain important challenges to its application. Despite their shortcomings, emerging technologies have already demonstrated a diagnostic advantage as well as a positive impact on patient outcomes [98]. Though data on test performance characteristics and clinical impact among transplant patients remains limited, it is likely that these modalities will translate into even greater utility given the increased risk for infection and propensity for multiple and uncommon pathogens in this population.

Key Points

- Transplant patients are at increased risk for community-acquired and opportunistic pathogens, multiple pathogens simultaneously, and multidrug-resistant organisms.
- Diagnostic microbiology has witnessed a shift toward culture-independent methods in the past decade.
- Molecular methods applicable directly to blood samples for the diagnosis of BSI benefit from very short processing times but suffer from lower sensitivity due to circumvention of a growth phase.
- Molecular assays performed on positive blood cultures are more sensitive except for fastidious or unculturable organisms.
- T2 magnetic resonance-based testing is rapid and highly sensitive, but translating the reported diagnostic performance into real-world utility has been problematic.
- Metagenomic next-generation sequencing has massive potential for rapid and broad detection of pathogens in multiple specimen types, but current methods remain less sensitive than targeted PCR tests.
- Breath-based diagnosis has been shown to improve the diagnosis of invasive aspergillosis, yet there remain important challenges to its application.
- Despite shortcomings, emerging technologies have already demonstrated a diagnostic advantage as a well as a positive impact on patient outcomes.
- Though data on test performance characteristics and clinical impact among transplant patients remains scarce, it is likely that these modalities will translate into even greater utility in this population.

Introduction

Due to immunosuppression, solid organ transplant (SOT) and hematopoietic stem cell transplant recipients are highly susceptible to a host of cutaneous infections. Often, exaggerated and atypical cutaneous manifestations are due to impaired immunological surveillance of common and ubiquitous pathogens. In the immediate post-transplant period, patients are most likely to present with cutaneous infections due to nosocomial pathogens, while opportunistic pathogens become more prevalent once patients have had longer exposure to immunosuppression. Here, we will explore the incidence, diagnosis, and management of cutaneous infections that are commonly observed in SOT recipients, and compare them against findings seen in the stem cell transplant population.

Superficial Fungal Infections

Disease Epidemiology

Superficial fungal infections are quite common in SOT recipients. In one series of 223 renal transplant recipients (RTRs), 60% of transplanted patients developed a superficial fungal infection with the majority presenting within the first year after transplantation [1, 2]. The majority of these cases are related to organisms normally found on the human skin or mucosa, such as oral candidiasis [3]; however *Malassezia* and dermatophytes, such as *Trichophyton rubrum*, are also frequently seen. Penetrative injuries to the skin, however, can introduce a much wider variety of soil and environmental fungi that should also be considered.

Clinical Impact in Transplant

Disseminated disease is unlikely to result from superficial fungal infections and therefore reduction in immunosuppression is usually not warranted outside of severe or atypical cases. However, cutaneous infections can carry high symptomatic morbidity and therefore attention to and treatment of these conditions is important. Rarely, sporotrichoid spread of cutaneously inoculated molds can be associated with secondary dissemination and may warrant immunosuppression reduction.

As mentioned, deep and disseminated fungal infections are not discussed in this section. Please refer to ▶ Chaps. 45, "*Aspergillus* in Solid Organ and Stem Cell Transplant Patients: Emerging Options for Diagnosis and Management," and ▶ 47, "Non-*Aspergillus* Fungal Infections in Transplant Patients" for a more extensive discussion of these infections and their cutaneous extension.

Disease Diagnostics and Clinical Evaluation

Superficial fungal infections can have diverse cutaneous presentations. *Malassezia*, for example, classically presents as tinea versicolor with hyper- and hypo-pigmented

patches and plaques with fine scales that are commonly on the trunk. SOT recipients may present with tinea versicolor in unusual locations, like the genitalia [4]. *Malassezia* may also often manifest as a folliculitis-type rash, with erythematous papules and pustules on the face and upper trunk [2, 5]. This presentation can easily be confused with steroid acne, a not infrequent skin issue in the transplant population, owing to the use of prednisone as a component of the immunosuppressive regimen. *Malassezia* is also implicated in seborrheic dermatitis which was shown to affect about 10% of patients in one series of renal transplant recipients [6]. Seborrheic dermatitis presents with erythema and greasy scale, primarily on the scalp and face with trunk and back involvement reported as a feature of *Malassezia* infections as well [6]. Onychomycosis can also appear in SOT recipients, [7] although this condition, characterized by thickening and yellow discoloration of the nails, is most often caused by dermatophyte species like *Trichophyton rubrum* [3]. Other common presentations of dermatophyte infection include tinea cruris, tinea corporis, and tinea pedis [3].

Atypical dermatophyte infections are also seen in SOT recipients as in the of case of *T. rubrum* causing molluscum-like umbilicated papules on the face [8]. Superficial dermatophyte infections can lead to severe dermatophytosis in such a t-cell immunosuppressed host, presenting with lower extremity nodules that may ulcerate or become necrotic [9]. Tinea corporis can also present as diffuse erythema and scaling without classic annular lesions and can prove difficult to eradicate due to host immunosuppression.

Mucocutaneous candidiasis presents with erosions and a creamy exudate on the oral mucosa [10] and on the intertriginous regions with erythema, vesicles, pustules, and typical "satellite" lesions. There should be high suspicion for candidiasis early in the post-transplant course [11], especially after more intense induction immunosuppression, such as thymoglobulin or alemtuzumab.

The diagnosis of superficial fungal infections is largely clinical, but in unusual or refractory cases it can be aided at the bedside by potassium hydroxide (KOH) preparation and microscopy of skin scrapings. On KOH preparation, *Malassezia* species will reveal yeast-like bodies and hyphae [9], as opposed to dermatophytes which will show septate hyphae [12], and candida where hyphae and pseudohyphae are present. If the clinical diagnosis is not clear, tissue culture and histopathology can help provide certainty.

Management

Topical treatments are preferred for control of limited superficial fungal infections. These include the use of antifungal shampoos like ketoconazole and selenium sulfide as well as azole or allylamine antifungal preparations [2, 3]. For extensive or refractory disease, systemic therapy with oral fluconazole or itraconazole for *Malassezia* and oral terbinafine for dermatophyte infections is indicated [3]. Discussion with the transplant team regarding drug interactions is important if systemic therapy is considered, especially when considering the azole family. From a

dermatologic perspective, it is important for the physician to recognize the risks associated with voriconazole, specifically. Namely, voriconazole use is associated with significant photosensitivity and an overall 1.86-fold increase in squamous cell carcinoma incidence among lung and hematopoietic cell transplant patients, a population that is already at a significantly increased risk of cutaneous squamous cell carcinoma [13]. Importantly, these risks are positively correlated with the dose and duration of treatment [13]. Therefore, patients who do receive antifungal therapy with voriconazole should undergo regular full body skin examinations.

For oral candidiasis lesions, nystatin swish and swallow is the treatment of choice [10], and systemic therapy is limited to patients where drug-resistant candida is suspected or extension into the retropharynx or esophagus is documented.

Viral Infections

Disease Epidemiology

SOT recipients are susceptible to primary cutaneous infection and reactivation of common human viruses. Herpes simplex virus (HSV) and varicella zoster virus (VZV) are the most common offenders within the first year post-transplant, in the absence of prophylaxis, while oncogenic viruses like HPV and HHV-8 tend to be more relevant after years of immunosuppression [14]. Different studies of VZV incidence range from 5% to 40% in the first 1–2 years after transplant. CMV infection most often presents with systemic symptoms in the early post-transplant period but can have associated skin findings.

For a more extensive discussion on the systemic impacts of HSV, VZV, CMV, or HHV8 please refer to ► Chap. 26, "Herpes Simplex and Varicella Zoster in Transplant Candidates and Recipients."

Most SOT recipients are latently infected with alpha-herpes viruses HSV-1, HSV-2, and VZV prior to transplant [15] and reactivation is seen during acute and high levels of immunosuppression. CMV is the most common viral infection among SOT recipients, affecting up to 60% of patients, and cutaneous manifestations may be seen, although very rarely [16]. The now common use of viral prophylaxis for CMV, either valganciclovir or more recently letermovir, has reduced the rates of several viral infections in SOT recipients, including reduction in the rate of cutaneous HSV or VZV infections from nearly half of patients to less than 10% in the year after transplant [17–19].

Renal transplant recipients are 3.4 times more likely than the nontransplant population to have HPV-related genital warts and this increased risk persists for at least ten years after transplant [20]. The prevalence of HPV on cervical smears is about 30% with high-risk subtypes detected in the majority of cases [21, 22]. Whether the declines in HPV rates seen in some countries with high penetrance of HPV vaccination in early teenage years translates into lower incidence in the transplanted population is not yet known.

Clinical Impact in Transplant

Diffuse, morbilliform and nonspecific eruptions should alert the provider to possible systemic viral infection, especially in the acute post-transplant course. The rare occurrence of solid organ transplantation–associated graft-versus-host disease (GVHD) can similarly present with morbilliform, confluently erythematous, and desquamative eruptions. It is important to include GVHD in the differential of a suspected viral exanthem as it is critical to recognize this entity early [23]. Miliaria (crystallina and rubra) may also present similarly. Therefor, biopsy or viral smears and/or staining may be needed to differentiate all of these competing diagnoses.

Skin-limited viral infections, like HSV ulcers, can occasionally serve as a site for secondary bacterial infection in the susceptible host, therefore a thorough history and physical exam is important to identify any lesions and begin prompt treatment. HPV-associated warts are a risk factor for progression to squamous cell carcinoma, and these lesions are reported to be more common among non-White SOT recipients [24, 25]. Importantly, the majority of patients deny the presence of genital lesions although about half will have a lesion on physical exam [24]. Therefore, routine genital examination is important for the detection of HPV-associated genital lesions.

In one study of SOT recipients with HSV infection, immunosuppressive regimens were reduced in about 50% of patients in response to infection [19]. Interestingly, specifically for renal transplant recipients with refractory warts, replacement of cyclosporine with sirolimus has shown to result in resolution of cutaneous lesions [26]. Such studies are not available for other organ groups, although feasibly the same outcome may be expected. Indications for possible reduction of immunosuppression include large and multiple lesions, patient discomfort/impairment, as well as anal and vulvar lesions associated with AIN or VIN. Although rare, cutaneous manifestations of CMV may be a harbinger of graft rejection and therefore, careful reconsideration of the immunosuppressive regimen is advised [14].

Disease Diagnostics and Clinical Evaluation

The typical lesions of HSV-1 and HSV-2 are grouped vesicles or ulcers in the oral or genital regions, respectively [15]. Primary VZV infection, or varicella, is characterized by a diffuse vesicular eruption preceded by a viral prodrome, whereas VZV reactivation, or herpes zoster, presents with a unilateral and dermatomal distribution of painful vesicles preceded by dysesthesia in the same distribution [15]. Disseminated VZV, which does not respect the typical dermatomal distribution, is more common in solid organ recipients than in the immunocompetent population [15]. The diagnosis of HSV or VZV can often be made clinically, but should be confirmed with laboratory testing if there is any doubt or if the patient is acutely ill. Confirmation may also be important in determining infection control implications and isolation restrictions for an infected patient. It may also impact decision-making for the patient with other systemic symptoms in terms of confirming or refuting a diagnosis.

The diagnostic test of choice for all herpes viruses is PCR. Viral culture is now limited to cases where acyclovir-resistance is suspected [18, 27]. Tissue pathology can be confirmatory of the clinical and laboratory findings.

HPV-associated warts in SOT recipients are similar to those seen in immunocompetent individuals with distribution to the face, hands, and feet [14]. However, warts may be greater in number and larger in size with possible progression to acquired epidermodysplasia verruciformis, or generalized verrucosis, a condition characterized by the presence of greater than 20 verrucous lesions and associated with increased risk of cutaneous squamous cell carcinoma [28–30]. The diagnosis is clinical, but histopathologic evaluation can be confirmatory and serve to rule out carcinoma in particularly atypical appearing lesions, or in lesions that have grown rapidly or exhibit bleeding.

Molluscum contagiosum is characterized by isolated or scattered flesh colored umbilicated papules caused by Poxvirus and is diagnosed clinically. Up to ~7% of SOTRs with molluscum contagiosum may have an atypical presentation with more extensive disease, larger nodules, or a folliculitis-like appearance [31, 32].

Cutaneous manifestations of CMV infection are rare in SOT recipients but have been reported. Ulcerated lesions are most commonly reported with the majority of the lesions located in the genital area [33–35]. Ulcers located on the face and extremities have been reported as well [36, 37]. Punch biopsy for histopathologic examination as well as viral culture should be performed if cutaneous CMV is suspected as the differential is broad for such ulcerated lesions. CMV viremia should also be confirmed with hematologic testing.

Management

- Prophylaxis: Recent guidelines for the management of HSV in SOT recipients recommend acyclovir for prophylaxis in HSV-1- and/or HSV-2-positive patients who are not already receiving prophylaxis for CMV [15, 18]. Duration varies according to the organ type, and the degree to which they are immunosuppressed, but typically may continue for 3–6 months. Vaccination for primary VZV, or varicella, should be considered in the pre-transplant setting for the 2–4% of patients that are seronegative [27]. This is a live attenuated vaccine and is contraindicated after transplant but is effective in inducing a memory T-cell response in transplant candidates [38]. Vaccination for herpes zoster using the live attenuated Zostavax vaccine is now rare, and contraindicated in patients who are already transplanted due to rare circumstances where reactivation of attenuated virus occurs. [39]. The new herpes zoster subunit vaccine, Shingrix, is being investigated for use in the post-transplant setting with early promising results [39]. Certainly, it should be standard of care for patients who are over the age of 50 and contemplating transplant.

  Regarding HPV, current US guidelines recommend a three-dose vaccine regimen for patients between the ages of 9 and 26 years; this includes SOT recipients [40]. Between 27 and 45 years of age, shared decision-making is recommended for

HPV vaccination. One study showed that the quadrivalent vaccine was well tolerated in transplanted patients up to the age of 35, but with a sustained response in only about half of patients [41]. Interestingly, successful use of the four-valent and nine-valent vaccines as treatment for patients with active lesions has been reported [28, 42]. Furthermore, the nine-valent vaccine has been injected intratumorally simultaneously with systemic vaccination, resulting in tumor resolution in an immunocompetent patient [43]. These studies support the likely benefit of HPV vaccination for both the reduction of HPV-associated benign and malignant lesions in at-risk transplant recipients. Larger prospective trials in this population will be critical to better define who benefits and when the dosing should occur.

The utility of CMV prophylaxis is well established and should be prescribed per guidelines.

For more details on the management of CMV, please refer to ▶ Chap. 25, "Cytomegalovirus in Hematopoietic Stem Cell Transplant Recipients: Prevention, Diagnosis, and Treatment" on CMV management.

- Treatment: For HSV and VZV, oral therapy is indicated for limited mucocutaneous disease although IV Foscarnet may be appropriate for acyclovir-resistant or recalcitrant cases [15, 18]. Options for oral therapy of HSV and VZV include acyclovir, valacyclovir, and famciclovir [15]. First-line therapy for HPV-associated warts is localized destruction of tissue that is most often accomplished with cryotherapy. Intralesional Candida injections (available as a candida antigen solution in the USA) have also been used safely in transplant recipients with HPV-associated warts [44]. They are hypothesized to work by stimulating Tcell immunity that cross-targets infected cells. For treatment of recalcitrant warts, there are several reported therapies with limited success which include topical and intralesional cidofivir [45, 46], oral isotretinoin [47], and oral cimetidine [48]. Treatment options for molluscum contagiosum include topical cantharidin, cryotherapy, curettage, and pulsed dye laser [49]. First-line treatment for CMV is ganciclovir and duration is dependent on the clearance of viremia. For ganciclovir-resistant disease, CMV-specific immunoglobulin is an option and there are several promising novel antiviral agents currently undergoing clinical studies [50].

Bacterial Infections

Disease Epidemiology

All transplant recipients are susceptible to nosocomial bacterial pathogens like *Staphylococcus aureus*, especially in the very early post-transplant period when surgical site infections represent the most common site involved [14]. In one study of renal graft recipients, skin was the most common site of *Staphylococcus* aureus infection and the median time to infection after transplant was 29 days [51]. Interestingly, *Staphylococcus aureus* colonization tends to be higher in SOT compared to immunocompetent patients [52], with an increased risk of infection as a direct result [53]. *Nocardia* is another gram-positive opportunistic pathogen that has

been recognized in SOTRs with skin being the second most common site of infection [54]. Increasingly, transplant recipients are also recognized as being at increased risk for cutaneous mycobacterial infections, particularly in the first two years post-transplant when immunosuppression is at its greatest, and transplant surgical wounds are healing [14, 55]. Such infections include both *Mycobacterium tuberculosis* outside of north America, but also nontuberculous mycobacteria (NTM) such as *Mycobacterium abscessus* and less commonly *Mycobacterium chelonae* [56–59].

Clinical Impact in Transplant

Early recognition and treatment of cutaneous bacterial infection in an immunosuppressed host is important, with data suggesting that anti-rejection therapy plays a role in the loss of control of skin and soft tissue microbes. The skin frequently serves as the first recognizable portal of entry for subsequent severe systemic infection. Indeed, solid organ transplant recipients with skin and soft tissue infection, such as necrotizing fasciitis, are more than twice as likely to develop septic shock than immunocompetent controls [60]. Importantly, infection with *Staphylococcus aureus* has been associated with increased risk of graft loss [51, 53], through multiple direct and indirect pathways, highlighting the need for prevention and early recognition of bacterial infections which present on the skin.

Disease Diagnostics and Clinical Evaluation

The same bacterial pathogen can cause several different types of cutaneous infections with varying presentations. *Staphylococcus aureus,* for example, can be the pathogen in folliculitis, impetigo, erysipelas, cellulitis, and toxic shock syndrome or necrotizing fasciitis/panniculitis [14]. Folliculitis is characterized by erythematous follicular–based papules and pustules on the trunk and extremities. Impetigo is a superficial bacterial infection caused by common skin flora, including *Staphylococcus* and *Streptococcus* species, and characterized by honey-colored crusting of eroded plaques. Erysipelas describes bacterial infection limited to the upper dermis and superficial lymphatic system that presents with sharply defined, bright red plaques. On the other hand, cellulitis is infection of the deeper dermis and subcutaneous tissue that presents with ill-defined, pink, and tender plaques. Less common presentations of cutaneous infections due to *Staphylococcus* and *Streptococcus* include ecthyma, which is characterized by painful ulcers on the lower extremities, and necrotizing fasciitis, which is a polymicrobial infection that invades into the deep soft tissues.

Ecthyma gangrenosum is a rare presentation most classically associated with *Pseudomonas aeruginosa* infection, although it has been documented with other gram-negative infections especially. It is characterized by a rapidly developing hemorrhagic blister that may develop into a necrotic ulcer. This should be considered a sign of Pseudomonal bacteremia and has been reported in the transplant population [52, 61].

Cutaneous manifestations of *Nocardia* can be primary or secondary to disseminated infection. Primary cutaneous nocardiosis may present with cellulitis, abscesses, exophytic growths, blisters, or ulcers and may spread along the lymphatics in a "sporotrichoid" distribution [62–65]. Mycetomas, or draining nodules and plaques, may develop on the lower extremities.

Cutaneous manifestations of *Mycobacterium tuberculosis* are rare but can present with abscesses, ulcers, or verrucous nodules with possible sporotrichoid spread [55, 66, 67]. Miliary tuberculosis may present with diffuse erythematous, papular or vesicular rash [68]. Finally, tuberculids are cutaneous lesions caused by a hypersensitivty reaction in patients infected with M.tuberculosis. The pathogenesis of these reactive manifestations remains unknown. Typically these lesions respond to anti-tuberculosis treatment.

Scrofuloderma describes the development of ulcerating, draining nodules overlying affected lymph nodes. NTM infections in transplant recipients have been reported to present with extremity nodules and ulcers as well surgical site infections [56–59].

For a more detailed review of tuberculous and nontuberculous mycobacterial disease in transplants, please refer to ▶ Chaps. 18, "*Mycobacterium tuberculosis* in Transplantation," and ▶ 20, "Slow-Growing Nontuberculous Mycobacteria in Transplant."

When bacterial infection is suspected, cultures obtained via surface swabs are of limited value given the risk of contamination. Therefore, punch biopsy of the presenting lesion for tissue culture, speciation, and sensitivities as well as histopathologic analysis is recommended for diagnosis. Blood cultures should also be obtained prior to starting treatment if there is any concern for systemic involvement, e.g., fevers, hypotension, tachycardia, and rigors.

Management

- Prophylaxis: There is precedence and data to support the role of *Staphylococcus* decolonization as a cost-saving measure, but some studies have shown lack of efficacy [69, 70]. For example, a local decolonization protocol involves combination of 4% chlorhexidine for daily bathing, chlorhexidine mouth rinse, and 2% intra-nasal mupirocin twice daily, for 5 days. Some experts combine this with an anti-staphylococcal antibiotic, such as doxycycline, for those with larger or multiple pustules at the outset, although this is not uniformly done. Patients who are receiving prophylaxis with TMP-SMX for *Pneumocystis jiroveci* pneumonia may have a decreased rate of *Nocardia* infection. There is data to suggest some benefit to daily TMP-SMX for secondary prophylaxis in patients with a prior episode of nocardiosis [71].
- Treatment: For superficial infections like folliculitis and impetigo, topical antibiotics like mupirocin and clindamycin are often sufficient [52]. Oral therapy should be considered when the involved surface area is greater than that which can be covered easily with topical treatments or in those with refractory disease.

For purulent infections, incision and drainage is primarily indicated. Empiric oral or intravenous antibiotics may be helpful for complicated or more severe infections, for example, those >2 cm or with extensive cellulitis, or where multiple abscesses are present. Whether solid organ transplant alone puts the patient at sufficiently high enough risk to undertake broad spectrum empiric antibiotics is unclear, but in general patients with systemic immunosuppression should be managed with more caution [72]. In the case of cellulitis, erysipelas, or necrotizing infection, empiric oral or intravenous antibiotic treatment with an anti-staphylococcal penicillin, first-generation cephalosporin, or clindamycin should be initiated as first line [72]. Trimethoprim/sulfamethoxezole may also be used. For severe infections, broad spectrum empiric coverage should be initiated with prompt narrowing of coverage upon availability of culture and sensitivity data. Intravenous antibiotics are indicated with any sign of bacteremia or sepsis. Surgical debridement may also be necessary for infections [54] that appear to be necrotizing, especially those where the tissue exhibits crepitus, or the patient has signs of sepsis, therefore multidisciplinary care of these patients is necessary.

Special Considerations for the Blood and Marrow Transplant Patient

Hematopoietic stem cell transplantation (HSCT) is a commonly used treatment for hematologic malignancies, although it is also used for nonmalignant hematologic and autoimmune conditions [73–75]. Just like patients who undergo solid organ transplantation, the immunosuppressed state of HSCT patients puts them at risk for a variety of cutaneous and systemic infections that have skin manifestations. There are major immunologic differences among SOTRs and HSCT patients, however, that affect the type and timing of their cutaneous diseases. SOTRs expect to be on chronic immunosuppressive therapy for years. However, the goal of HSCT is to restore the patient's immune compartment, without requirement for prolonged immunosuppressive therapy. The exception is for patients who develop chronic graft-versus-host disease (GVHD), a common complication of allogeneic HSCT. Patient who develops chronic GVHD may require years of immunosuppressive therapy depending on the severity of their disease [76]. In contrast to SOTRs, patients who undergo HSCT go through an acute phase of profound immunosuppression. Patients who undergo HSCT are often treated with myeloablative chemotherapy, with or without total body irradiation, prior to infusion of either autologous or allogeneic hematopoietic stem cells. The post-HSCT neutropenic phase typically lasts for 1 month, but T and B cell recovery may not occur until after several months to even years after HSCT [77]. During the neutrophil recovery period, patients may develop an inflammatory reaction associated with immunologic engraftment, characterized by a morbilliform eruption or diffuse macular erythema and edema of the skin, fever, and manifestations of capillary leak syndrome [78].

Cutaneous Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) is a common complication of allogeneic HSCT and is a leading cause of nonrelapse mortality among these patients. This is a multisystem disease, but the skin is the most commonly involved organ, affecting up to 76% of patients with acute GVHD [79]. Acute GVHD has traditionally been defined as occurring within the first 100 days after allogeneic HSCT. The most commonly described appearance of acute cutaneous GVHD is a morbilliform reaction (see Fig. 1). This makes it difficult to differentiate from a cutaneous drug reaction. Drug hypersensitivity syndrome or drug reaction with systemic symptoms (DRESS) is a particularly challenging differential diagnosis, and severe cutaneous acute GVHD can be clinically and histologically similar to Stevens Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) [80]. A phototoxic drug reaction, especially to voriconazole, should be recognized, and can occur in both acute and chronic settings [81]. While acute phototoxicity presents with photodistributed erythema and bullae, chronic phototoxicity is characterized by dyspigmentation, poikilodermatous change, and even cutaneous malignancies. Certain clinical features, such as facial involvement, the presence of diarrhea, and hyperbilirubinemia can help distinguish acute GVHD from a morbilliform drug reaction [82]. The cutaneous eruption in acute GVHD can also be characterized by follicular scaly papules and can simulate a bacterial or fungal folliculitis [83]. In our experience, however, the follicular form of acute GVHD tends to be more monomorphic, and less pustular when compared to a bacterial folliculitis. Other atypical manifestations of acute GVHD may be more papulosquamous in appearance, and may mimic pityriasis rubra pilaris, acquired ichthyosis, and psoriasis (see Fig. 2) [84].

Chronic cutaneous GVHD is a long-term immunologic complication of allogeneic HSCT [85]. In contrast to acute GVHD, the skin manifestations of chronic GVHD mimic a variety of autoimmune cutaneous disorders [84, 85]. The diagnosis

Fig. 1 Acute GVHD

Fig. 2 Eczematous acute GVHD

of chronic cutaneous GVHD relies on clinical features, although a skin biopsy may sometimes be helpful. The sclerotic form of chronic cutaneous GVHD is the most severe phenotype, and is associated with increased morbidity [86]. Other diagnostic manifestations include poikiloderma, lichen planus-, morphea-, and lichen sclerosus-like changes (for sclerotic GVHD, refer to Fig. 3).

Cytomegalovirus Reactivation Among HSCT Patients

CMV reactivation remains a common challenge in the post-HSCT period. As many as 40% of allogeneic HSCT patients have CMV reactivation within 1 year of their transplant when both donor and recipient have positive serologies for CMV [87]. The median time to CMV reactivation is 41 days. The classic cutaneous manifestation of CMV consists of oral ulcerations and round, crusted perianal papules [88, 89]. However, these papules can appear in other parts of the body, and disseminated forms of the disease may occur, especially in the setting of total body irradiation [90]. Vasculitis and vasculopathic cutaneous lesions from CMV have been described, and are not surprising given the tendency of CMV to localize and proliferate in endothelial cells [89, 91, 92]. Coinfection with bacteria and other herpes viruses are not uncommon, and is a potential pitfall in diagnosis [89, 90].

Conclusion

Transplant recipients are at an increased risk for common community-acquired and nosocomial cutaneous infections. The presentation of such diseases may be typical or atypical and importantly may follow a more aggressive clinical course. Patients may not report the presence of lesions, especially those in sensitive body areas, therefore routine and thorough skin examinations are indicated in all SOT and HSCT recipients. Vaccination and antimicrobial prophylaxis are two important strategies for preventing

Fig. 3 Sclerotic chronic GVHD

cutaneous infections, and the use of HPV vaccines in this population warrants further study. Treatment of cutaneous infections in transplant requires a multidisciplinary and multimodal approach with careful consideration of any changes in the immunosuppressive regimen, depending on the severity and morbidity of the infection.

Key Points

- Solid organ transplant recipients are at an increased risk of common community-acquired and nosocomial cutaneous fungal, viral, and bacterial infections.
- Drug reactions, viral infection, a cutaneous eruption from immune reconstitution, and GVHD are important differential diagnoses to consider in a HSCT patient who presents with a rash.
- Cutaneous manifestations may have typical or atypical presentations, but often follow a more aggressive course in this population.
- Diagnosis is often clinical but skin biopsy, tissue culture, and PCR are important useful diagnostic tools.
- Voriconazole use for severe fungal infections is associated with a significantly higher risk of squamous cell carcinoma in SOTRs.

- The use of CMV prophylaxis has decreased the rates of HSV and VZV infection in SOTRs.
- HPV vaccination may be a useful tool in preventing and treating HPV-associated benign and malignant lesions in SOTRs but further study is needed to understand the safety and efficacy.
- SOTRs may not report cutaneous lesions, especially in sensitive body areas, therefore routine and thorough skin examination is indicated in all patients.
- Decisions regarding treatment modalities and reduction in immunosuppression requires a multidisciplinary approach.

Introduction

Ocular infections are rare but serious complications of solid organ and hematopoietic stem cell transplantation. Infection must be considered as a part of the differential diagnosis of ocular pathology after transplant, and any ocular symptoms in this patient population should prompt evaluation by an ophthalmologist. Here we summarize the epidemiology, clinical manifestations, and treatment of the most common causes of ocular infection among transplant recipients. While different frameworks may be useful for conceptualizing this class of infections, such as dividing infections by anatomic site, causative organism, or chronicity of symptoms, we subdivide this review chapter by causative organism for two reasons. First, the causative organism dictates diagnosis and

treatment. Second, infections in immunocompromised hosts are frequently not restricted to a single anatomic subdivision within the eye. We provide easily referenced tables and, where possible, offer guiding principles for diagnosis and management.

Epidemiology of Ocular Infections After Organ Transplantation

The transplant recipient is at risk for a variety of community-acquired and opportunistic pathogens including viruses, bacteria, fungi, parasites, and mycobacteria. Several large surveys provide insight into the type, frequency, and morbidity of these infectious ocular complications after transplant. In a retrospective series from Australia, Ng et al. evaluated 860 heart, lung, and liver transplants, identifying ocular complications in 2%; among those, 65% were opportunistic infections comprised of viral retinitis (77%) and fungal chorioretinitis (22%) [1]. Papanicolaou studied 684 patients who underwent orthotopic liver transplantation in the United States and identified ocular infections in 1.3%, with cytomegalovirus (CMV) retinitis the most commonly identified infection followed by fungal endophthalmitis [2]. Fungal infections tended to occur early (mean 42 days), whereas viral infections occurred later (mean 128 days) [2]. Tarabishy et al. conducted a retrospective analysis of 545 lung transplant recipients in the United States [3]. Among 46 who underwent ophthalmologic evaluation, 6 patients with infectious ocular complications were identified, 3 had herpesvirus infections (1 CMV retinitis, 1 varicella zoster virus (VZV) keratouveitis, and 1 zoster ophthalmicus due to VZV), and 3 had fungal infections including 2 cases of disseminated *Pseudallescheria boydii* infection and 1 rhinocerebral mucormycosis. Tabbara et al. conducted a retrospective analysis of 620 patients who underwent allogeneic hematopoietic stem cell transplantation in Saudi Arabia. The authors found a similar pattern in which CMV retinitis was the most common infection (0.7%) followed by fungal endophthalmitis (0.2%) [4]. Chung et al. surveyed 1198 cases of solid organ and bone marrow transplantation, finding 21 (1.8%) infections including 11 cases of CMV retinitis, 5 cases of fungal chorioretinitis, 3 cases of acute retinal necrosis (ARN), 1 case of progressive outer retinal necrosis, and 1 case of toxoplasma retinochoroiditis [5]. In addition to these large series, case reports and smaller series describe a long list of other organisms, such as parasites, spirochetes, and atypical bacteria that have been found to cause ocular infection but appear to do so less commonly [6–11]. In summary, the available data identify ocular infectious complications in 1–2% of transplant recipients, frequently as an organ-specific manifestation of a systemic infection, and highlight the role of herpesviruses and opportunistic fungi but also a variety of other pathogens.

Ocular Anatomy

A clear understanding of ocular anatomy is essential for accurate diagnosis and treatment of infectious complications because ocular infections tend to be classified and identified by the affected anatomic site(s). The eye is divided into anterior and

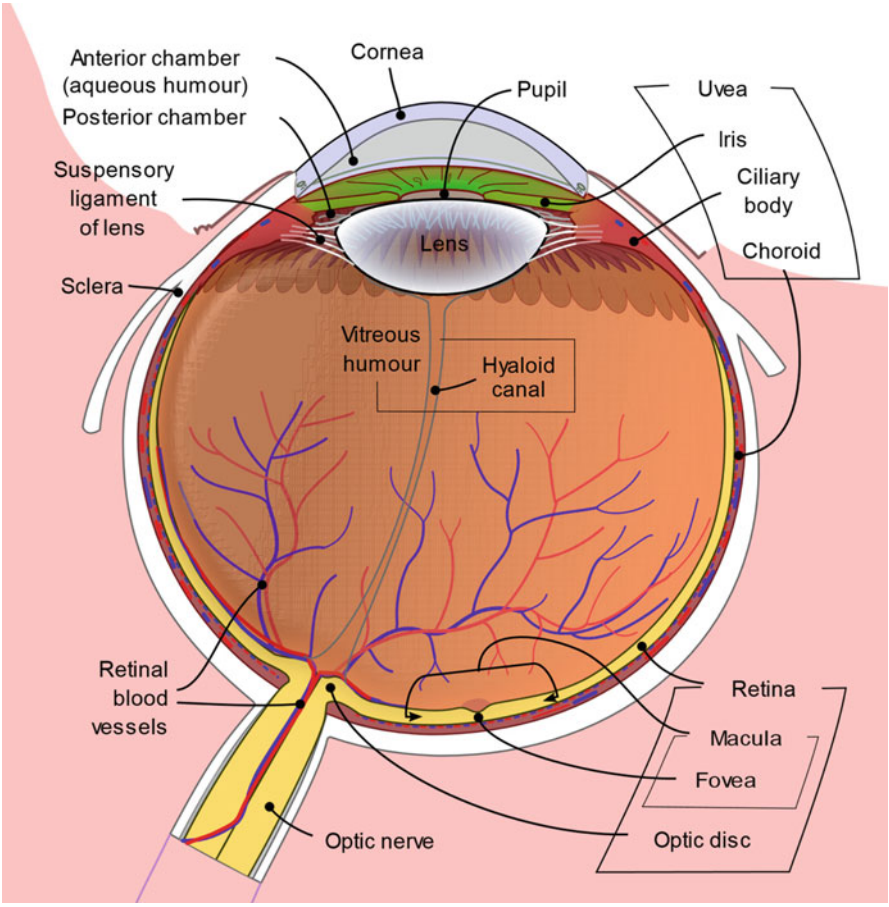

Fig. 1 Anatomy of the eye "Schematic diagram of the human eye with English annotations" by Rhcastilhos and Jmarchn is licensed under CC BY-SA 3.0. https://commons.wikimedia.org/w/index.php?curid=1597930. No changes were made. Retinitis refers to inflammation of the retina and retinal vessels. In the transplant population, retinitis is most commonly caused by herpesviruses and *Toxoplasma*. Endophthalmitis refers to inflammation of the aqueous or vitreous humors and is commonly caused by fungi such as *Candida* spp. in the transplant population. Anterior uveitis refers to inflammation of the iris and ciliary body; posterior uveitis refers to inflammation of the choroid, retina, or vitreous. Panuveitis denotes inflammation affecting both the anterior and posterior uvea. Among transplant recipients, a variety of pathogens can cause uveitis, including viruses, fastidious bacteria, mycobacteria, fungi, and parasites

posterior segments. The anterior segment contains the cornea, anterior chamber (containing the aqueous humor), iris, lens, and ciliary body. The posterior segment contains the vitreous, retina, and choroid (Fig. 1). The uvea is the term for the continuous pigmented layer of the eye that is comprised of the iris and ciliary body (anterior uvea) and choroid (posterior uvea). Anterior uveitis therefore denotes inflammation of the iris and/or ciliary body. Posterior uveitis refers to inflammation

of the choroid, retina, and/or vitreous. Panuveitis denotes inflammation involving both the anterior and posterior uvea. Endophthalmitis refers to bacterial or fungal infection of the aqueous or vitreous humors and is subdivided into endogenous endophthalmitis (from bloodstream seeding) and exogenous endophthalmitis (infection inoculated from the external world). Dacryocystitis refers to inflammation, often in the presence of obstruction, of the lacrimal sac. Since ocular infections often have characteristic exam findings that guide the differential diagnosis, it is imperative that the medical specialist clearly understands the findings of the clinical exam. Direct communication with the ophthalmologist who examined the patient is recommended, as it is, in our experience, almost always the most important source of information for diagnosing ocular infections and monitoring the response to treatment.

Approach to the Patient with Suspected Ocular Infection

Any visual symptom(s) in a transplant recipient should prompt timely evaluation by an ophthalmologist, given the wide spectrum and sight- or life-threatening nature of potential conditions. The initial ophthalmologic exam should describe the findings in detail and will often lead to a clinical diagnosis. The anatomic site(s) involved, timing after transplant, and associated systemic signs and symptoms all provide vital clues to the underlying pathophysiologic process and etiologic agent. Since the eye is frequently a site of metastatic infection from a systemic, disseminated process, a concurrent medical evaluation is essential. The results of this initial evaluation should be used to narrow and prioritize the differential diagnosis to establish a working clinical diagnosis, empiric treatment regimen, and confirmatory testing plan. If infection is being considered, an aggressive effort to obtain a diagnosis based on focused microbiologic testing should be made before initiating empiric treatment. This may include specific PCRs and serologies and/or cultures for viral causes and broad stains and cultures for bacterial, fungal, and mycobacterial causes. In cases where there is a greater degree of diagnostic uncertainty and/or the risk of missed or incorrect diagnosis is high, invasive procedures to obtain appropriate diagnostic specimens may be warranted.

Herpesvirus Infections

Herpesviruses are the most commonly reported infection in this patient group [1, 4, 5]. This is likely due to their ubiquity, propensity to reactivate, and potential to acquire resistance to antiviral drugs. Individual herpesviruses are preferentially associated with particular clinical syndromes – CMV with retinitis, VZV and HSV with ARN, VZV with zoster ophthalmicus, and HSV and VZV with keratitis – but there is also overlap between clinical syndromes caused by each pathogen, particularly in immunocompromised hosts [12–15]. A confirmed microbiological diagnosis is usually desirable and is imperative when the response to empiric treatment is inadequate. In comparison to

immunocompetent patients, the spectrum of infections is broader, and the infections may be more severe, harder to treat, and more likely to develop resistance to first-line treatments [13].

Retinitis: CMV is the most commonly identified agent in most series. CMV typically causes a characteristic retinitis that presents with floaters and visual loss. The exam demonstrates retinitis marked by hemorrhages and whitish-yellowish infiltrates and may include perivascular exudation and a granular appearance to the retinitis. CMV retinitis occurs most commonly in the late-transplant period and is associated with lymphopenia and prolonged immunosuppression [2]. Systemic illness with CMV including viremia and manifestations in other organs, such as pneumonitis, may or may not be present. Treatment is typically with intravenous ganciclovir at induction doses for 2–3 weeks, followed by a longer duration of valganciclovir if gastrointestinal absorption is adequate. For site-threatening retinitis, intravitreal ganciclovir or foscarnet should be added to systemic therapy. Implantable sustained-release ganciclovir, previously available as an adjunctive treatment option for CMV retinitis, is no longer manufactured. Treatment should be monitored with serial exams and PCR for systemic viremia. Failure to respond to these agents should prompt genotyping for resistance mutations, in accordance for CMV management among transplant recipients, discussed elsewhere in this book and in expert guidelines [16].

Acute Retinal Necrosis: ARN refers to a characteristic clinical appearance of retinitis that is most classically characterized by peripheral confluent retinitis. The pattern is not specific to herpesviruses, although they are overwhelmingly the most common etiology. Toxoplasmosis in an immunocompromised host can also present with ARN. ARN typically presents with visual loss and necrotizing retinitis, often in association with pain. It progresses to retinal detachment in at least half of patients, but this does not typically occur until 2 months after the initial infection. VZV is the most common cause of this syndrome, which results from reactivation of latent virus and may involve one or both eyes. Available data suggest that this is a late complication of transplant, like CMV retinitis (which can also present with an ARN pattern). In the series of Ng et al., five cases of ARN were observed with a mean of 540 days posttransplant [1]. Treatment with intravenous acyclovir (for HSV and VZV) or ganciclovir (for suspicion of CMV) should begin immediately once a diagnosis of ARN is suspected, as appropriate treatment has been shown to limit damage to the affected eye and prevent injury to the fellow eye [17]. If ARN is sight-threatening, intravitreal ganciclovir or foscarnet should be added to systemic therapy. ARN usually is associated with intense inflammation of the uveal tract and/or optic nerve. When the inflammation is substantial, and/or contributes to visual impairment, glucocorticoids are frequently given as an adjunct to antivirals. While there are no high-quality clinical data to guide when to administer steroids, glucocorticoids do not appear to increase the risk of retinal detachment, at least in small series. Thus, glucocorticoids may be considered as an adjunctive therapy, particularly when inflammation is substantial. Glucocorticoids should not be started until there is clear improvement on an antiviral therapy. Once infection is controlled with IV antiviral therapy, transition to oral antiviral therapy is often possible. When

possible, or infections felt likely to be from HSV or VZV, we prefer the use of valacyclovir over acyclovir and famciclovir, given the better bioavailability. Typically valganciclovir is used for oral therapy for CMV. Antiviral therapy is continued for at least 6 weeks with an oral agent, and often longer, to control the primary syndrome as well as to prevent damage to the contralateral eye. On the basis of documented efficacy for prolonged acyclovir for ARN, and efficacy of suppressive acyclovir for other conditions such as recurrent genital HSV and prevention of VZV in transplant, long-term suppressive oral antivirals may be given in the hopes of decreasing the chances of recurrent vision-threatening infection. If there is no response to acyclovir, alternate causes such as CMV or acyclovir-resistant VZV or HSV should be considered (discussed below in "Therapeutic Failure"), and additional ocular and systemic diagnostic testing may be indicated.

Progressive Outer Retinal Necrosis: A related necrotizing retinitis preferentially involving the outer retina and forming coalescent patches with minimal vitreal inflammation is known as progressive outer variant (PORN). While initially considered a variant of ARN, PORN is now recognized as a distinct clinical entity, more aggressive than ARN and with a worse visual prognosis [18]. Despite these clinical differences, PORN is caused by the same herpesviruses that cause ARN, and diagnosis and treatment are similar. PORN occurs exclusively in immunocompromised hosts, whereas ARN can occur in immunocompetent or immunocompromised individuals.

Zoster Ophthalmicus: Zoster most commonly presents as a peripheral or cranial neuritis. When this involves the ophthalmic branch of the trigeminal nerve, ocular structures can be affected, including the cornea, conjunctiva, and uvea. Vesicles on the tip of the nose (Hutchinson's sign) are suggestive of ocular involvement, as such vesicles indicate involvement of the nasociliary nerve that also innervates multiple ocular structures [19].

Keratitis: Herpesviruses may also cause a keratitis. The clinical syndrome is marked by severe pain, and HSV is the most common cause. The exam is notable for dendritic ulceration of the cornea, particularly visible with fluorescein staining. Treatment is with oral or intravenous acyclovir.

PTLD: Rarely, ocular proliferation of EBV-transformed lymphocytes may occur as a result of a systemic or localized lymphoproliferative disorder. This rare disorder requires multidisciplinary treatment that may include reduction of immunosuppression, radiation, and other therapies.

Therapeutic Failure: Treatment of ARN with acyclovir or ganciclovir usually leads to improvement or stabilization within 48–72 h even in cases of severe immunocompromised hosts [20], and the lack of such a response should raise the possibility of treatment failure. Therapeutic failure is not uncommon among herpesvirus infections, and a number of factors should be considered including suboptimal drug levels, drug resistance, or an incorrect diagnosis. *Drug levels:* Intravenous acyclovir and ganciclovir reach relatively high levels in the vitreous and retina, and oral absorption of the valylated derivatives valacyclovir and valganciclovir is greatly

improved compared with earlier agents. However, intravenous therapy remains the most reliable way to achieve consistent drug levels and should be strongly considered in treatment failure, particularly if oral absorption may vary as a result of gastrointestinal disease such as GVHD. *Drug resistance:* CMV can develop resistance to ganciclovir; in some cases, this resistance is dose-dependent and can be overcome by increasing drug doses and/or switching to intravenous therapy [21–23]. Adjunctive therapies such as CMV immunoglobulin and reduction of immunosuppressive therapy may be considered [16]. Alternate agents may also be considered, including foscarnet and letermovir, and some experts might use experimental agents such as maribavir, brincidofovir, and leflunomide. Cellular immunotherapy has been used experimentally [24]. Rarely, HSV can develop resistance to acyclovir and derivatives, in which case fewer alternative agents are available and treatment typically involves foscarnet [25, 26]. Since the genetic mutations that confer drug resistance to these agents are well understood, in most cases resistance can be evaluated by sending a genotype, which should be pursued in the case of treatment failure for a microbiologically confirmed diagnosis with adequate drug levels. *Incorrect diagnosis:* Herpesvirus syndromes overlap to a great degree, particularly in immunosuppressed transplant recipients, and other organisms including viruses, fungi, parasites, and bacteria, as well as a wide array of noninfectious causes, can mimic Herpesvirus retinitis [6, 15, 27]. Coinfection is also possible. In the case of non-response on appropriate antivirals, alternate diagnoses should be considered, and invasive procedures such as anterior chamber paracentesis, diagnostic vitrectomy, and/or retinal biopsy may be necessary to establish a diagnosis. Effective treatment is available for herpesvirus retinal infection, so treatment failure in the presence of adequate drug delivery and in the absence of drug resistance should prompt an aggressive search for another diagnosis.

Summary: Herpesviruses are the most commonly identified cause of ocular infection in transplant recipients in most large series. Herpesvirus infections may occur at any point during the posttransplant period but most commonly occur late and in the setting of heavy immunosuppression or poor immune reconstitution. Herpesviruses cause a variety of overlapping clinical syndromes, most commonly CMV retinitis but also vitritis, necrotizing retinitis, keratitis, and neuritis. While individual viruses are associated with particular syndromes, there is substantial clinical and microbiological overlap, particularly in transplant recipients, where the overlapping clinical manifestations among herpesviruses are magnified by the propensity of immunocompromised hosts to present with atypical clinical manifestations. Therefore, in the case of non-response, the initial diagnosis may need to be reassessed with additional testing. In addition to herpesviruses, retinitis and related syndromes can be caused by a wide variety of organisms including other viruses, fungi, bacteria, and parasites. Management of most cases begins with intravenous antivirals and intravitreal antivirals, followed by a switch to oral valacyclovir or valganciclovir to complete a course, as detailed in Table 1.

Table 1 Clinical syndromes, causative pathogens, and treatment strategies for infections caused by herpesviruses (medication doses assume normal renal function)

Syndromes	Pathogens	Exam features	Diagnostic tests	Treatment
Retinitis	CMV	Hemorrhages, retinal infiltrate, and may include perivascular exudates and a granular appearance to the retinitis	Serum/ ocular fluid PCR, serologies	2–3 weeks induction with ganciclovir 5 mg/kg IV q12 hr.; followed by suppressive valganciclovir 900 mg PO daily thereafter, prolonged, e.g., 3–6 months Intravitreal ganciclovir and/ or foscarnet
Acute retinal necrosis	VZV	Confluent areas of retinitis, most often in the periphery; necrosis	Serum PCR, serologies	Acyclovir 10–15 mg IV q8 hrs induction, then valacyclovir 1–2 g PO TID, at least 6 weeks; lifelong suppression is often given with acyclovir 400 mg bid particularly if immune suppression cannot be weaned. Systemic steroids are commonly used as adjunctive therapy Intravitreal foscarnet
Zoster ophthalmicus	VZV	Vesicles, conjunctivitis, iritis		Acyclovir 10 mg/kg IV q8 hrs, then valacyclovir 1000 mg PO TID 7-14d
Keratitis	HSV	Dendritic ulceration of fluorescein staining		Acyclovir 10 mg/kg IV q8 hrs, then valacyclovir 1000 mg PO TID 7–14d. Topical agents also effective, including trifluridine 1% q1–2 hr × 14 days, ganciclovir 0.15% five times daily until epithelial healing then TID × 1 week

Fungal Infections

Fungal infections are the second most common cause of ocular infections in transplant patients [28, 29]. There are several key distinctions between fungal infections and herpesvirus infections. First, in contrast to herpesvirus infections that occur commonly in both immunocompetent and immunocompromised hosts, endogenous fungal infections occur almost exclusively in immunosuppressed hosts. Second, in contrast to herpesvirus infections that tend to occur later in the transplant course and are associated with chronic immunosuppression, fungal infections most commonly present within the first few months after transplantation, around the time of greatest

Table 2 Clinical syndromes, causative pathogens, and treatment strategies for infections caused by fungi (medication doses assume normal renal function)

	Pathogens	Exam features	Diagnostic test	Treatment
Candida endophthalmitis	*Candida* spp.	Fluffy yellow, possibly vitreal infiltrates	Candida blood cultures, vitreous samples for stains/cultures/PCR; vitrectomy provides a more substantial amount of material for diagnostic studies and is associated with higher diagnostic yield than "tap and inject" samples	Systemic fluconazole; systemic (800 mg loading dose then 600 mg daily) if susceptible; otherwise voriconazole or amphotericin (echinocandins have poor ocular penetration and limited clinical efficacy for ocular infection); intravitreal voriconazole or amphotericin. Vitrectomy is often needed for debridement
Mold endophthalmitis				
	Aspergillus spp.	Fluffy yellow, possibly vitreal infiltrates	Blood cultures, vitreous samples for stains/culture/PCR; vitrectomy provides a more substantial amount of material for diagnostic studies and is associated with higher yield than "tap and inject" samples	Voriconazole or isavuconazole although there is limited clinical experience with isavuconazole for ocular infection; systemic + intravitreal. Vitrectomy is often needed for debridement
	Pseudallescheria boydii	Fluffy yellow, possibly vitreal infiltrates	Blood cultures, vitreous samples for stains/culture/PCR; vitrectomy provides a more substantial amount of material for diagnostic studies and is associated with higher yield than "tap and inject" samples	Voriconazole; systemic + intravitreal Vitrectomy is often needed for debridement

(continued)

Table 2 (continued)

	Pathogens	Exam features	Diagnostic test	Treatment
Rhinocerebral mucormycosis	Genera *Rhizopus* *Mucor* *Rhizomucor* *Cunninghamella* *Apophysomyces* *Absidia* species (now *Lichtheimia*) *Saksenaea* species	Necrotic eschar in sinuses, proptosis	Fungal stains and culture	Liposomal amphotericin 5 mg/kg systemic (some add posaconazole, isavuconazole, or micafungin) +/− emergent surgical debridement

immunosuppression; however, they may also occur late, particularly in the setting of heavy, chronic immunosuppression such as for GVHD. Third, invasive fungal infections in transplant recipients are rarely limited to the eye; typically ocular infection is a complication from a disseminated process. Aggressive treatment, including both medical and surgical treatment, may be necessary. Despite these efforts, mortality remains high in published series [28–30].

Endophthalmitis: Endogenous endophthalmitis is the most common presentation of ocular fungal infection seen in transplant recipients [4, 5, 31]. Clinical symptoms include blurred vision, pain, and redness. Ocular examination typically demonstrates white, fluffy infiltrates in the vitreous or retina. Among transplant recipients, fungal endophthalmitis is almost always endogenous endophthalmitis as a complication of a disseminated infection involving the bloodstream. Both yeasts and molds may cause endophthalmitis. Among yeasts, *Candida* spp. are the most common cause of endophthalmitis (Table 2). Among molds, *Aspergillus* spp. and *Pseudallescheria* (*Scedosporium*) spp. are reported most often in transplant patients [32]. Endophthalmitis caused by molds usually progresses rapidly and carries a graver prognosis than infection caused by yeasts. Rarely, endophthalmitis can occur without frank ocular symptoms; some cases are diagnosed at autopsy [28].

In all cases of endophthalmitis, close attention must be paid to the systemic complications and other sites of metastatic involvement. *Candida* may be associated with hepatosplenic abscesses. Abscesses in the brain, skin, and lungs are common among invasive molds [27, 33, 34]. The eye may serve as the sentinel site that signals a disseminated invasive fungal infection. The finding of endophthalmitis should trigger a detailed search for symptoms and complete physical exam including the head and neck, oral cavity, lungs, abdomen, skin, and central nervous system along with blood cultures. Conversely, findings of fungemia or evidence of disseminated fungal infection should prompt consideration of a dilated ophthalmological exam, as early fungal endophthalmitis may be asymptomatic, and some patients may not report symptoms due to medical comorbidities or diminished consciousness [28].

In some cases, surveillance examinations are warranted, especially with neutropenia, in accordance with IDSA guidelines [35].

Treatment of endogenous endophthalmitis is multidisciplinary, often medical and surgical, and depends on the causative organism and involvement of other sites [34, 36, 37]. Typically, systemic therapy is required, but intraocular therapy may also be necessary. Some cases require vitrectomy not only for diagnosis but also for treatment to debulk infectious material. Serial assessment of clinical status, including repeated fundoscopic exams, is important early in the course of therapy to evaluate the response to therapy and guide need for more alternative management strategies. With the possible exception of *Candida* endophthalmitis, oral therapy is typically reserved for step-down therapy once control of the infection has been achieved through a combination of parenteral antifungals, intraocular antifungal infections, and vitrectomy, as indicated. Ocular penetration of liposomal amphotericin B is poor, while most azoles achieve better intraocular levels, especially when the eye is inflamed [38]. Among the azoles, fluconazole and voriconazole have been used most extensively for treating endophthalmitis [39–41]. Posaconazole appears to have low vitreous concentrations, but successful use has been reported [42]. There is accumulating experience with isavuconazole [43, 44].

Therapeutic Failure: Therapeutic failure unfortunately is common in fungal endophthalmitis. Combined medical and surgical therapy is often required, and vitrectomy should be considered in all cases of fungal endophthalmitis, both for diagnostic purposes on initial evaluation and for therapeutic purposes to remove fungal debris and microabscesses [45–47]. As in the cases of therapeutic failure for herpesvirus infections, the possibility of suboptimal drug levels, drug resistance, an incorrect diagnosis, and the need for adjunctive therapies should be considered. The use of sensitivities to guide the selection of antifungal therapy and therapeutic drug monitoring can be helpful if an organism has been cultured, and therapeutic drug levels are known to correlate with improved outcome [48–50]; however, culture is not always available. Unfortunately, for some fungi such as *Scedosporium* spp., existing therapies are not fungicidal, and there is little clinical data from controlled human trials to guide antifungal agent selection, although retrospective clinical series have identified voriconazole and surgical management as associated with improved outcomes [33, 51].

Rhinocerebral Mucormycosis: Mucormycosis is a rare but devastating infectious complication of transplant that may involve the eye through direct invasion or metastatic spread of systemic infection [52]. Clinical exam may identify an eschar on mucosal surfaces such as the palate or nasal passages and/or proptosis [53, 54]. Imaging may demonstrate sinus disease extending into the orbit and/or skull base [55]. Management decisions must be made promptly as mucormycosis progresses rapidly. Treatment usually involves amphotericin-based antifungal therapy along with surgical evaluation that may include debridement with potential orbital exenteration [52, 56]. Histopathology may demonstrate thrombosis with angioinvasion. Other fungi, including *Aspergillus* spp., can cause a similar syndrome.

Summary: Endogenous fungal endophthalmitis is the second most common ocular infection among transplant recipients. In contrast to herpesvirus infections

that are typically a late complication of transplant, fungal endophthalmitis usually occurs during periods of profound immunosuppression and neutropenia. Most cases occur early, particularly around engraftment for HSCT, but may also occur late, particularly in patients with GVHD when heavier immunosuppression is required. Rhinocerebral mucormycosis is a rare but dreaded fungal infection. Fungal infections among transplant recipients are typically severe and represent a metastatic complication of a disseminated process involving the bloodstream. These infections may portend a grave prognosis; however, medical and surgical treatment strategies can be effective, so urgent or emergent evaluation and management are important to limit morbidity and mortality. Bacterial Infections

Transplant patients are also at risk for bacterial infections. This includes Gram-positive and Gram-negative bacteria as well as atypical infections such as those caused by mycobacteria, intracellular bacteria, and spirochetes.

"Typical" bacteria: For Gram-positive and Gram-negative bacterial infections (here referred to as "typical" bacteria), the spectrum of disease resembles that of the community-acquired ocular infections that are caused by such bacteria. Ocular manifestations of bacterial infection include abscess, dacryocystitis, preseptal cellulitis, and orbital cellulitis. These infections are commonly caused by pyogenic bacteria such as *Staphylococcus* and *Streptococcus* spp. Diagnosis is guided by clinical features. Preseptal and orbital cellulitis both present with inflammation in periorbital skin and soft tissues; however, in orbital cellulitis, there are associated "orbital" signs that may include proptosis, restricted extraocular movements, and impaired visual acuity. These infections often originate in the sinuses, which should be evaluated carefully by specialists in otolaryngology as well as with imaging (typically CT) in affected patients. Abscess can occur in any of the soft tissues of the eye and face. In these cases, incision and drainage procedures are both diagnostic and therapeutic, and a course of antibiotics targeting causative pathogens should be provided to complete therapy. Empiric treatment usually targets polymicrobial oral flora using a beta-lactam plus beta-lactamase inhibitor and may also include agents active against MRSA, depending on patient and epidemiologic risk factors. Infectious dacryocystitis can result from lacrimal duct obstruction and bacterial proliferation and can be managed similar to an abscess. Dacryocystorhinostomy is often

considered following resolution of dacryocystitis. Bacterial endophthalmitis is managed similarly in immunocompetent and immunocompromised hosts.

"**Atypical" Bacterial Infections** *Mycobacterial Infections:* Tuberculosis (TB) and non-tuberculous mycobacteria (NTM) can cause serious ocular infections affecting all ocular structures [57–59]. Ocular TB is an underreported manifestation of TB and most commonly presents as choroidal nodules or scars, with or without granulomatous features; however, the clinical spectrum is broad and includes papillitis, macular lesions, vitritis, choroidal tuberculoma, dacryoadenitis, posterior scleritis, retinal vasculitis, anterior uveitis, and retinal detachment [58]. A confirmed diagnosis rests upon microbiologic or histologic identification of organism in a compatible clinical syndrome; a probable diagnosis may be made on the basis of immunoreactivity with TB antigen (positive purified protein derivative or interferon-gamma release assay) and/or chest x-ray showing granulomatous disease in the presence of compatible ocular manifestations and exclusion of other etiologies. While a thorough pretransplant screening should facilitate appropriate treatment for latent tuberculosis prior to transplant-associated immune suppression, the clinician should be aware that ocular symptoms may sometimes be the first clinical manifestation of systemic TB, particularly in transplant recipients and other immunosuppressed individuals [9]. In these cases, other manifestations of TB are frequently identified when sought, as ocular manifestations are rare in the absence of a systemic syndrome in this population. NTMs are less commonly found in ocular infections but have recently been found to cause a wide spectrum of ocular disease [59], including endophthalmitis among transplant recipients [8, 60]. Although data are limited on management of ocular TB, it is treated with the same regimens as used for active TB, typically for 9–12 months. A fluoroquinolone is sometimes substituted for ethambutol to reduce the likelihood diagnostic of confusion between infectious and drug-induced optic neuritis, which is a potential side effect of ethambutol but also a rare complication of ocular TB. For additional information on TB screening and treatment in transplant recipients, please (see ▶ Chap. 18, "*Mycobacterium tuberculosis* in Transplantation").

Fastidious bacteria: Fastidious bacteria such as spirochetes and intracellular bacteria are an increasingly recognized and likely underappreciated cause of ocular infection in the non-transplant population. For example, Bodaghi et al. studied 1321 European patients with uveitis of unknown etiology and identified infections with fastidious bacteria in 78 cases with serologies and advanced molecular techniques [61]. This included 21 cases of *Bartonella* spp., 9 cases of *Treponema pallidum,* 9 cases of *Coxiella burnetii* (agent of Q fever), and 14 cases of *Borrelia burgdorferi* (the agent of Lyme disease), as well as a number of other agents in smaller numbers. Case series and reports from the transplant literature also suggest that fastidious organisms are important in transplant patients. For example, *B. henselae* was reported as a cause of chorioretinitis in a renal transplant patient in 2008 [62] and has since been recognized in two additional cases [10]. *Tropheryma whipplei* (the causative agent of Whipple's disease) has been reported in a single case of uveitis in a renal transplant recipient. In light of these emerging data, infection with fastidious bacteria should be considered in the differential diagnosis for unexplained ocular infection in transplant recipients.

Parasitic Infections

Toxoplasma chorioretinitis: The Apicomplexan parasite *Toxoplasma gondii* is an important cause of chorioretinitis in the general population and among transplant recipients [6, 7, 63]. *T. gondii* can cause a severe retinochoroiditis that is easily and commonly confused with herpetic retinitis, fungal endophthalmitis, and non-infectious retinopathies [7, 64]. In immunocompetent hosts, the retinitis is often focal and in cases of reactivation, adjacent to a pre-existing retinal scar. In immunocompromised hosts, atypical presentations with larger areas of retinitis can be seen [64]. Clinicians should consider *T. gondii* as a potential cause of necrotizing retinitis, particularly if risk factors such as immigration from an endemic area, cat exposure, or consumption of raw meat are present [65, 66]. The diagnosis of ocular toxoplasmosis is made on the basis of clinical, serological, microbiological, and histopathological grounds, although it is important to recognize that the clinical presentation and immune response allowing serodiagnosis may be atypical or absent in immunocompromised transplant recipients. When the diagnosis is in question, direct microbiological assessment of anterior chamber and vitreous fluid by PCR should be performed [67]. Treatment is effective using a variety of agents, including sulfadiazine-pyrimethamine, trimethoprim-sulfamethoxazole, clindamycin, azithromycin, and atovaquone [68, 69]. For hard-to-treat cases, intravitreal injections of antiparasitic agents such as clindamycin or trimethoprim-sulfamethoxazole may be considered, although there are limited data to guide therapy in refractory cases.

Other parasites: A variety of other less-common parasitic infections have the potential to cause ocular disease among transplant recipients. *Leishmania* parasites can reactivate during immunosuppression, causing systemic illness which may include ocular manifestations [11]. Free-living *Acanthamoeba* spp. cause disease in immunocompetent contact lens wearers and have been reported as a cause of endophthalmitis following transplant as a part of a disseminated infection [70].

Summary and Key Points

Ophthalmologic infections are an uncommon but serious complication after transplant. Historical series estimate the rate of symptomatic ocular infection among transplant recipients at approximately 1–2% [1, 4, 5]. We have reviewed the epidemiology, presentation, and management of the most common causes of ocular infection in transplant recipients. In doing so, some general themes emerge: First, the epidemiology of ocular infections in this patient population indicates that fungal and viral opportunists cause the majority of infectious pathology in this group. Herpesviruses tend to involve the retina and surrounding structures and affect patients late in the transplant course, particularly those with chronic, more intense immunosuppression. In contrast, fungal infections preferentially seed the vitreous and adjacent structures via the bloodstream, a process which tends to occur early in the posttransplant course during the period of maximal immunosuppression. Nevertheless, there is a long list of other infections that may present with overlapping

clinical manifestations and must also be considered, particularly if initial or empiric treatment fails. Second, the nature of these infections requires multidisciplinary collaboration between ophthalmologists, transplant specialists, and infectious disease specialists. Finally, ocular infection is frequently a complication of systemic infection and should trigger an evaluation for systemic disease and other metastatic foci of infection.

As with all infections in the immunocompromised population, ocular infections should trigger careful workup and antimicrobial treatment as well as consideration about whether immune function can be improved by weaning immunosuppressive agents. More research is needed to define further the spectrum of ocular pathology among transplant recipients and to create new therapies that improve unsatisfactory rates of cure, particularly for fungal infections. Despite these challenges, effective treatment is available for a great many of the ocular infections encountered in transplant recipients. An understanding of the epidemiological and clinical patterns of disease along with a considered, timely, and multidisciplinary approach to diagnosis and treatment will limit the morbidity and mortality of this potentially devastating complication of organ transplantation.

Acknowledgments The authors gratefully acknowledge Ramy Elshaboury, PharmD, for guidance with pharmacotherapy administration and dosing.

Introduction

Infectious and noninfectious pulmonary syndromes remain significant contributors to morbidity and mortality after solid organ and hematopoietic stem cell transplantation [1–3]. Multiple factors increase the risk pulmonary complications including

the surgical trauma from solid organ transplantation (SOT), chemotherapy and radiation therapy prior to hematopoietic stem cell transplantation (HSCT), the degree of immunosuppression, and the immune responses leading to organ rejection and graft-versus-host disease (GVHD) [1, 2]. The first section of the chapter reviews the timeline of pulmonary syndromes among SOT and HSCT patients. The second section provides an approach to the evaluation of a transplant patient presenting with pulmonary symptoms or infiltrates. Chapters on specific pulmonary pathogens should be referenced for additional information on clinical presentation, diagnostic evaluation, and management.

Solid Organ Transplantation

Infectious Pulmonary Complications

The spectrum of microorganisms responsible for pulmonary infections after SOT has increased with the introduction of new diagnostic assays, the emergence of antimicrobial-resistant organisms, and advances in surgical technique and immunosuppressive therapies leading to prolonged patient survival [4]. Pulmonary infections present in a predictable pattern related to the changing risk factors in the recipient over time: the time since surgery or transplant, degree of immunosuppression, prophylactic antibiotics, and hospital and community exposures [4]. The timeline of pulmonary infections after SOT is classified into three risk periods (Fig. 1):

Phase 1: Perioperative period to 30 days after SOT
Phase II: 1 to 6–12 months after SOT
Phase II: Beyond 6–12 months after SOT [4]

Variations in the incidence, timeline, and microbiology of pulmonary infections exist based on the type of organ transplanted. Lung transplant recipients have the highest incidence of pneumonia related to surgical trauma to the allograft, donor-derived infections, recipient airway colonization, and constant exposure of the allograft to the environment [5].

Phase I: Perioperative Period to 30 Days After SOT

During the first risk period after SOT, pulmonary infections are primarily related to surgery and hospitalization [6–10]. Early postoperative pneumonias are primarily caused by healthcare and ventilator-associated pathogens including methicillin-resistant *Staphylococcus aureus* (MRSA) and antimicrobial-resistant gram-negative bacilli (*Pseudomonas* species, *Stenotrophomonas* species). Risk factors for pneumonia with multidrug-resistant organisms (MDRO) include prolonged hospitalization pretransplant, extended postoperative mechanical ventilation, and preexisting lung pathology (chronic obstructive pulmonary disease and bronchiectasis). Aspiration pneumonia may occur in patients who are unable to protect their airways

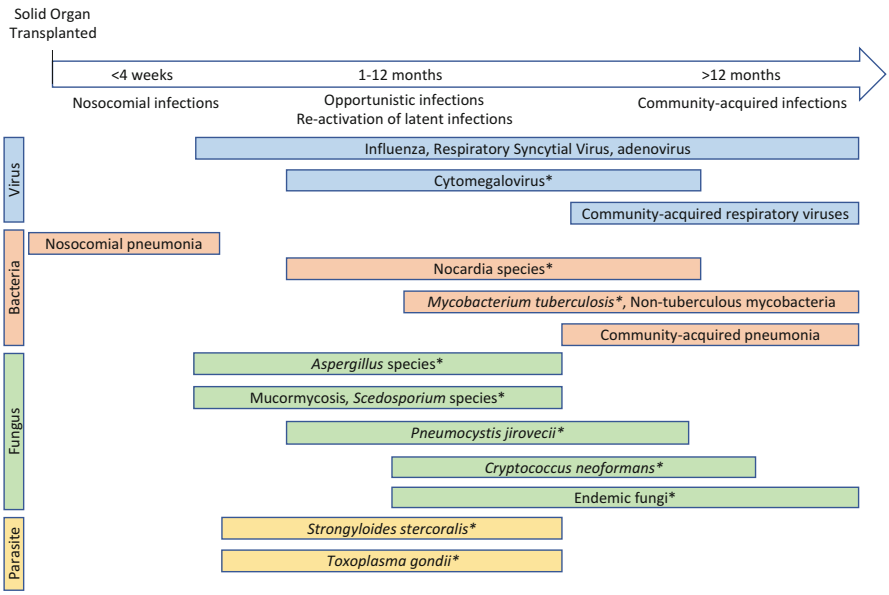

Fig. 1 Timeline of infectious pulmonary complications after solid organ transplant [3]. *Prophylaxis alters risk and the timeline

because of altered mental status, debilitation, or renal or hepatic dysfunction after transplant [6–10].

Lung transplant recipients are at increased risk of postoperative nosocomial pneumonia related to the surgical trauma of the transplanted lung, prolonged intubation, and preexisting colonization of donor and recipient lungs with MDRO [5, 11, 12]. Surgical disruption of the lung allograft vasculature and innervation compromises the anatomical and functional protections against pulmonary infection such as ciliary function, airway patency, and cough reflexes [5]. In the early postoperative period, the diminished vascular supply to the bronchial anastomosis leads to mucosal ischemia placing the area at increased risk of bacterial and fungal infections [13].

Phase II: 1 to 6–12 Months After SOT

The second risk period spans 1 to 6–12 months after SOT when the maximal sustained immunosuppression is administered, leading to the emergence of opportunistic infections and reactivation of latent infections [4]. Antimicrobial prophylaxis reduces the risk of opportunistic infections; however, excessive prolonged use is discouraged given adverse effects and selective pressure towards antimicrobial-resistant pathogens. Protocols for the indication and duration of prophylaxis vary by transplant center. Once antimicrobial prophylaxis is discontinued, opportunistic infections should be considered in the evaluation of pulmonary symptoms [4].

Trimethoprim-sulfamethoxazole (TMP-SMX) administered daily prevents pneumonia from *Pneumocystis jirovecii*, *Toxoplasma gondii*, and *Nocardia* species [14]. The risk for *P. jirovecii* pneumonia (PJP) is highest during the first 6 months

and declines after the first year [14]. Among lung transplant recipients, the risk remains elevated indefinitely, leading to the practice of lifelong prophylaxis with TMP-SMX [15]. Similarly, antifungal agents are used for prophylaxis in some lung transplant programs as recipients are at higher risk for fungal pneumonia; they are less commonly used with other organ transplants [16]. Valganciclovir prevents pneumonia from the herpes viruses cytomegalovirus (CMV), varicella zoster virus (VZV), and herpes simplex virus (HSV). The risk for CMV infection depends on the recipient and donor serostatus: seronegative recipients who receive an allograft from a seropositive donor (CMV D + R-) have the highest risk for CMV infection followed by CMV D + R+, CMV D-R+, and CMV D-R- patients [17]. CMV pneumonitis presents most frequently among lung transplant recipients since the lungs are a large reservoir for latent CMV [5].

During the second risk period, causes of viral pneumonia include community-acquired viruses (adenovirus, influenza, parainfluenza, respiratory syncytial virus [RSV], metapneumovirus) and herpes viruses (CMV, HSV, VZV). Community-acquired viruses present in the general population as a mild self-limited upper respiratory tract illness but tend to cause a more severe lower respiratory tract infection among SOT recipients [18–21]. Respiratory viruses may increase the risk of chronic allograft rejection among lung transplant recipients related to the stimulation of alloimmune processes targeting the bronchial epithelium [22].

Invasive fungal infections in the second risk period may present as a primary infection or invasion of a previously colonizing organism. The most common fungal pneumonias during the second risk period include *Aspergillus* species, *Cryptococcus neoformans*, and *P. jirovecii* [23, 24]. Lung transplant recipients are at increased risk for endobronchial aspergillosis where devitalized cartilage at the bronchial anastomosis provides a hospitable environment [13]. Other causes of fungal pneumonia to consider include mucormycosis, *Scedosporium*, *Fusarium*, and endemic fungi (*Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*) [23, 25].

In the second risk period, pneumonia may be caused by reactivation of latent infections including *Strongyloides stercoralis*, *T. gondii*, and *Mycobacterium tuberculosis. Strongyloides* hyperinfection syndrome occurs when filariform larvae reactivate in the setting of immunosuppression, penetrate the intestinal wall, and disseminate to the lungs causing pulmonary hemorrhage, pneumonitis, and edema [26]. Patients at the highest risk of *T. gondii* infection are seronegative heart and lung transplant recipients who receive an allograft from a seropositive donor [27]. Tuberculosis is a relatively uncommon infection in developed countries after transplant, but the rate of infection among SOT recipients is 30- to 100-fold higher than the general population [28]. While reactivation of latent infection is the primary mechanism for the development of active tuberculosis, donor-derived infection and primary infection after transplant have also been described [28]. The treatment of tuberculosis in SOT recipients is challenging because of the drug interactions between combination therapy and immunosuppression: rifampin is an inducer of the hepatic P-450 enzyme system and increases clearance of cyclosporine and tacrolimus [28].

Phase III: Beyond 6–12 Months After SOT

At 6–12 months after SOT, the allograft function stabilizes, and immunologic tolerance develops, allowing for a reduction in maintenance immunosuppression [4]. During the third risk period, the most common causes of pneumonia are community-acquired pathogens including *S. pneumoniae*, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, and *Chlamydophila pneumoniae*. The differential diagnosis should remain broad depending on the patient's occupational, environmental, and travel exposures (see section "Donor and Recipient Epidemiologic Exposures"). SOT recipients with prolonged hospitalizations and recurrent courses of antimicrobial therapy remain at risk for antimicrobial-resistant bacterial pneumonias. Opportunistic infections should be considered during any period of augmented immunosuppression for the treatment of acute or chronic rejection [6–10].

Noninfectious Pulmonary Complications

Lung Transplant Complications

Airway Complications

Airway complications after lung transplantation result from decreases in systemic blood supply to the anastomosis between the donor and recipient bronchus during surgery [13]. In the first month posttransplant, the ischemic injury places the airway at risk for multiple complications ranging from focal necrosis with mucosal sloughing to partial or complete dehiscence of the anastomosis [13]. In the several months after transplant, excessive granulation tissue deposited in ischemic areas of the bronchial anastomosis can lead to airway stenosis or bronchomalacia (narrowing of the airway lumen by more than 50% during expiration) [13]. Patients with airway complications present with dyspnea, stridor, wheezing, recurrent episodes of postobstructive pneumonia, and progressive airflow obstruction on spirometry [13]. Diagnosis is confirmed with direct visualization on bronchoscopy [13]. Bronchial anastomotic narrowing is addressed with a variety bronchoscopic techniques: balloon dilatation, forceps debridement, laser therapy, cryosurgery, and endobronchial stenting [13]. Surgical management options include sleeve resection of stenotic area, lobectomy, and re-transplantation [13]. Bronchopleural, bronchomediastinal, and bronchovascular fistulas are rare airway complications that can lead to abscesses requiring immediate drainage and antimicrobial therapy [13].

Primary Lung Graft Dysfunction

After lung transplantation, a mild transient pulmonary edema develops related to multiple factors including ischemia-reperfusion injury, increases in microvascular permeability, surgical trauma, and lymphatic disruption [29]. Progression of lung allograft injury results in a type of acute respiratory distress syndrome (ARDS) termed primary graft dysfunction [29]. A diagnosis of primary graft dysfunction is defined as impaired oxygenation within the first 72 h of transplantations with

widespread radiographic infiltrates and exclusion of other causes of early graft dysfunction such as volume overload, pneumonia, and rejection [29]. Additional clinical findings include decreased pulmonary compliance, increased pulmonary vascular resistance, and intrapulmonary shunting [29]. Treatment is supportive with lung-protective ventilation using low tidal volumes and optimal fluid management [30]. The administration of inhaled nitric oxide or epoprostenol can decrease pulmonary artery pressures and improve oxygenation [30].

Acute Lung Rejection

Acute cellular rejection is the predominant form of acute lung rejection affecting more than a third of lung transplant recipients within the first year of transplant [31]. Acute cellular rejection is mediated by reactive T lymphocytes against donor human leukocyte antigens (HLA) and other antigens [31]. Patients with acute cellular rejection may be asymptomatic or present with nonspecific pulmonary symptoms (low-grade fever, dyspnea, productive or nonproductive cough) [31]. Abnormalities on pulmonary function testing (PFT) include airflow obstruction with decreased forced expiratory volume in 1 s (FEV_1) [31]. Chest imaging findings are nonspecific including ground-glass opacities, septal thickening, volume loss, and pleural effusion [31]. Diagnosis is confirmed with transbronchial biopsy demonstrating a lymphocyte inflammatory response around blood vessels and/or airways [32]. A histologic classification system developed by the International Society for Heart and Lung Transplantation (ISHLT) categorizes acute cellular rejection based on the severity of the vascular and/or airway abnormalities [32]. Treatment of acute cellular rejection consists of a course of high-dose steroids [31].

Antibody-mediated rejection (AMR) of lung transplant is a less commonly encountered form of acute rejection mediated by antibodies against donor HLA and other antigens [33]. Hyperacute rejection is a rare form of AMR mediated by preexisting donor-specific antibodies (DSA) that causes profound hypoxemia, diffuse noncardiogenic pulmonary edema, and alveolar hemorrhage within the first minutes to hours following lung allograft reperfusion [31]. Screening for HLA incompatibility by identifying HLA antibodies to donor HLA epitopes prior to lung transplant prevents episodes of hyperacute rejection [31]. Acute AMR presents weeks to months after lung transplant with nonspecific symptoms including fever, dyspnea, cough, and hemoptysis [33]. The ISHLT diagnostic criteria for acute AMR include the presence of DSA, acute lung injury on pathology, complement deposition in alveolar capillaries, and allograft dysfunction with the exclusion of other causes of dysfunction [33]. Treatment for hyperacute rejection and acute AMR includes therapies to deplete antibodies including immunoglobulin, rituximab, bortezomib, and therapeutic plasma exchange [33].

Chronic Lung Rejection

Chronic lung allograft rejection affects about half of the lung transplant recipients at 5 years after transplant and threatens the long-term survival of the allograft and the patient [34]. Bronchiolitis obliterans syndrome, the predominant form of chronic lung allograft rejection, presents as a progressive and irreversible airflow obstruction

characterized by chronic inflammation and fibrosis of the bronchiolar walls on pathology (bronchiolitis obliterans) [34, 35]. Chronic vascular rejection may present concurrently with atherosclerosis in the pulmonary vasculature [34, 35]. Risk factors for BOS include recurrent episodes of acute lung rejection, primary graft dysfunction, gastroesophageal reflux with aspiration, and CMV and respiratory viral infections [34, 35]. Patients with BOS present with dyspnea, cough, and recurrent episodes of purulent tracheobronchitis. Diagnostic findings include expiratory air trapping on imaging and progressive airflow obstruction on spirometry with declines in FEV_1 [34, 35]. Multiple strategies are employed to slow the progression of BOS including macrolide antibiotics, alteration of immunosuppressive therapy, anti-lymphocyte antibodies, extracorporeal photopheresis, plasmapheresis, and total lymphocyte irradiation; however, the only definitive treatment for BOS is lung re-transplantation [36].

Drug-Induced Lung Toxicity

Pulmonary toxicity is associated with the mammalian target of rapamycin (mTOR) inhibitors sirolimus and everolimus used for induction and maintenance immunosuppression in SOT [37]. Although the pathogenesis is not completely understood, evidence suggests mTOR inhibitors cause direct lung injury and stimulate immune-mediated injury to the interstitial and alveolar space [37]. Patients typically present with nonspecific pulmonary symptoms (dry cough, progressive dyspnea) within the first 6 months of drug initiation, but later presentations have been described. Radiographic abnormalities include bilateral interstitial infiltrates, alveolar consolidation, and nodular opacities [37]. Diagnosis is confirmed with transbronchial lung biopsy; histopathological findings include interstitial lymphocytic infiltrates, bronchiolitis obliterans with organizing pneumonia, non-necrotizing granulomas, and diffuse alveolar hemorrhage [37]. Discontinuation of the mTOR inhibitor leads to resolution of symptoms, but radiographic abnormalities may take several months to resolve [37].

Malignancy

Malignancy should be considered in the evaluation of SOT recipients presenting with pulmonary symptoms as the comorbidities leading to end-stage organ disease also place the patient at risk for cancer. Liver transplant patients with a pretransplant history of hepatocellular carcinoma are at risk for recurrence with the lung being the most common site of recurrence [38]. Among lung transplant recipients, lung cancer is the most common de novo malignancy, and certain underlying disease etiologies (idiopathic pulmonary fibrosis, interstitial lung disease, and cystic fibrosis) are predictors for malignancy [39].

Posttransplant lymphoproliferative disorder (PTLD) is the abnormal proliferation of B-cells stimulated by Epstein-Barr virus (EBV) in the setting of a decreased cytotoxic T-cell response [40]. Risk factors for PTLD include primary infection with EBV at the time of transplant, higher intensity immunosuppression, and receipt of anti-lymphocyte antibody [40]. The incidence is highest among lung and heart transplant recipients related to the receipt of higher-intensity induction

immunosuppression compared to other SOT recipients [40]. Heart and lung transplant recipients are also more likely to present with intrathoracic PTLD including pulmonary nodules, regional adenopathy, and pleural effusions [40]. Treatment involves the reduction of immunosuppression and immunotherapy with rituximab (anti-CD20 monoclonal antibody) [40].

Hematopoietic Stem Cell Transplantation

Infectious Pulmonary Complications

Infectious pneumonia is a common complication following hematopoietic stem cell transplantation. The spectrum of pulmonary infections varies depending on the donor source of stem cells, conditioning regimen, and the degree and type of immunodeficiency the patient encounters at any particular time. The timeline of pulmonary infections after HSCT can be divided into three risk periods (Fig. 2):

Phase I: Pre-engraftment neutropenia
Phase II: Early post-engraftment (engraftment until day +100)
Phase III: Late post-engraftment (beyond day +100) [41, 42]

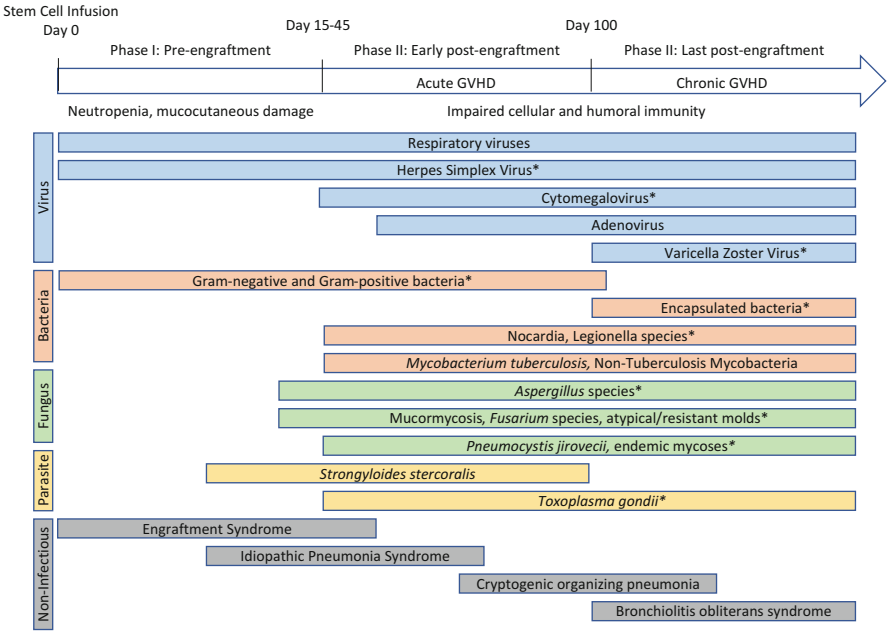

Fig. 2 Timeline of infectious and non-infectious pulmonary complications after hematopoietic stem cell transplant. *GVHD* graft-versus-host-disease, *ARDS* acute respiratory distress syndrome, *TRALI* transfusion related lung injury. *Prophylaxis alters risk and the timeline [2]

Phase I: Pre-engraftment Neutropenia

In the early pre-engraftment period, the majority of pulmonary infections are secondary to prolonged neutropenia and mucositis following conditioning chemotherapy. The duration of neutropenia is less prolonged in recipients of autologous stem cell transplants and those receiving non-myeloablative conditioning regimens prior to allogeneic stem cell transplants.

Bacterial pathogens causing pneumonia in the pre-engraftment period are similar to those encountered in patients with chemotherapy-induced neutropenia and mucositis including *Enterobacteriaceae*, *Pseudomonas* species, and MRSA [43]. MDROs need to be considered depending on the local epidemiology, the length of hospital stay, and the recipient's antibiotic, infection, and colonization history [44]. Viridans streptococcal sepsis (VSS) is a unique cause of ARDS among HSCT recipients caused primarily by *Streptococcus mitis* and *Streptococcus oralis* [45]. Risk factors for VSS include age, mucositis, cytarabine exposure, and prophylaxis with fluoroquinolones or TMP-SMX [45].

Aspergillosis is the most common cause of invasive fungal pneumonia secondary to prolonged neutropenia. There are two periods of increased incidence of invasive aspergillosis: the first peak occurs during the prolonged neutropenic phase, and the second occurs later in the context of GVHD and corticosteroids [42]. Additional risk factors include myeloablative conditioning, leukemia, delayed engraftment, marrow failure, prior history of fungal pneumonia, and marijuana use [46]. The incidence of invasive pulmonary aspergillosis in the early period can be reduced by decreasing the duration of neutropenia and initiating voriconazole prophylaxis [47].

Phase II: Early Post-Engraftment

The early post-engraftment phase encompasses the period following engraftment until day +100 when neutropenia has resolved but cell-mediated immunity has yet to normalize. T-cell function is suppressed due to lingering effects from conditioning chemotherapy as well as immunosuppressive therapy for GVHD prophylaxis, such as tacrolimus or cyclosporine. Viral (CMV, adenovirus, respiratory viruses) and fungal pathogens predominate during the early post-engraftment period [2, 41, 48].

Although the incidence of CMV pneumonitis has reduced in recent decades, it remains a significant cause of morbidity and mortality post-HSCT [49, 50]. The risk for CMV infection is highest among recipients with D−/R+ mismatch and can be reduced with antiviral prophylaxis or a preemptive therapy approach with regular viral polymerase chain reaction (PCR) monitoring. Letermovir is a novel antiviral agent approved for prophylaxis post-allogeneic HSCT in seropositive recipients [51]. The risk of CMV infections remains elevated in patients with acute GVHD and on immunosuppressive therapies.

Seasonal respiratory viruses, such as influenza, parainfluenza, RSV, human metapneumovirus, and adenovirus, can migrate from the upper to lower respiratory tract leading to a more severe clinical presentation among HSCT recipients [48]. Adenovirus can also present as a reactivation disease causing a spectrum of illnesses ranging from a limited upper respiratory tract infection to disseminated disease with hemorrhagic cystitis and colitis [52].

The second risk period for aspergillus occurs during the early post-engraftment period related to the development of GVHD and administration of high-dose corticosteroid therapy [42]. CT imaging of the lung may demonstrate consolidations, tree-in-bud opacities, and nodular infiltrates [42]. The "halo sign" (a dense area of consolidation surrounded by ground glass representing a region of alveolar hemorrhage) is associated with invasive pulmonary aspergillosis; however, it can be seen with other infectious and noninfectious etiologies [53, 54].

Phase III: Late Post-Engraftment

Immunosuppressive agents used to prevent GVHD, such as cyclosporine and tacrolimus, are usually tapered at day +100 after HSCT. At day +100 after transplant, allogeneic stem cell recipients remain at high risk of pulmonary infections related to functional hyposplenism and immunosuppressive therapy for the treatment of chronic GVHD [47]. Although bacterial pneumonias are less common during this period, the risk for encapsulated bacterial pneumonia such as *S. pneumoniae* and *H. influenzae* persists as many patients remain on immunosuppressive therapy and are unable to mount an appropriate response to vaccination. Strategies to reduce the incidence of infection related to encapsulated organisms include antibiotic prophylaxis and vaccination when clinically appropriate [47].

Patients with persistent immune deficits from chronic GVHD or other transplant-related conditions remain at increased risk for recurrent respiratory viral, resistant bacterial, and breakthrough fungal pneumonias. Late CMV infection can present in association with GVHD and after discontinuation of preventative and preemptive strategies. The use of agents such as letermovir for prolonged chemoprophylaxis is being studied [55]. Breakthrough fungal infections, including mucormycosis, *Fusarium*, and *Scedosporium*, should be considered in patients on antifungal prophylaxis [47]. While aspergillus and mucormycosis infections have similar risk factors among HSCT recipients, mucormycosis should be suspected among patients presenting with pulmonary nodules on voriconazole prophylaxis with negative serum and BAL galactomannan on evaluation. A "reverse halo sign" (a ground-glass opacity surrounded by a peripheral ring of consolidation) may be seen on chest imaging [53, 54]. *Fusarium* infections present as nodular pulmonary infiltrates and may be accompanied by cutaneous lesions and fungemia in the setting of disseminated disease. Among HSCT recipients, mortality rates for mucormycosis and *Fusarium* infections remain high related to the inability to reverse underlying immunosuppression and toxicities related to induction antifungal therapy liposomal amphotericin B [56].

The risk for PJP, highest during the first 6 months following HSCT, is significantly reduced with standardized chemoprophylaxis regimens, particularly with TMP-SMX. Many cases of PJP occur late after prophylaxis has been administered and completed per institutional protocol or discontinued early due to adverse effects despite ongoing immunosuppression. Breakthrough infections can be seen in those receiving alternative agents such as dapsone, atovaquone, or pentamidine [57].

Reactivation of *T. gondii* is a rare cause of pneumonia after HSCT, usually occurring during the first year in seropositive recipients who cannot tolerate or have discontinued prophylaxis with TMP-SMX. Toxoplasmosis pneumonia presents with diffuse interstitial lung infiltrates, and ring-enhancing brain lesions similar to those typically seen in HIV/AIDS may be present [58].

Noninfectious Pulmonary Complications

Noninfectious pulmonary complications are a frequent cause of pulmonary infiltrates in stem cell transplant recipients and may present concurrently with pulmonary infections [2]. Many common pulmonary syndromes, such as pulmonary embolism, pulmonary edema, pleural effusions, ARDS, and transfusion-related lung injuries, can occur at any period during the posttransplant period. These syndromes usually occur in the earlier phases of transplant, and the clinical presentation is not unique to transplant recipients. The two most common noninfectious pulmonary syndromes post-HSCT are idiopathic pneumonia syndrome and bronchiolitis obliterans syndrome.

Early

Idiopathic Pneumonia Syndrome

Idiopathic pneumonia syndrome (IPS) describes a spectrum of conditions causing acute lung injury early after HSCT. The median time of onset is 21 days post-transplant [59, 60]. IPS is defined by signs and symptoms of pneumonia, abnormal pulmonary physiology, the presence of diffuse interstitial infiltrates on chest imaging, the absence of lower respiratory tract infection on BAL, and no other identifiable alternative causes such as cardiac/renal failure or iatrogenic fluid overload [60]. Two clinically relevant IPS subtypes include diffuse alveolar hemorrhage and engraftment syndrome [59].

Diffuse alveolar hemorrhage (DAH) is a subtype of IPS occurring in 2–6% of patients after transplant. DAH is diagnosed with a progressive bloody return on BAL. Alternatively it can also be diagnosed in the presence of $\geq$20% siderophages among alveolar macrophages on BAL. Treatments vary by institution and include steroids, platelet transfusions, antifibrinolytic therapies [59, 60].

Engraftment syndrome (ES) occurs before or soon after neutrophil return usually within 5 days of engraftment [59]. ES is characterized by fever, rash, and/or acute respiratory failure with the exclusion of other infectious and noninfectious pulmonary syndromes. The pathogenesis is related to degranulating neutrophils causing capillary leakage and subsequent acute lung injury. Chest imaging reveals diffuse pulmonary infiltrates and pulmonary edema. ES is seen more frequently in autologous compared to allogeneic transplant recipients, and the syndrome is associated with higher doses of infused mononuclear cells and the use of granulocyte colony-stimulating factor [61]. Treatment is usually supportive with steroids reserved for severe cases.

Late

Bronchiolitis obliterans syndrome (BOS), a common late pulmonary complication following allogeneic HSCT, is considered the pulmonary manifestation of chronic GVHD. The onset of BOS is usually from 6 months to 2 years after HSCT and presents in 10% of patients with chronic GVHD [62]. The exact cause is unknown, but an alloimmune mechanism is suspected as BOS after HSCT can be prevented with T-cell depletion of the graft and its histology shares similarities with BOS in lung allograft recipients [62]. Patients usually develop respiratory symptoms insidiously and demonstrate new-onset airflow obstruction on PFTs with a progressive decline in FEV_1 on spirometry. The diagnosis is often delayed due to its nonspecific presentation and can often be masked by concomitant pulmonary conditions such as infection. The main goal of therapy is to delay further decline in pulmonary function. Treatment consists of prompt recognition and control of underlying chronic GVHD with immunomodulators and supportive care, such as intravenous immunoglobulin replacement, antimicrobial prophylaxis, and macrolide antibiotics in combination with inhaled therapies such as bronchodilators and steroids [63]. Prevention strategies are limited and mainly consist of surveillance using PFTs to monitor pulmonary function.

Cryptogenic organizing pneumonia (COP) is an interstitial lung disease that can present early after engraftment but more frequently occurs in the late period. Unlike BOS, the hallmark is a restrictive airway disease and is usually responsive to steroid therapy [42, 60].

Evaluation of Patient with Pulmonary Symptoms

The evaluation of pulmonary symptoms is challenging as transplant patients present with atypical signs and symptoms related to a blunted immune response from exogenous immunosuppression [4]. A broad differential diagnosis should be established as pulmonary infectious and noninfectious processes frequently occur simultaneously or sequentially [4]. Factors to consider include the timing after transplantation, the degree of immunosuppression, donor and recipient exposures, and hospital and regional epidemiology [4]. Given the high morbidity and mortality associated with pulmonary infections, an aggressive approach is required including the early use of diagnostics and prompt initiation of empiric antimicrobial therapy [1–3]. Establishing a specific diagnosis is essential for de-escalation to targeted antimicrobial therapy with avoidance of adverse effects (including the development of antimicrobial resistance) from broad-spectrum antibiotics.

Recipient and Donor Epidemiologic Exposures

A thorough assessment of the recipient and donor epidemiologic exposures is essential to guide diagnostic testing and initiation of empiric antimicrobial therapy. A detailed

medical and social history should include recent hospitalizations, prior infections, travel history, occupation, sexual practices, hobbies, and pets. Certain pulmonary pathogens are associated with geographical and environmental exposures as follows:

- Geography and travel:
  - Ohio and Mississippi River Valleys in the United States of America: *Histoplasma capsulatum*, *Blastomyces dermatitidis* [25]
  - Southwestern United States of America, Central and South America: *Coccidioides* and *Paracoccidioides* species [25, 65]
  - Southeast Asia: *Burkholderia pseudomallei* and *Talaromyces (Penicillium) marneffei* [65]
  - Endemic countries: *Strongyloides stercoralis* [26], *Mycobacterium tuberculosis* [28]
- Contaminated water supply – *Legionella pneumophila*, *Pseudomonas aeruginosa*, nontuberculous mycobacteria [4]
- Gardening and soil – *Aspergillus* species, *Nocardia* species, hantavirus [4]
- Animals – *Chlamydophila psittaci*, *Rhodococcus equi*, *Francisella tularensis*, *Coxiella burnetii*, *Pasteurella multocida*, *Cryptococcus neoformans*, *Toxoplasma gondii*, *Echinococcus granulosus* [66]
- Seasonal – winter (influenza, RSV, human metapneumovirus), spring-fall (rhinovirus), all seasons (adenovirus, parainfluenza, SARS-CoV-2) [20, 67]
- Nosocomial – MRSA, vancomycin-resistant enterococci (VRE), multidrug-resistant gram-negative bacteria [68]

Diagnostic Evaluation

The diagnostic evaluation is tailored based on the patient's medical history, degree of immunosuppression, exposures, and clinical presentation. The initial evaluation includes blood testing, sampling of the respiratory tract, and radiographic imaging [3]:

- The complete blood cell count with differential, electrolyte chemistries and liver function tests assist with the diagnosis and identify any toxicities to guide empiric antimicrobial therapy [3].
- Blood cultures obtained prior to initiation of empiric antimicrobial therapy are recommended. The yield of blood cultures is low in the setting of pneumonia; however, positive culture results provide useful information for tailoring antimicrobial therapy [69].
- Although urine *Legionella* antigen testing has low sensitivity for *L. pneumophila* and fails to detect other *Legionella* species, testing is recommended as positive results establish a diagnosis for appropriate de-escalation to antibiotic therapy for atypical pneumonia [70].
- Nasopharyngeal influenza molecular testing is recommended in seasonally appropriate times for initiation of antiviral therapy [20, 71]. Nasopharyngeal respiratory viral panels screen for multiple viruses simultaneously. In a patient with clinical

presentation consistent with viral pneumonia, a positive result may encourage early discontinuation of antibiotic therapy [67].
- Noninvasive lower respiratory tract testing includes sputum samples sent for gram stain and bacterial cultures. The yield of sputum cultures is generally low, but positive results allow for adjustments in antimicrobial therapy [68, 71].
- Chest X-ray is recommended for immunocompromised patients presenting with pulmonary symptoms. Chest computed tomography (CT) may be indicated in the initial evaluation based on patients with prolonged respiratory symptoms, high acuity clinical presentations, and a high net state of immunosuppression [1, 3].

Additional diagnostic evaluation is indicated if the patient does not improve clinically after the first 24–48 h after empiric antimicrobial therapy and a diagnosis has not been established with the initial work-up [3]:

- If not performed during the initial evaluation, CT chest is recommended as the location and characteristics of radiographic abnormalities narrow the differential diagnosis and identify the best diagnostic procedure for lower respiratory tract sampling (see "Imaging" section) [1, 3].
- Fungal antigen testing is indicated if patient exposures, net state of immunosuppression, clinical presentation, and radiographic findings are suggestive of fungal pneumonia. Serum testing includes *Cryptococcus* antigen, *Histoplasma* antigen, *Blastomyces* antigen, galactomannan (*Aspergillus*) antigen, and (1,3)-β-D-glucan. Urine antigen tests include *H. capsulatum* and *B. dermatitidis* [72].

Invasive diagnostic testing is recommended if the patient fails to improve clinically on empiric antimicrobial therapy and a diagnosis has not been established [1–3]. Diagnostic procedures used to sample the lower respiratory tract include bronchoscopy with bronchoalveolar lavage (BAL) and transbronchial biopsy, percutaneous needle biopsy, video-assisted thoracoscopic biopsy, and open lung excision [3]. The benefits of establishing a diagnosis must be weighed against the risks of invasive diagnostic testing. The initial BAL fluid and transbronchial biopsy evaluation include gram potassium hydroxide (KOH) and acid-fast bacilli (AFB) stains; bacterial, AFB, and fungal cultures; cytology; and histology with hematoxylin and eosin (H&E) and methenamine silver stains. Based on the clinical suspicion, additional testing can be performed on the BAL fluid including antigen (*Histoplasma*, *Blastomyces*, *Aspergillus* galactomannan), direct fluorescent antibody (DFA) (HSV, VZV, PJP, *Legionella*), and molecular testing (respiratory viruses, herpes viruses, atypical bacteria, *Legionella*, *M. tuberculosis*, *P. jirovecii*, *Aspergillus)* [72] (Table 1). Lung biopsy establishes the diagnosis of infectious pulmonary syndromes based on the pattern of inflammation on histology along with viral, bacterial, and fungal stains. Lung biopsy is essential for the diagnosis of noninfectious pulmonary syndromes including malignancy, rejection, and graft-versus-host disease.

Table 1 Studies for bronchoalveolar lavage fluid in the evaluation of pulmonary infection in transplant patients [3]

Infection	Stain	Culture	Antigen	PCR	DFA

PCR polymerase chain reaction, *DFA* direct fluorescent antibody, *AFB* acid-fast bacilli.

Imaging

Chest imaging is an essential component of the diagnostic evaluation as many pulmonary syndromes present with characteristic radiographic abnormalities with predictable rates of progression (Table 2). Acute abnormalities (less than 48 h) are suggestive of viral or bacterial pneumonias, while subacute and chronic findings (greater than 48 h) typically represent mycobacterial or fungal infections [4]. Radiographic abnormalities include consolidation, interstitial disease, nodules, cavitation, and lymphadenopathy [3]. Consolidations with air bronchograms represent alveolar air replaced with tissue density material with superimposed airways [3]. Interstitial infiltrates are suggestive of CMV, respiratory viruses, *Mycoplasma*, *Legionella*, PJP,

Table 2 Differential diagnosis of pulmonary syndromes based on radiographic appearance on chest radiograph or computed tomography by rate of disease progression [4]

Radiographic abnormality	Rate of disease progression	
	Acute	Subacute or chronic
Consolidation	Any organism	*Nocardia* species, *Actinomyces* species Mycobacteria Fungi Bronchiolitis obliterans syndrome
Bronchopneumonia	Community-acquired viruses Atypical bacteria (*Mycoplasma*, *Chlamydophila*)	Mycobacteria Bronchiolitis obliterans syndrome
Diffuse interstitial infiltrates	Community-acquired viruses CMV, EBV, HSV *Pneumocystis jirovecii* Pulmonary edema, pulmonary hemorrhage Acute respiratory distress syndrome	Mycobacteria Drug toxicity, radiation toxicity Metastatic cancer Pulmonary alveolar proteinosis
Nodular infiltrates	CMV Bacteria, septic emboli *P. Jirovecii*	*Nocardia* species, *Actinomyces* species Mycobacteria Fungi Kaposi sarcoma, Castleman disease Lung cancer
Adenopathy	Mycobacterium tuberculosis *Cryptococcus neoformans*	Mycobacterium tuberculosis PTLD Kaposi sarcoma, Castleman disease Lung cancer
Pleural effusion	Bacteria Tuberculosis Postoperative Heart, kidney, or liver failure	Non-Hodgkin's lymphoma Primary effusion lymphoma

CMV cytomegalovirus, *EBV* Epstein-Barr Virus, *HSV* Herpes Simplex Virus, *PTLD* posttransplant lymphoproliferative disorder.

fluid overload, and lung transplant rejection. Nodules are space-occupying, non-anatomic defects with well-defined rounded edges typically associated with *Nocardia*, mycobacteria, invasive mold infection, endemic fungal infections, and malignancy. Cavitation represents a necrotizing infection caused by gram-negative bacilli, anaerobic bacteria, mycobacteria, and fungi. Lymphadenopathy has a broad differential including pneumonia (viral, mycobacterial, fungal), sarcoidosis, PTLD, and lymphoma [3].

Chest radiograph is an inexpensive imaging modality with the ability to delineate many radiographic abnormalities; however, the image quality may be limited by suboptimal patient positioning. Chest CT provides more details on the features and location of the radiographic abnormality. Identifying the precise location of lung pathology helps determine the best procedure for tissue sampling [3].

Empiric Antimicrobial Therapy

The regimen chosen for empiric antimicrobial therapy should consider a variety of factors including the degree of immunosuppression, the rate of disease progression, epidemiological exposures, and prior microbial colonization history. Antibacterial therapy is the main component of empiric antimicrobial therapy in patients after transplant. During the influenza season, empiric antiviral therapy against influenza should be initiated while awaiting results of influenza-specific testing. Empiric antifungal therapy is rarely initiated unless the clinical and radiographic presentation is strongly suggestive of a fungal pathogen.

In patients without any risk factors for opportunistic or hospital-acquired pneumonia, empiric antimicrobial treatment should be initiated against community-acquired respiratory pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and atypical intracellular pathogens (*Mycoplasma* species, *Legionella* species). Recommended regimens for community-acquired pneumonia include (1) combination therapy with a beta-lactam and a macrolide or (2) respiratory fluoroquinolone monotherapy [71]. Adverse drug effects and local resistance patterns should be considered when choosing between empiric regimens. Macrolides lead to increases in the levels of immunosuppressive agents. Fluoroquinolones are active against penicillin-resistant *Streptococcus pneumoniae* and macrolide-resistant *Mycoplasma* species, but its use may be limited due to its association with altered glucose metabolism, QTc prolongation, aortic aneurysm rupture, and *Clostridioides difficile* colitis [71].

Empiric antimicrobial therapy with coverage of MRSA and *Pseudomonas* species is recommended for patients with chronic bronchiectasis, airway colonization with these pathogens, hospital-acquired pneumonia, or ventilator-associated pneumonia [68]. Patients who fail to improve clinically on empiric community-acquired treatment may also benefit from broadening antimicrobial therapy. Antibiotics with MRSA coverage include vancomycin and linezolid; daptomycin is not recommended for primary pneumonia since it is inactivated by a pulmonary surfactant [68]. Anti-pseudomonal beta-lactam agents include cefepime, ceftazidime, aztreonam, piperacillin-tazobactam, imipenem, and meropenem [68]. Double coverage for

Pseudomonas species with fluoroquinolones, aminoglycosides, and polymyxins (and sometimes novel antibiotics) is recommended for patients at risk and hospital units with a high prevalence of MDRO [68].

Conclusions

Despite advances in surgical techniques, immunosuppressive regimens, and antibiotic prophylaxis, pulmonary syndromes remain significant contributors to morbidity and mortality in transplant recipients. A predictable timeline of pulmonary infections presents after transplant related to the patient's changing risk factors over time including the time after transplant, degree of immunosuppression, prophylactic antibiotics, and hospital and community exposures. Evaluation of transplant patients presenting with pulmonary symptoms begins with performing a detailed medical and social history to guide diagnostic testing and initiation of empiric antimicrobial therapy. Diagnostic assessment includes serum and urinary antigen assays, molecular assays, microbiology cultures, chest imaging, and lung tissue sampling. An aggressive approach to establishing a specific diagnosis is recommended for the initiation of targeted antimicrobial therapy and avoidance of adverse effects from broad-spectrum antibiotics.

Key Points

- Infectious and noninfectious pulmonary syndromes remain significant contributors to morbidity and mortality after solid organ and hematopoietic stem cell transplantation.
- The timeline of pulmonary infections after SOT can be divided into three risk periods related to the changing risk factors in the recipient: the time since surgery, degree of immunosuppression, prophylactic antibiotics, and hospital and community exposures.
- Noninfectious pulmonary syndromes related to lung transplantation include airway complications, primary graft failure, acute allograft rejection, and bronchiolitis obliterans syndrome.
- Medications and malignancy are noninfectious pulmonary syndromes to consider after SOT.
- Factors to consider in the differential diagnosis of pulmonary syndromes include the timing after transplantation, the degree of immunosuppression, donor and recipient exposures, and hospital and regional epidemiology.
- Given the high morbidity and mortality associated with pulmonary infections, an aggressive approach is required including the early use of diagnostics and prompt initiation of empiric antimicrobial therapy.
- Establishing a specific diagnosis is essential for de-escalation to targeted antimicrobial therapy with avoidance of adverse effects from broad-spectrum antibiotics.

Introduction

Diarrhea, affecting 20–52% of solid organ transplant (SOT) recipients and up to 40–80% of hematopoietic stem cell transplant (HSCT) recipients, can lead to dehydration, malabsorption, electrolyte imbalance, drug toxicity, hospitalization, rejection, and adverse impact on patients' quality of life [1–4]. Diarrhea is defined by $\geq$3 bowel movements/day associated with a change in the consistency of stool [1]. In intestinal transplant recipients with chronic diarrhea or with an ostomy, diarrhea is defined as an increase in stool output by 50%. Depending on the

chronicity of the symptoms, diarrhea is classified by the duration of symptoms as acute (<14 days), persistent (14–29 days), and chronic (>30 days) [1].

Etiology of Diarrhea in Transplant Recipients

The causes of posttransplant diarrhea are presented in Table 1. It is estimated that community-onset diarrhea is more common than hospital-onset diarrhea (80% vs. 20%) [2].

The etiology of diarrhea in SOT recipients can be identified in about 80% of the patients [5]. The noninfectious causes of diarrhea should be considered after all infectious etiologies are excluded. Medications (i.e., immunosuppressant agents, antibacterial agents, laxatives, proton-pump inhibitors, antidiabetic drugs) are the most common culprits of diarrhea in SOT, followed by infections [1]. Mycophenolate mofetil (MMF) and its active metabolite, mycophenolic acid, inhibit the cell cycle of rapidly dividing cells causing diarrhea in up to 36% of SOT recipients [2, 6]. MMF-related diarrhea has been described mainly during the first 6 months of treatment, but it can occur at any point after transplantation [5, 7]. Calcineurin inhibitors affect gastrointestinal motility through a macrolide effect and are less frequently associated with diarrhea than MMF [6]. Dose reduction or change in the putative immunosuppressant leads to resolution of diarrhea but increases the risk of acute rejection and graft loss. Graft-versus-host disease (GVHD) in solid organ transplantation is infrequent and more commonly occurs in intestinal transplant recipients (6–9%) compared to recipients of other allografts [6]. Posttransplant lymphoproliferative disorder (PTLD) of the gastrointestinal tract may manifest with diarrhea, but commonly extraintestinal involvement (lymphadenopathy, cytopenia, masses in the liver or lung) is also seen at the same time [1]. A significant number of diarrheal episodes are self-limited and have no identifiable etiology, mainly due to the presence of other concurrent illnesses (i.e., peritonitis) or medical interventions (i.e., discontinuation of antibiotics or laxatives).

The etiology of diarrhea in HSCT recipients can be multifactorial and varies according to the cell source and timing posttransplantation. The highest incidence of diarrhea occurs within the first several weeks posttransplant and is most commonly related to the enteral mucosal injury due to the conditioning chemotherapy and/or radiotherapy [4]. Diarrhea can also be a manifestation of neutropenic colitis in the pre-engraftment period, a serious consequence of the chemotherapy-induced cytotoxic injury in the setting of prolonged neutropenia; the cellular injury allows bacterial organisms colonizing the gastrointestinal tract to invade the bowel wall or even to translocate into the bloodstream [8]. Acute graft-versus-host disease (aGVHD) is another common cause of diarrhea, responsible for up to 30% of diarrheal episodes in allogeneic transplant recipients, and typically occurs between engraftment and the first 100 days posttransplantation [9]. Cord colitis, a relatively newly recognized syndrome in umbilical cord blood transplant recipients, is reported to cause non-bloody diarrhea in the first 3–11 months after transplant and responds to treatment with metronidazole [10]. Engraftment syndrome occurs within a week of engraftment and encompasses a constellation of symptoms, including diarrhea,

fever, pulmonary edema, and rash [11]. Infections account for 6–40% of diarrheal illnesses in HSCT recipients [3, 12].

Emerging Infections

Astroviridae (astroviruses), *Picornaviridae* (bocavirus, cosavirus), and *Caliciviridae* (noroviruses, sapoviruses) are emerging infectious agents of enteritis in transplantation. Other viruses such as parvovirus, Epstein-Barr virus, human herpesvirus 6, and lymphocytic choriomeningitis virus can cause diarrhea as part of a systemic illness [5]. Viruses such as cosavirus, bocavirus, astrovirus, and sapovirus have been identified by conventional real-time PCR or nested reverse transcription PCR in transplant patients with diarrhea [5, 13].

Astroviruses causing protracted enteritis with prolonged viral shedding and even disseminated disease have been reported mainly in stem cell transplant recipients. HAstV-4, HAstV-VA1/HMO-C/PS, and MBL2 astroviruses have been associated with more severe disease such as progressive encephalitis, meningitis, and even death; headache, sensorineural hearing loss, motor incoordination, ataxia, brainstem dysfunction, progressive cognitive impairment, and seizures are the most commonly reported manifestations [14, 15].

Human bocavirus (HboV) usually causes respiratory symptoms, fever, and sometimes diarrhea. HBoV was described to cause severe diarrhea with profound hypovolemia and disseminated disease in a pediatric liver and stem cell transplant recipient, followed by prolonged shedding of the virus [16]. HboV can be detected at a high rate in the stool of pediatric patients, commonly as coinfection with other intestinal pathogens; its role as a primary cause of gastrointestinal infections remains to be determined [16]. Human cosavirus (HCoSV) has been detected in fecal samples from healthy children and adults and from children with acute non-polio flaccid paralysis. HCoSV infection was reported in a pediatric liver and an adult lung transplant recipient both of whom presented with persistent diarrhea, nausea, vomiting, fever, and abdominal pain [5, 13].

Torovirus in the family *Tobaniviridae* has been reported to cause nosocomial gastroenteritis in immunocompromised children. Although nonspecific, bloody diarrhea is the hallmark feature of torovirus infection [17]. Corona-like viral particles can be detected in the stool; the final diagnosis is made by electron microscopy in correlation with enzyme immunoassay with Breda virus reference antiserum [17].

Food poisoning with vomiting from ingestion of preformed *S. aureus* toxin is a well-described gastrointestinal syndrome, but a rare entity, staphylococcal enterocolitis, has also been published [18]. *S. aureus* can affect both the small and the large intestine, causing edema and ulcerations of the mucosa [18].

Leclercia adecarboxylata, a Gram-negative bacterium, has been described as an opportunistic pathogen causing mainly bacteremia and wound infections; a case of diarrhea, urinary tract infection, and pneumonia in a lung transplant recipient has been reported [19]. The prevalence of *L. adecarboxylata* infections is not known and probably underestimated given its close resemblance to *Escherichia* spp. [19]. The

identification of the bacteria can be done based on morphological and metabolic properties or with MALDI-TOF [19]. The bacterium tends to be sensitive to most of the antibiotics routinely used to treat *Enterobacteriaceae* but sometimes displays resistance to ampicillin and fosfomycin [19].

Laribacter hongkongensis, a Gram-negative facultative anaerobic bacterium, has been isolated from patients with community-acquired diarrhea and can cause prolonged non-bloody gastroenteritis with potential for invasive disease in transplant recipients [20]. *L. hongkongensis* infections should be suspected in patients who have recently traveled or consumed freshwater fish [20]. The diagnosis can be confirmed with MALDI-TOF or culture on special media [20]. Based on susceptibility testing and information that beta-lactamases (sometimes ampC and ESBL) have been previously detected, ampicillin and cephalosporin should not be used [20].

Diagnostic Evaluation

Broad stool testing for infectious pathogens in immunocompromised patients has a low yield; a more targeted approach based on epidemiological factors and clinical syndrome should be used instead [1]. Febrile patients might have a viral illness (i.e., cytomegalovirus, adenovirus), bacterial infection (i.e., *C. difficile*, *E. coli*), or a parasitic infection (i.e., *Cryptosporidium*). Detection of blood in the stool, abdominal pain, and cramps would suggest certain viral infections (i.e., cytomegalovirus), invasive bacterial infections (i.e., *E coli*, *Shigella*, *Salmonella*), parasitic infection (*Entamoeba*), or GVHD. Coinfections should always be taken in consideration; hence, a tiered approach to testing should be used in immunocompromised patients with diarrhea (see Fig. 1). In cases of prolonged diarrhea, stool culture on different special media should be given consideration, especially if the patients screen negative on multiplex PCR. Infectious etiologies should be assessed before modifying the immunosuppressive regimens, to avoid allograft rejection or uncontrolled progression of infection.

Multiplex PCR. Traditionally, the diagnosis of gastrointestinal infections has relied on a combination of several antigen detection tests, microscopy, culture, and several individual PCR assays. These test methods have good performance, allow targeted approach for diagnosis of diarrhea, but overall they are time-consuming and labor-intensive [21]. Multiplex molecular diagnostic panels seem to be better testing modalities, especially in critically ill patients and immunocompromised hosts, providing faster and more reliable results and allowing for detection of coinfections. Rapid identification of the etiology of diarrhea would allow adequate infection control and epidemiologic measures and reduce further testing, invasive procedures, and unnecessary medication changes [21]. There are laboratory-developed multiplex PCR assays and commercially available multiplex assays, of which only three assays are approved by the US Food and Drug Administration (FDA): Luminex xTAG gastrointestinal panel (Lumitex GPP, Lumitex Corp.), BioFire FilmArray gastrointestinal panel (BioFire GIP, BioFire Diagnostics, LLC), and Verigene Enteric Pathogens (Verigene EP) (see Table 2) [21, 22]. These tests have excellent sensitivity and

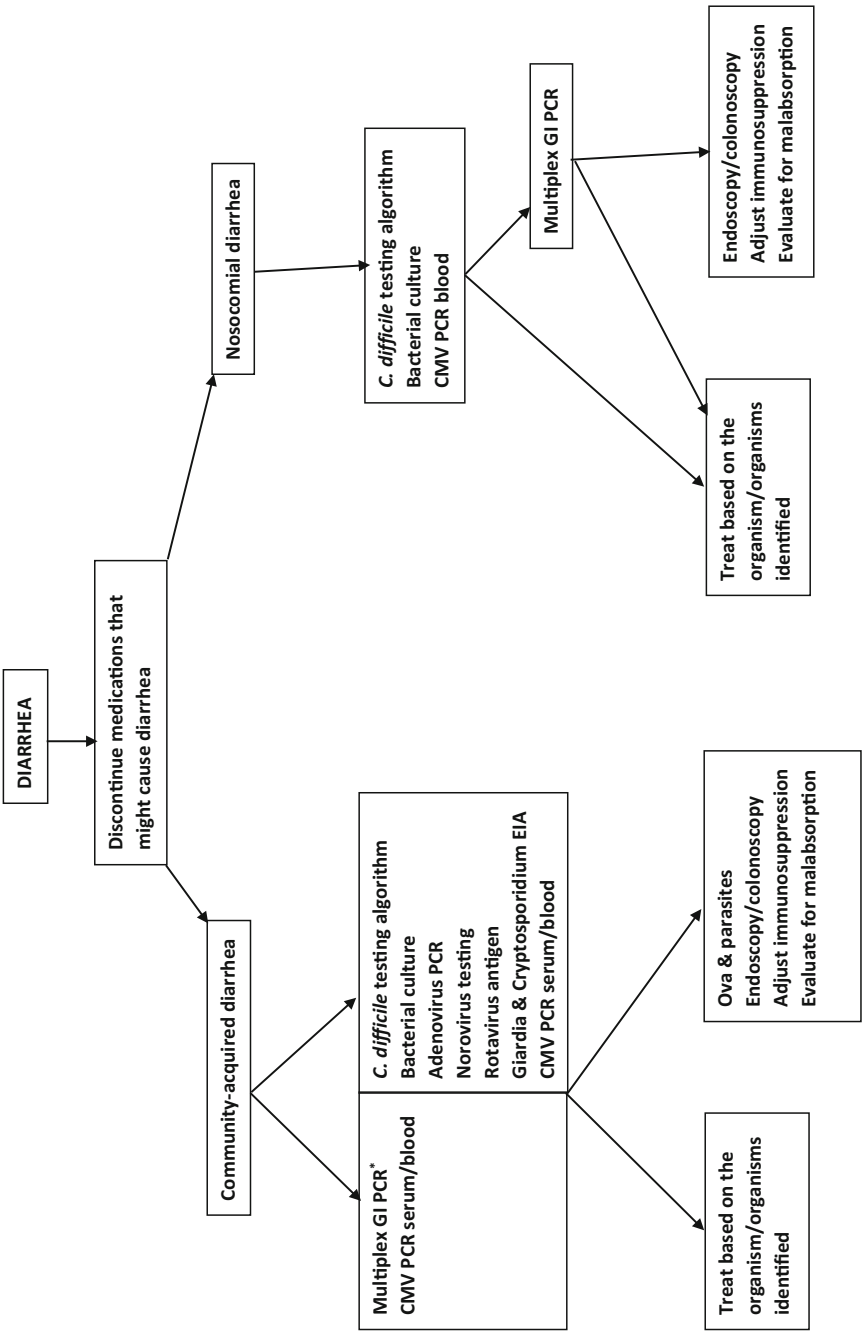

Fig. 1 Algorithm for diarrhea work-up

specificity and very high negative predictive value [22]. In many centers, syndromic testing through multiplex gastrointestinal panel is becoming the preferred approach, replacing less sensitive and slower methods (stool culture, viral antigen detection). However, multiplex gastrointestinal panels, by targeting microbial nucleic acid, cannot differentiate between viable and nonviable pathogens, cannot differentiate between shedding and active infection (e.g., in cases when *Salmonella*, norovirus, or adenovirus are detected) or between colonization with *C. difficile* and true infection [21]. The use of the gastrointestinal panels significantly increases the detection of pathogens by two- to fourfold compared to conventional methods and enables detection of new pathogens (i.e., sapovirus, EPEC). The multiplex PCR assays also lead to a higher reported rate of coinfections [21, 23]. Limited available data has demonstrated that multiplex gastrointestinal panels might be cost-effective by decreasing downstream expenses, despite increased laboratory cost [21].

CMV PCR serum/blood. When transplant recipients have diarrhea, CMV enteritis and colitis are always considered in the differential diagnosis, as CMV is the most common viral infection after transplantation. No single test can identify all cases of CMV colitis. Qualitative CMV PCR seems to have good sensitivity (up to 85%) and excellent specificity (95%) for diagnosis of the gastrointestinal tract infections in transplant recipients [24, 25]. The quantitative assay is preferred over the qualitative assay since it reflects CMV replication (associated with high viral load) [26]. The sensitivity and specificity of the test seems to be influenced by CMV donor/recipient serostatus (sensitivity 100% in D+/R− and 72% in D+/R+) and the timing after transplantation [24–26]. In CMV D+/R+ and D−/R+ solid organ transplant recipients more than 6 months after transplantation, endoscopy should be performed, especially in the absence of viremia when CMV colitis is considered. In D+/R− solid organ transplant recipients, the absence of viremia would argue against CMV colitis [25].

Clostridium difficile. Numerous diagnostic tests for *Clostridium difficile* infection (CDI) are now available. The historic gold standard is the cell culture cytotoxicity assay, which is both sensitive and specific, but as it requires cell cultures to demonstrate the cytopathic effect, it is a time-consuming and resource-intensive test and therefore not commonly used in the clinical setting. Glutamate dehydrogenase (GDH) is an enzyme present in all *C. difficile* isolates, and a GDH immunoassay (EIA) can detect this antigen. However, as this test cannot distinguish between toxigenic and nontoxigenic strains, it is not adequately specific to be used as a stand-alone test. Detection of toxins A and B produced by *C. difficile* can be performed using EIA, and while these tests are very specific, sensitivity varies. Nucleic acid amplification testing (NAAT) detects gene targets specific to toxigenic strains but cannot differentiate between clinical infection with toxin production and asymptomatic carriage. The optimal modality for *Clostridium difficile* diagnostic testing remains controversial, and expert guidelines recommend utilizing a multistep algorithm to increase sensitivity and specificity of testing [27]. Options for initial testing include (1) GDH plus toxin assay; (2) GDH plus toxin assay arbitrated by NAAT; or (3) NAAT plus toxin assay. If NAAT alone is performed, guidelines recommend placing criteria on when the testing for *C. difficile* should be performed

Table 2 Comparison between the targets of the FDA-approved multiplex gastrointestinal assays

GPP gastrointestinal pathogen panel, *GIP* gastrointestinal panel

[27–29]. Such criteria include a strong clinical suspicion for CDI in patients with new onset diarrhea with at least three or more episodes of unformed stools within a 24-h period, including patients who are not receiving laxatives and have no other explanation for diarrhea [27]. The presentation of CDI may be atypical in transplant recipients; the diagnosis may also be considered in patients with unexplained abdominal pain, leukocytosis, or fevers in a patient with an ileus [28, 29].

Enteric Bacterial Pathogens (*Salmonella, Shigella, Campylobacter, E. coli, Yersinia, Vibrio* sp.)

Given the rapid turnaround time, high sensitivity, and relative ease of testing, the multiplex panels are widely utilized in the diagnosis of bacterial enteric pathogens

[30, 31]. Most commercial multiplex tests include *Campylobacter, Salmonella, Yersinia enterocolitica, Vibrio* spp., *Shigella*, and significant pathogenic *E. coli* stains, such as Shiga-like toxin producing *E. coli* (STEC) and enteroinvasive *E. coli* (EIEC) on their panels (see Table 2) [21]. Some of the panels also include enteroaggregative *E. coli* (EAEC), enteropathogenic *E. coli* (EPEC), and enterotoxigenic *E. coli* (ETEC) (see Table 2) [21]. However, multiplex PCRs cannot distinguish between active infection and nonviable microbes and cannot test for antibiotic susceptibilities. Therefore, sometimes stool cultures are indicated, and if planned, the specimens should be collected early in the illness, preferably prior to initiation of antibiotics. Some bacterial organisms require specialized media. If a clinician is concerned for a particular pathogen, they should alert their microbiology lab.

Adenovirus. Qualitative and quantitative adenovirus polymerase chain reaction (PCR) assays are the most commonly used tests for detection of adenovirus in blood, respiratory secretions, stool, and tissue specimens, replacing older diagnostic methods such as viral culture [32]. PCR assays are rapid and highly sensitive. PCR assays specifically targeting adenovirus are more sensitive and specific than multiplex stool or respiratory PCR assays that include adenovirus, and also they detect all adenovirus serotypes, while multiplex assays test for a selected number of serotypes [32]. PCR assays can also be performed serially, helping to decide if and when to initiate therapy and to monitor response to therapy. In HSCT recipients, detection of adenovirus in the stool often precedes the detection of adenovirus in blood [33]. Persistently high viral loads or a 0.5–1.0 log increase might suggest the need for treatment, especially in HSCT recipients. In contrast, decreasing viral loads would suggest that therapy is not necessary or that there is clinical improvement [33]. PCR results should always be correlated with clinical presentation and histopathology, when available, in an attempt to differentiate between asymptomatic infection and disease. Histopathologic evaluation remains the gold standard to diagnose adenovirus invasive disease by identification of “smudge cells” (cells with large nuclei with basophilic inclusions and a thin rim of cytoplasm and positive immune-peroxidase and in situ hybridization staining) [34].

Culture, serology, and electron microscopy are available, but not routinely used in clinical practice [34]. All adenovirus serotypes (except serotypes 40 and 41) can be grown in human epithelial cells, but this diagnostic method is not practical [34]. The rapid antigen detection kits are commercially available and provide rapid and specific results. Immunofluorescence assays are often used for respiratory specimens, while enzyme immunoassays can be used for stool samples; most of the assays detect only the common adenovirus serotypes [34].

Norovirus. Noroviruses cannot be grown in cell culture; therefore, diagnosis is based on detection of norovirus antigens or RNA in stool [5]. Several enzyme immunoassays (EIAs) are commercially available for the detection of noroviruses GI and GII antigens in stool specimens with 31.6–80% sensitivity and 65.3–100% specificity. EIAs are more sensitive in the outbreak setting compared to sporadic gastroenteritis [35]. Several commercial rapid antigen assays via lateral flow immunochromatography are alternative stool testing for noroviruses, with good sensitivity (57.1–90.2%) and specificity (93.7–100%) [35]. EIAs and antigen

assays do not require special diagnostic facilities, are simple to perform, and have a short turnaround time. Their sensitivity and specificity depend on the norovirus viral load and the viral genotypes present in the stool specimens. RT-PCR is now considered the gold standard for the detection and typing of noroviruses and can be performed in stool, vomitus, food, and environmental specimens [5]. There are several conventional and real-time norovirus RT-PCR assays that have the advantage of detection of GI and GII noroviruses in a single reaction. However, norovirus genotyping (or genogrouping) does not impact clinical management, but it is useful in outbreak settings to track individual strains. Of the commercially PCRs currently available, some allow for qualitative detection of GI and GII noroviruses, while others allow a broader viral detection (e.g., the RT-PCR identifies caliciviruses and astroviruses, but does not distinguish between noroviruses and sapoviruses) [35]. The newer assays have a short turnaround time (a few hours).

Rotavirus. Historically a disease of young children, rotavirus is becoming a more well-recognized pathogen in transplant recipients, with highest rates in the intestinal, liver, and HSCT populations. The test most commonly used to diagnose rotavirus in children is the enzyme-linked immunosorbent assay (ELISA), which detects rotavirus antigens in stool. Other options include electron microscopy (EM), latex agglutination, immunochromatography, and nucleic acid testing via polymerase chain reactive (PCR), which is the most sensitive and specific modality [36]. Rotavirus testing is included as part of all three of the commercially available multiplex stool assays (see Table 2) [21].

Sapovirus. Enzyme-linked immunosorbent assays (ELISAs) for sapovirus are not commercially available and not used for diagnosis due to antigenic diversity of the strains [37]. Reverse transcription-PCR (RT-PCR) is the preferred method of diagnosis for sapovirus detection from stool samples, with good specificity, sensitivity, and broad reactivity. RT-PCR can also be used for genotyping [37].

Astrovirus. The diagnosis of astrovirus disseminated disease, including encephalitis, requires a high index of suspicion, even when HAsV PCR is negative. Deep sequencing needs to be performed to have a more definite diagnosis, to detect HAstV-4, HAstV-VA1/HMO-C/PS, and MBL2 astroviruses [15].

Giardia. Fecal microscopy had been the traditional gold standard for diagnosing parasitic infections, including *Giardia*, but compared to other available testing, it has lower sensitivity (approximately 46%) due to intermittent excretion of parasites. This, combined with the need for repeated testing and variability in technician expertise, has resulted in decreased utilization of this modality. The preferred diagnostic procedures are enzyme immunoassays and nucleic acid amplification tests performed in stool specimen [31]. There are a number of available immunoassays to detect *Giardia* antigens or antibodies in fecal specimens with sensitivities and specificities of up to 100% and 98%, respectively; these assays are more valuable in clinical practice [38, 39]. Molecular testing via PCR for giardiasis can be performed either as part of the multiplex panel or as a stand-alone test. PCR can also be performed on environmental and zoonotic specimens as part of source investigation [38].

Cryptosporidium. Stool microscopy, the cheapest diagnostic method, is labor-intensive and has low sensitivity even with Ziehl-Neelsen staining or fluorescent techniques (auramine-rhodamine) [40, 41]. Direct immunofluorescence can be a stand-alone test or a combined *Cryptosporidium*/*Giardia* diagnostic kit [40, 41]. Enzyme-linked immunosorbent assays (ELISAs) are more automated and have 66–100% sensitivity with very good specificity [41, 42]. Immunochromatographic tests provide results in minutes, are easy to perform, but are sensitive to detect mainly *C. parvum* and *C. hominis* [41, 42]. Molecular methods described previously (multiplex PCR) became the preferred testing since they have the highest sensitivity and specificity. Direct fluorescent immunoassay, ELISA, and nucleic acid amplification tests are the preferred methods for diagnosis [31]. Histopathology is a useful method for diagnosis, especially when stool testing has been negative but suspicion for cryptosporidiosis or coinfection or other underlying disease persists. Parasites can be seen with hematoxylin staining lining the epithelial surfaces or in the lumen [41, 42].

Cyclospora. Diagnosis of cyclosporiasis can be established utilizing direct microscopy and either modified acid-fast staining or light microscopy as the oocysts auto-fluoresce. To increase sensitivity, microscopy should be performed on multiple fecal samples taken in 2–3 day intervals [43]. Molecular testing using PCR is more sensitive in diagnosing cyclosporiasis and is becoming more widely used particularly as part of the multiplex GI panels [21, 43].

Microsporidia. Spores can be detected using light microscopy after trichome staining on a concentrated specimen with the fungi appearing pink against a blue-green background [31, 44]. Sometimes microsporida can be seen when Giemsa stain is performed on fluid or tissue, but this is not the preferred modality to diagnosis microsporidiosis as it is not very sensitive, and cellular debris may be confused for microsporidia spores [44]. Tissue examination by electron microscopy is considered to be the preferred approach to diagnosis, but this testing is not available at all labs, is time intensive, and cannot reliably identify organisms to the species level. The use of immunofluorescence antibodies has been successful in detecting *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* species [45]. Certain species can also be detected using PCR, and this testing is available through several reference laboratories and the CDC [46].

Entamoeba. It is important to distinguish amebiasis due to *Entamoeba histolytica* from colonization due to one of the nonpathogenic *Entamoeba* species [47]. Stool microscopy can be performed but requires at least three stool samples, and concentration and fixation of specimens is typically recommended to increase diagnostic yield. Direct visualization of the parasite, either in the trophozoite or cyst form cannot differentiate *E. histolytica* from the nonpathogenic *E. dispar*. Therefore, stool microscopy is often performed in combination with serologic or antigen testing. Serology testing can distinguish *E. histolytica* from other *Entamoeba* species and is usually positive within a week of infection. However, serology testing cannot differentiate between previous and acute infection, so this test is best used in patients who do not reside in an endemic region. Antigen detection on stool utilizes monoclonal antibodies specific to antigens unique to *E. histolytica* and can therefore

differentiate this species from the others. The sensitivity and specificity of antigen detection is higher compared to stool microscopy and must be performed on fresh or frozen stool. Molecular methods that detect parasitic DNA in stool are the most sensitive and specific modalities to diagnosis amebiasis due to *E. histolytica*, but are not widely available and are expensive [47, 48].

Strongyloides. As strongyloidiasis is often a chronic parasitic infection, the recommended initial diagnostic test is the *Strongyloides* immunoglobulin G (IgG) ELISA antibody testing [49]. ELISA cannot distinguish between active and past infections and might be falsely negative in immunocompromised patients who are unable to mount an antibody response [50]. Stool examination for ova and parasites is less reliable, as larvae are passed infrequently and in small numbers. A single stool specimen has a sensitivity of only 15–30%, but consecutive daily sampling for a week increases the sensitivity to almost 100% [49, 50].

Colonoscopy

If stool testing or serologic testing is unrevealing for an infectious diagnosis, colonoscopy or sigmoidoscopy is typically the next step in establishing a diagnosis. While macroscopic findings may be nonspecific, histologic features can often help distinguish infectious from noninfectious etiologies. Once a diagnosis is established, a repeat scope to document improvement or resolution is usually not indicated as long as the patient is clinically improving. In cases where the diagnosis was initially established, but there is no improvement or even further clinical deterioration in spite of adequate therapy, endoscopy with ileum or colon biopsies would be recommended to diagnose possible coinfection.

While a high CMV viral load in the setting of diarrhea and colitis is suggestive of CMV colitis, histopathology remains the gold standard for diagnosing enteric CMV disease [26, 51]. On direct visual examination, CMV disease often appears as occasional erosions, ulcerations, or even mucosal hemorrhages. Less frequently it can cause confluent ulcerations, similar in appearance to inflammatory bowel disease, or even pseudomembranes [51]. Histopathologic features of enteric CMV disease are typically characterized by enlarged cells containing intranuclear inclusion bodies (known as "Cowdry bodies") surrounded by a halo [51]. Positive immunohistochemical staining for CMV antibodies confirms the diagnosis [26, 51].

Patients with MMF-associated colitis can have normal macroscopic findings (in 50% of the cases) or erythema, erosions, and ulcers; rectal involvement is not common [7]. Histologic findings consistent with MMF toxicity, more common in the right colon than in the left colon, are mucosal vascular injury, crypt architectural distortion, cryptitis, apoptosis, intraglandular lymphocytes, and increased neuroendocrine cells [7].

GVHD of the gastrointestinal tract is characterized by epithelial cell apoptosis and is most easily identified in areas of regenerating mucosa, particularly intestinal crypts in cases of lower tract involvement. In more severe cases, crypts have cystic dilation containing cellular debris or crypt destruction and loss [52]. Some of these

histologic features are nonspecific and can be seen in the setting of infection and medication toxicity, so staining for infectious etiologies and clinical response to immunosuppression needs to be considered in formulating a diagnosis [52].

Management of Transplant Recipients with Diarrhea

The initial step and the most important component of therapy in patient with diarrhea remains supportive care with oral or intravenous rehydration that should include potassium, magnesium, and bicarbonate in severe cases. Rehydration can be done orally in mild-to-moderate cases of dehydration and intravenously with normal saline or Ringer's lactate solution in severe cases, shock, altered mental status, ileus, or insufficient oral rehydration [1]. Antiemetic drugs (i.e., ondansetron) can be given for symptom control and to facilitate oral rehydration [31]. Antimotility and antisecretory agents (i.e., loperamide) decrease the duration of diarrhea but should be avoided when toxic megacolon is suspected [31]. Transplant recipients with IgG levels <350 mg/dl seem to be at high risk for opportunistic infections and might benefit from immunoglobulin administration (400 mg/kg) [33].

In severe cases, watery diarrhea after international travel, or when inflammatory diarrhea is suspected (due to symptoms such as fever, abdominal pain, blood in the stool), empiric therapy should be started early, with a quinolone or azithromycin for suspected bacterial pathogens [1, 31]. If clinical features of sepsis are identified, broad-spectrum antibiotic therapy should be chosen [31]. STEC O157 and non-O157 STEC infections present as inflammatory diarrhea, and treatment with antibiotics (beta-lactams, fluoroquinolones, trimethoprim/sulfamethoxazole) should be avoided [31]. Therapy should be targeted once the diagnosis is made to shorten the duration of illness and decrease the potential for allograft rejection [1]. Targeted antimicrobial therapy depends on reported resistance patterns in the location where the patient acquired the infection [31].

Ideally, in patients with infectious diarrhea, especially in severe cases, immunosuppression should be adjusted. Most likely, the severity of the disease is a reflection of the degree of immunosuppression, including low CD4 counts and lymphocyte dysfunction. The role of immune reconstitution in certain infections (i.e., cytomegalovirus and adenovirus infections) is highlighted by partial or total resolution of some infections after reduction of immunosuppression. Currently, there is no consensus on which immunosuppressive agent to reduce or discontinue first. Potential antimicrobial or antiparasitic properties of individual immunosuppressants should be taken in consideration when adjusting the regimen. Changes from calcineurin inhibitors (tacrolimus) to one of the mTOR inhibitors (sirolimus or everolimus) have been reported to influence recovery from infections [5].

Cytomegalovirus. The first-line antiviral drugs for treatment of gastrointestinal CMV disease are intravenous ganciclovir and oral valganciclovir, while foscarnet and cidofovir are second-line agents [26]. The dosing is described in Table 3. Virologic response should be monitored weekly with quantitative CMV PCR [26].

Table 3 Targeted treatment of posttransplant diarrhea

Etiologic agent	Treatment	Notes
Cytomegalovirus [1]	IV GCV 5 mg/kg every 12 h or oral VGC 900 mg twice daily, doses adjusted for creatinine clearance Secondary prophylaxis is not recommended** IVIG or CMV IG can be considered for CMV pneumonitis, life-threatening disease, drug-resistant CMV infections, and hypogammaglobulinemia Foscarnet 60 mg/kg IV every 8 h or 90 mg/kg every 12 h, doses adjusted for creatinine clearance Cidofovir 5 mg/kg once weekly for then every 2 weeks	IV GCV should be the initial treatment for severe or life-threatening CMV disease, patients with very high VL, and diarrhea that impairs absorption of VGC. CMV QPCR or pp65 antigenemia should be performed once weekly to assess virologic response Treatment should be continued until CMV VL or antigenemia are undetectable or below a predefined VL threshold Second-line agent used for UL54 and UL97-mutant ganciclovir-resistant CMV infection or disease Third-line agent may be used for UL97-mutant ganciclovir-resistant CMV infection or disease
Adenovirus [2]	Cidofovir 1 mg/kg three times weekly or 5 mg/kg/week induction for 2 weeks followed by 5 mg/kg every other week (see text) For creatinine clearance <50 ml/min (adult) and <0.3 ml/kg/min (children), the dose should be decreased 50% Probenecid (0.5–1.25 g/m^2) administered 3 h before, 2–3 h and 8 h after cidofovir Normal saline solution at 5 ml/kg/h administered the same time with probenecid A lipid conjugate of cidofovir (CMX001, Brincidofovir) was in development	5 mg/kg/week regimen might be more nephrotoxic, but it might be associated with less emergence of resistance and fewer breakthrough CMV and HSV infections
Rotavirus [3]	Rotavirus vaccine in all infants	
C. difficile [3, 4]	For first episode Oral vancomycin 125 mg QID × 10 days Fidaxomicin 200 mg BID × 10 days Fulminant colitis: oral or rectal vancomycin 500 mg QID + IV metronidazole 500 mg Q8H	Rectal vancomycin can be added if ileus is suspected

Salmonella enterica (typhi and paratyphi) [3, 4]	Ceftriaxone TMX/SMX Ciprofloxacin Amoxicillin	
Shigella spp. [3, 4]	Azithromycin Ciprofloxacin Ceftriaxone	
Campylobacter spp. [3, 4]	Azithromycin[a] Ciprofloxacin[b]	
Non-*Vibrio cholera* [3, 4]	Ceftriaxone+doxycycline TMX/SMX+aminoglycosides	Treat only invasive disease
Yersinia enterocolitica [4]	TMP/SMX Cefotaxime Ciprofloxacin	
Enteropathogenic *E. coli* [3, 4]	Fluoroquinolones Cephalosporins	
Enterohemorrhagic *E. coli* [3, 4]		Avoid antimotility agents Avoid antibacterial agents
Bacterial overgrowth [4]	Fluoroquinolones Amoxicillin-clavulanate	
Microsporidia		
Enterocytozoon bieneusi *Encephalitozoon* spp. [3, 4]	Fumagillin 20 mg TID × 14 days Albendazole 400 mg BID × 1–3 weeks	
Giardia [3, 4]	Tinidazole Metronidazole Nitazoxanide	
Cryptosporidium [3, 4]	Nitazoxanide Paromomycin	

(continued)

Table 3 (continued)

Etiologic agent	Treatment	Notes
Cyclospora [3, 4]	TMP/SMX Nitazoxanide	
Cystoisospora [3, 4]	TMP/SMX Pyrimethamine	
Trichinella spp. [3]	Albendazole Mebendazole	
Strongyloides [49, 50]	Ivermectin 200 mcg/kg PO for 2 days; repeat in 2 weeks Albendazole 400 mg PO BID for 10–14 days	In suspected or proven hyperinfection, repeat dosing daily until stools negative for O and P for 2 weeks Less effective; longer for hyperinfection

All antimicrobial doses should be adjusted for the patient's renal and hepatic function and potential interaction with concomitant medications as appropriate *BID* twice daily, *CMV* cytomegalovirus, *GCV* ganciclovir, *Ig* immunoglobulin, *IV* intravenous, *IVIg* intravenous immunoglobulin, *Q8H* every 8 hours, *QID* four times daily, *QPCR* quantitative polymerase chain reaction, *SOT* solid organ transplant recipients, *TMX/SMX* trimethoprim/sulfamethoxazole, *VGC* valganciclovir, *VL* viral load

Patients should be treated for a minimum of 2 weeks, but the length of therapy depends on resolution of clinical symptoms and clearance of viremia [26].

Adenovirus. High-risk allogeneic HSCT recipients (unrelated donor grafts, cord blood grafts, pediatric recipients of T-cell depleted grafts, severe graft-versus-host disease, severe lymphopenia, and treatment with alemtuzumab or antithymocyte globulin) should be screened and preemptively treated for adenovirus [53]. Serum adenovirus PCR should be monitored weekly starting at transplantation in high-risk HSCT recipients until immune reconstitution occurs. If patients develop viremia, immunosuppression should be reduced when possible; if viral loads increase above 1000 HAdV copies/ml or if the patient has persistent viremia, some centers may initiate preemptive therapy with cidofovir. If patients develop evidence of organ disease, such as colitis, or disseminated infection, treatment with cidofovir may be considered [53]. In SOT screening and preemptive therapy are not recommended [33]. Furthermore, no set threshold value or specific algorithm regarding when antiviral therapy should be started for adenovirus viremia in SOT has been developed [33]. Duration of therapy with cidofovir for adenovirus viremia or invasive disease in transplantation is not well defined. It has been suggested that cidofovir be continued until complete resolution of the signs and symptoms of disease and documentation of 1–3 negative adenovirus samples taken 1 week apart from sites that originally tested positive [33]. However, there are few caveats, the treatment should take in consideration the type of transplant and site of infection. In HSCT, hemorrhagic cystitis should be treated until hemorrhage resolves; adenovirus viremia would be a more reliable marker to follow rather the adenovirus viruria. In intestinal transplant recipients, the treatment should be determined based on the pathology results (finding of adenovirus inclusions) rather than adenovirus PCR in the tissue or stool. In SOT recipients, the treatment is usually reserved for severe cases, especially when immunosuppression cannot be adjusted. The cidofovir regimens are described in Table 3. The benefit of intravenous immunoglobulins for the treatment of adenovirus infections remains unclear [33].

Norovirus. No specific therapy for the treatment of norovirus enteritis is FDA approved. A Phase 2 study (NCT033395405) is currently ongoing to evaluate the safety and efficacy of nitazoxanide for the treatment of norovirus enteritis in HSCT and SOT recipients. Oral administration of human immunoglobulins (50 mg/kg four times/day) can be considered as an alternative treatment option for immunocompromised patients with prolonged norovirus diarrhea [54]. Although a favorable trend in resolution of diarrhea and a decreased stool output at 7 days after treatment was reported, this treatment did not shorten the length of hospital stay or decrease cost of hospitalization [1, 54].

Rotavirus. The role of orally administered human immunoglobulin and nitazoxanide for the treatment of rotavirus infections in immunocompromised patients has yet to be defined. Oral human immunoglobulins are immunologically active against rotavirus in the gastrointestinal tract, and their administration was associated with rapid improvement due to temporary neutralization of the virus, followed sometimes by recurrent symptoms. In a small study, nitazoxanide

administration was associated with shorter duration of clinical symptoms compared with treatment with oral human immunoglobulins or a combination of nitazoxanide and oral human immunoglobulin [55].

Astrovirus. No specific therapy is available for astrovirus infections. For disseminated cases (including encephalitis), treatment with ribavirin (30 mg/kg per day intravenously, then 15 mg/kg every 6 h for 4 days, followed by 8 mg/kg every 8 h for 3 days, then oral), intravenous immunoglobulin (1 g/kg), steroids (1 g/day for 3 days), and interferon alpha-2b (50 ug/kg) have been administered with unclear effectiveness [15].

Clostridium difficile. In SOT recipients, *C. difficile* is accountable for 3–31% of the diarrhea cases, with up to 33% rate of recurrence and up to 16% progression toward fulminant colitis [56]. First-line treatment for an initial episode is oral vancomycin with the addition of intravenous metronidazole in cases of fulminant CDI [27]. Vancomycin administered per rectum can also be considered in fulminant colitis or in patients with ileus. Recurrent episodes can be treated with either oral vancomycin followed by a tapered dosing regimen or with fidaxomicin. The use of proton-pump inhibitors and unnecessary antibiotics should be avoided if possible as they are associated with increased risk of recurrence. In patients with multiple recurrences, fecal microbiota transplantation (FMT) may be considered, but it is unclear if restoration of the microbiome would be associated with more infectious complications (related to the bacterial translocation or to the procedure) and changes in pharmacodynamics of the immunosuppressive drugs [27, 57]. In immunocompromised patients, most commonly reported adverse events – nausea, vomiting, abdominal pain, and procedure-related diarrhea – were self-limited. However, worsening of underlying inflammatory disease and reactivation of cytomegalovirus infections have been reported [56]. The cure rates with FMT for recurrent severe or fulminant *C. difficile* in SOT recipients are about 64% at 1 month, 59% at 3 months, and up to 95% after additional therapy (repeat procedure with or without antibiotics) [56]. Several factors were described as predictors of FMT failure: severe or fulminant colitis, presence of pseudomembranous colitis, and administration of antibiotics with no *C. difficile* activity at the time of FMT [56]. FMT, compared with different antibiotic regimens (metronidazole, vancomycin, and fidaxomicin), seems to be the most cost-effective treatment for recurrent *C. difficile* infections [57].

Enteric pathogens. Targeted antimicrobial therapy by pathogen is presented in Table 3. However, no specific dose or length of therapy in immunocompromised patients was recommended in the recently published guidelines [1, 31]. Immunocompromised patients might require more prolonged therapy compared with immunocompetent patients. The length of antimicrobial therapy must be carefully weighed against unintended and potentially harmful consequences such as antibiotic side effects, the prolongation of a carrier state (particularly in *Salmonella*), drug resistance, and the possibility of induction of disease-producing phages by antibiotics (such as Shiga toxin phage induced by quinolone antibiotics).

Cryptosporidium. When adjusting immunosuppression in cryptosporidiosis, the possibility that tacrolimus level might be increased due to enteritis and

that mycophenolate mofetil might have some antiparasitic activity against *Cryptosporidium* should be taken into consideration [41]. To date, no randomized clinical trial for the treatment of cryptosporidiosis with paromomycin, nitazoxanide, or azithromycin has been conducted in an immunocompromised population; most of the recommendations are from case series or extrapolated from patients with human immunodeficiency virus infection [41]. Treatment recommendations are presented in Table 3. Nitazoxanide is FDA approved for treatment of cryptosporidiosis. Nitazoxanide reduced the duration of diarrhea and eradicated *Cryptosporidium* cysts from stool [41]. Paromomycin, useful in reducing oocyst excretion, has not been proven to be efficacious as a stand-alone agent, though it may be useful as part of combination therapy with nitazoxanide and azithromycin for refractory cases [41]. Less data is available for azithromycin, clarithromycin, and spiramycin, and they also have significant drug-drug interactions with tacrolimus and cyclosporine. All three drugs reduce the duration of symptoms and oocyst shedding and are usually used in refractory cases [41]. Data on combination therapy relies on case reports and small case series, which may only reflect positive outcomes.

Conclusion

Diarrhea is a frequent complication of SOT and HSCT and can be associated with significant morbidity, healthcare costs, and adverse impacts on patient quality of life. Evaluation for infectious causes should be tailored based on clinical presentation, timing posttransplantation, and risk factors. While common etiologies should be high on the differential diagnosis, clinicians need to consider emerging infections, especially in patients with atypical presentations or where initial work-up is unrevealing.

Key Points

- Diarrhea complicates up to 50% of SOT, and most common causes in this population include infections; medications, particularly immunosuppressants (mycophenolate mofetil≫calcineurin inhibitors); GVHD; and PTLD. At least 20% of diarrheal episodes are self-limited and without a defined etiology.
- Up to 80% of HSCT recipients have diarrhea with the highest rates occurring in the first few weeks posttransplantation. Diarrhea is most commonly related to chemotherapy agents, neutropenic colitis, aGVHD, and infections.
- Viral agents, including *Astroviridae*, *Picornaviridae*, and *Caliciviridae* are important emerging infections in transplant recipients.
- Multiplex PCR testing of the stool is a practical, convenient modality to evaluate common infectious etiologies of diarrhea in posttransplant populations.

Introduction

Altered mental status describes any change in a patient's baseline mental status and covers a broad range in acuity and severity, from confusion to delirium to stupor and coma. A broad differential diagnosis, such as primary neurologic, metabolic, infectious, and psychiatric diseases, should be considered in patients with altered mental status [1]. In addition to usual causes, factors exclusive to transplant populations, including pretransplant neurologic dysfunction, immunosuppressive regimen,

antimicrobial prophylaxis, epidemiology, as well as metabolic abnormalities and drug toxicities related to transplantation, contribute to altered mental status in the posttransplant setting [2, 3]. Many cases are multifactorial [4].

The spectrum of conditions leading to altered mental status in transplant recipients depends on the time elapse since transplantation as well as transplanted organ type [5, 6]. A systematic approach, taking into consideration the timeline after transplantation, enables early identification and treatment of these causes (Table 1).

Timeline of Etiologies for Altered Mental Status

Postoperative Period (<1 Month)

Postoperative delirium is common after liver, heart, and lung transplantation, occurring in 10–70% of cases [7, 8], while in a recent report, only 0.8% of kidney transplant patients developed delirium [9]. It is associated with adverse outcomes, including prolonged hospital stay, decline in functional status, graft rejection, mortality, and a major economic impact on healthcare systems [10, 11].

Infections due to surgical complications, such as bile leak, surgical site infections, nosocomial infections (catheter related bloodstream infections, *Clostridium difficile* infections, aspiration), pre-existing recipient infections, and donor-derived infections can cause altered mental status [12]. Donor-derived infections can be especially challenging to identify and fatal [13, 14]. Information from organ procurement organizations regarding information on other organ recipients from the same donor might be needed for diagnosis. Opportunistic infections are uncommon during this period in the absence of prior immunosuppressive therapies as full effect of transplant immunosuppression is not yet present [15] and usually occur only in the setting of intense epidemiologic exposures [2].

Anesthetics and perioperative pain medications play a significant role in mental status changes. Antibiotics used for surgical prophylaxis or for treatment of postoperative infections can also be implicated. Fluoroquinolones can be associated with confusion, seizures, and psychosis among their other side effects [16]. Beta-lactam antibiotics (especially cefepime) can lead to confusion, hallucinations, encephalopathy, or seizures [17]. Trimethoprim-sulfamethoxazole can lead to encephalopathy or aseptic meningitis [18]. Corticosteroid use and withdrawal of steroids following prolonged use can lead to metabolic derangements resulting in delirium. Calcineurin inhibitors (CNIs, i.e., tacrolimus, cyclosporine), especially with high serum levels, can lead to posterior reversible encephalopathy syndrome (PRES), a syndrome caused by vasoconstriction resulting in alterations in brain perfusion [19]. PRES can present with headache, visual abnormalities, focal neurologic signs, and altered mental status, seizure activity, or a combination of these symptoms. CNIs can also cause psychosis, hallucinations, seizures, and encephalopathy, especially at higher drug levels [8].

Metabolic derangements during organ recovery and fluid and electrolyte shifts can result in altered mental status. Patients with alcohol-related liver disease or

Table 1 Timeline of etiologies for altered mental status [2, 6, 20]

Postoperative (<1 month)
Infectious causes:
Nosocomial infections
Systemic infections (sepsis, catheter-related infections)
Pneumonia
Urinary tract infections
Infections due to technical complications (bile leak, wound infection)
CNS infections (donor, recipient, or transfusion derived)
Active or incubating infections in recipient prior to transplant
Noninfectious causes
Drugs
Antibiotics (fluoroquinolones), steroids, benzodiazepines, narcotics, anesthetics, CNI
DRESS syndrome
Epilepsy
Electrolyte imbalances
Osmotic demyelination
Liver failure
Hyperammonemia
Low oxygen
Anemia
Hypoxia
Poor cardiac output
Coagulopathy

Metabolic/Wernicke's encephalopathy
Early posttransplant (1–6 months)
Infectious causes:
Opportunistic infections
Viral: Cytomegalovirus, Epstein-Barr virus, varicella zoster
Fungal: *Cryptococcus neoformans*, *Aspergillus* sp.
Parasitic: *Toxoplasma gondii*
Noninfectious causes:
Drugs, including PRES
Malignancy: PTLD, lymphoma
Rejection, IRIS
>6 months
Infectious causes:
Community-acquired infections
Opportunistic infections in the setting of rejections
PTLD

(continued)

Table 1 (continued)

Noninfectious causes:
Transplanted organ failure
Disease recurrence
Rejection episode
Renal failure due to immunosuppressives (e.g., CNI)
Malignancy
PTLD
Skin cancer with local or CNS metastasis (SCC, melanoma)
Unusual neurologic syndromes
Giant cell arteritis
Multiple sclerosis (optic neuritis)
Neuro-Whipple's disease
Sarcoidosis
NMDA receptor encephalitis

severe hepatic encephalopathy tend to have more prolonged encephalopathy in the posttransplant period [8].

Seizures occur in 5–10% of transplant patients and are commonly due to metabolic disorders (electrolyte disturbances), organ dysfunction, ischemic or hemorrhagic stroke, central nervous system infection, or PRES in the first month after transplant [5]. Alcohol withdrawal or Wernicke's encephalopathy can manifest in the perioperative period, especially as anesthetics are weaned off. Central pontine myelinolysis (CPM) can occur in 1–4% of liver transplant recipients, mainly in those who have had prolonged hyponatremia leading to fluctuations in consciousness [8].

Early Posttransplant Period (1–6 Months)

During this period of most intense immunosuppression, opportunistic infections and reactivation of latent infections peak. Bacterial infections such as *Nocardia* sp., *Listeria* sp., and *Mycobacterium* sp. can lead to central nervous system (CNS) infections and altered mental status. Herpesvirus infections (cytomegalovirus (CMV), herpes simplex (HSV), or varicella zoster (VZV)) are uncommon in patients on prophylaxis, but can occur upon discontinuation of prophylaxis or as breakthrough infections. Endemic mycoses, *Cryptococcus neoformans* infection, and mold infections can lead to severe disease, including CNS infection (Fig. 1). *Toxoplasma gondii* CNS infection is rare on patients on trimethoprim-sulfamethoxazole for *Pneumocystis jirovecii* prophylaxis [2].

Decrease in immunosuppression in the setting of infections can precipitate immune reconstitution syndrome (IRIS), which may present with encephalomyelitis [20]. CNS IRIS should be considered in patients with a previous diagnosis of invasive fungal infections, tuberculosis, toxoplasmosis, cryptococcal infection, CMV, or progressive multifocal leukoencephalopathy [20].

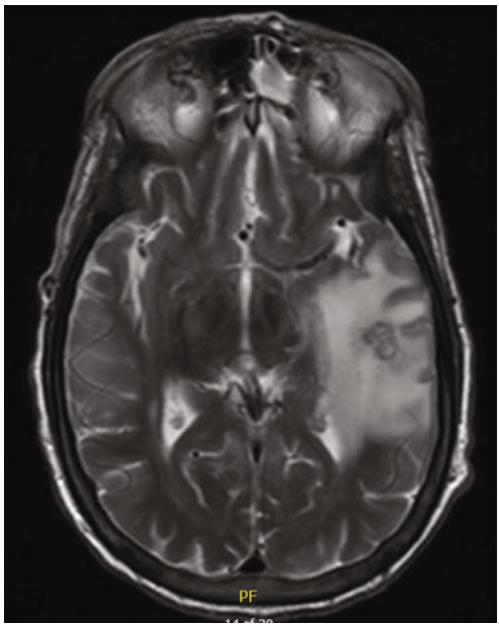

Fig. 1 T2-weighted magnetic resonance imaging of brain in a liver transplant recipient with altered mental status and left temporal lobe abscess, found to be *Scedosporium apiospermum/ Pseudallescheria boydii*. (Image: Courtesy of Dr. Camille Nelson Kotton)

Metabolic derangements, electrolyte abnormalities, electrolyte, and fluid shifts are uncommon during this period in the absence of an inciting event, such as rejection leading to graft dysfunction. Changes in medications or increased CNI levels due to graft dysfunction can lead to altered mental status.

Late Posttransplant Period (>6 Months)

Infection risk is usually decreased in the late posttransplant phase due to reduced maintenance immunosuppression and reflects the degree and duration of immunosuppression necessary to prevent rejection. Among infectious etiologies, community-based epidemiologic exposures including viruses, foodborne diseases, exposures related to hobbies (i.e., endemic mycoses, zoonotic illness, tick-borne disease), travel (i.e., malaria, dengue, ▶ Chap. 40, "West Nile Virus and Transplantation"), or residence and work (mold exposures) can lead to CNS infections or systemic infections resulting in altered mental status [15, 20]. Increase in immunosuppression for rejection therapy can set the timeline back and lead to mental status changes associated with opportunistic infections. Reactivation of herpesviruses leading to encephalitis can occur following discontinuation of prophylaxis. Infections with rare atypical organisms such as progressive multifocal leukoencephalopathy due to JC virus infection may also be encountered, mostly in the setting of prolonged intense immunosuppression [21].

A change in immunosuppressive regimen or other medications can suggest new drug-related encephalopathy and need to be reviewed carefully. Solid organ

transplant recipients have a fourfold increased risk of malignancy due to decreased immune surveillance in transplant recipients and increased susceptibility to oncogenic viruses due to immunosuppression [21]. Lymphoma is the most common brain tumor in transplant recipients, presenting as either primary CNS lymphoma or associated with posttransplant lymphoproliferative disorder (PTLD) [4]. Metastatic skin cancer (squamous cell cancer or melanoma) can also lead to altered mental status. CNS autoimmune diseases can be encountered despite ongoing immunosuppression and can be triggered by infections (such as NDMA receptor encephalitis) [6, 20].

Organ-Specific Risk Factors and Complications Leading to Altered Mental Status

Liver Transplantation

Postoperative delirium is more frequent among patients who had alcoholic cirrhosis as an indication for liver transplantation, especially those with increased pretransplant serum ammonia levels and shorter duration of abstinence [7, 8]. Other risk factors include metabolic liver disease, Model for End-Stage Liver Disease (MELD) scores above 15, and mechanical ventilation prior to transplantation [8]. Hepatic encephalopathy symptomatic at the time of transplantation was the strongest predictor of postoperative encephalopathy in one series [22].

Common complications following liver transplantation that can lead to altered mental status include cerebrovascular accidents (ischemic or hemorrhagic), osmotic demyelination, PRES, and seizures [22]. Seizure etiology is diverse and can vary from metabolic (hypoglycemia, hyponatremia, uremia), medications (CNIs), PRES, hemorrhage, and mitochondrial dysfunction secondary to acute hyperammonemia [20].

Kidney Transplantation

Major preoperative risk factors for delirium in kidney transplant patients included age greater than 65, frailty, and increasing comorbidities [9]. Postoperative complications specific to kidney transplantation leading to altered mental status include uremic encephalopathy and hypertensive stroke [20]. Cerebrovascular stroke or hemorrhage is seen frequently in kidney transplant recipients, with an incidence of stroke or transient ischemic attack of 5% in the first year and 9.5 in the second year [21]. A large proportion of these cases can be explained by comorbidities such as diabetes, age, prior stroke, polycystic kidney disease, or hypertension.

Risk of PTLD is lower following kidney transplant (1–2%) compared to other organs, with the highest risk factors being EBV serostatus and immunosuppression [21]. Incidence of PTLD is highest in the first year after transplant, with rates decreasing significantly afterward.

Heart Transplantation

Ischemic stroke is more frequent in heart transplant recipients than other organ transplants, occurring in up to 10% [23] and commonly leading to altered mental status. Heart transplant recipients also have the highest risk for toxoplasmosis, including cerebral toxoplasmosis among solid organ transplant recipients [20, 23], especially in those not on trimethoprim-sulfamethoxazole prophylaxis.

Lung Transplantation

In a retrospective series, the most common neurologic sequela following lung transplantation were postoperative delirium (40%) and PRES (4%), followed by stroke and TIA [24].

Idiopathic hyperammonemia syndrome is a rare but often fatal complication following solid organ transplantation and is predominantly seen in lung transplant recipients with an incidence of 0.5–4.1% in this patient population [25]. Patients present with encephalopathy and hyperammonemia in the absence of liver disease or congenital metabolic disorders, usually within 2 weeks of transplantation, though cases up to months after transplantation have been reported [26]. Infection with urease producing bacteria have been proposed as the etiology (i.e., ▶ Chap. 22, "*Mycoplasma* and *Ureaplasma* Infections in Transplantation: A Big Impact Despite the Lack of a Cell Wall"), though immunosuppressive therapy with tacrolimus has also been implicated [25].

Intestinal and Multivisceral Transplantation

Complex metabolic derangements, nutritional insufficiencies, and high immunosuppression requirements lead to relatively high neurologic complications following intestinal and multivisceral transplantation compared to other organ transplantations, with altered mental status (43%) and seizures (17%) being among the most common neurologic complications [27]. Liver failure commonly related to cholestatic TPN-related liver injury, but also hepatic allograft rejection, liver cirrhosis, bacterial overgrowth, and urea cycle enzyme abnormalities can occur resulting in hepatic encephalopathy. The more intense immunosuppression required in intestinal and multivisceral transplantation increases the risk of infections, including early invasive fungal infections [27]. Rejection leads to intestinal barrier defect and sepsis, which can result in altered mental status [20].

Workup of Transplant Recipient with Altered Mental Status

Timely diagnosis and treatment of altered mental status in a transplant recipient requires a thorough clinical assessment, followed by directed laboratory testing (sometimes including cerebrospinal fluid), and, if indicated, imaging, electrophysiology tests, and tissue sampling [28] (Table 2).

Table 2 Evaluation of altered mental status in solid organ transplant recipient [2, 6]

History
Prior neurologic symptoms
Graft function
Immunosuppression (length and degree)
Other drugs
Pace of illness
Intraoperative complications
Social history
Residence
Travel, place of birth, military service
Tuberculosis exposure
Sexual history
Substance abuse history
Pets and hobbies
Vaccination history and serologic data
Prior infection/colonization history
Physical examination
Vital signs (fever, tachycardia, tachypnea, hypotension)
Crackles, pleural effusion, heart murmur, sinus tenderness, skin lesions
Back and spine
Costovertebral angle tenderness
Spinal tenderness
Neurology
Focal or global deficits
Meningitis
Cranial nerve findings
Laboratory examination
Complete blood count and differential
Renal and liver, pancreatic chemistries, NH3
Lactate
Drug levels (calcineurin inhibitors)
Toxin screen
CMV, Epstein-Barr virus viral load
Antigen/antibody testing for endemic mycoses
Serum cryptococcal antigen
Cultures as appropriate (blood, urine, sputum)
Chest X-ray or chest CT
Neuroimaging
Lumbar puncture (cell count and differential, glucose, protein
Smears and culture for bacteria, fungi and mycobacteria
Molecular studies by PCR: HSV, VZV, CMV, HHV-6, EBV, JC virus, West Nile virus
▶ Chap. 40, "West Nile Virus and Transplantation" IgM
Cryptococcal antigen
Syphilis testing
Electroencephalography
Biopsy (brain, skin, lung, lymph node)

Initial evaluation should include detailed patient and donor demographics, prior infection/colonization data, comorbidities, underlying disease leading to transplantation, graft function, immunosuppressive regimen, and other medications. Detailed social history, including residence, employment, hobbies, travel history, sexual and substance abuse history, and pets, can give insights into prior exposures and emerging infectious diseases. Immunization records and serologic data should be reviewed, with the caveat that not all immunizations lead to protective immunity in the immunocompromised host [2].

Clinical presentations and physical examination findings can be delayed and atypical in transplant patients [29]. Fever can be absent in the setting of immunosuppression. Kernig and Brudzinski signs can be subtle or absent in transplant patients with meningitis [30]. A detailed physical exam can identify findings of common systemic or neurologic diseases that can lead to altered mental status [2].

Lab evaluation should include complete blood count with differential, kidney, and liver chemistries and drug level assays, such as for calcineurin inhibitors. Cultures including blood and if appropriate urine and sputum should be performed. Viral load assays for CMV and Epstein-Barr virus and antigen testing for endemic mycoses and cryptococcal infection can shorten time to diagnosis of infectious etiologies. Serologies can be delayed or negative in transplant patients depending on the intensity of immunosuppression.

Neuroimaging is recommended for most immunocompromised patients with altered mental status, and urgent brain imaging is needed for those with focal neurologic deficits. Cerebrospinal fluid evaluation should include cell count and differential, chemistry, routine bacterial, fungal and mycobacterial smears and cultures, meningoencephalitis panel, or at least HSV nucleic acid testing and cryptococcal antigen. Syphilis testing should be performed in the setting of fever or in those with no clear etiology of altered mental status. Additional specialized testing, such as viral nucleic acid testing, antigen and antibody, and 16S ribosomal RNA, may be required based on the clinical scenario [30].

Electroencephalography can identify seizures, including status epilepticus. Biopsies of focal lesions (skin, pulmonary, lymph node, brain) may be required to make a diagnosis [2, 30].

Management and Prevention

Prognosis and management for patients with altered mental status is largely dependent on the underlying cause. Patients with altered mental status due to drug toxicity or reversible metabolic causes usually do well, whereas patients with altered mental status due to CNS infections, hypoxic-ischemic encephalopathy, or CPM often do poorly [4].

In patients with toxic-metabolic encephalopathies, treatment is directed toward correcting the underlying cause (withdrawal of implicated drug, correction of metabolic derangement) while providing supportive care. If infection is suspected,

empiric antimicrobials should be started after appropriate samples for cultures are obtained.

Immunosuppression is managed individually, though reduction of immunosuppression is common for most infections. Immune reconstitution syndrome is usually treated with steroids.

Conclusions

Transplant recipients have a high prevalence of altered mental status, which is associated with poor outcomes. A systematic approach to evaluation is key to identify and manage the often coexisting causes of altered mental status in transplant recipients.

Key Points

- A variety of infectious and non-infectious etiologies can lead to altered mental status in solid organ transplant recipients.
- Organ transplanted and timeline after transplantation can give clues to the etiology.
- Urgent evaluation with physical examination, comprehensive laboratory evaluation and imaging can help identify etiology.
- Prognosis and management is dependent on the underlying cause.

Introduction

Transplant recipients with cytopenias are commonly encountered in the clinical setting, and new cytopenias may occur throughout the post-transplant period. This chapter discusses the range of etiologies of transplant-associated cytopenias, followed by a general approach to diagnosis and management.

Overview of Cytopenias and Their Relevance in Transplantation

Various terminologies are used to define cytopenia and its severity. Using published reference standards [1], thrombocytopenia is defined as a platelet count of <150,000/uL and anemia as a hemoglobin of <12 g/dL. As neutrophils comprise the majority of leukocytes in the peripheral blood and bone marrow, most cases of leukopenia manifest as neutropenia. However, there is ongoing debate regarding the WHO definition of neutropenia based on the Absolute Neutrophil Count (ANC), calculated as the total WBC/uL x percent (neutrophils + bands)/100 [2]. The normal threshold level for ANC is currently defined as >1800 cells/mm^3, but this may vary based on age, sex, and race [1]. In the post-transplant setting, lymphopenia may also substantially contribute to overall leukopenia. Pancytopenia refers to depression of all three hematopoietic lineages. Bicytopenia refers to depression of two lineages. The Common Terminology Criteria for Adverse Events (CTCAE) provides further breakdown of these definitions by grading based on severity [3]. Though numerical cutoffs guide diagnostic and treatment approaches for clinical syndromes, actionable levels directed to cytopenia itself are not always clear-cut and depend on the clinical context.

Cytopenias, whether involving one or multiple cell lines, occur due to one or more general mechanisms: bone marrow infiltration, blood cell destruction/sequestration, and/or bone marrow dysplasia or in its most severe form, aplasia. The differential diagnosis within each category is broad (Table 1), with some conditions causing cytopenias by more than one mechanism. Mild cytopenias may go unnoticed by the patient or cause only mild symptoms. However, in more severe cases, the manifestations can be life-threatening, with sepsis and bleeding as the greatest concerns.

Solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients are particularly vulnerable to developing cytopenias because of their comorbidities, complex drug regimens, and altered immune systems. Accordingly, there are frequently more than one cytopenia mechanism at play simultaneously. Post-transplant timing is also an important factor to consider as potential etiologies may shift over time, with varying timelines depending on the type of transplant, post-transplant clinical course, and periodic adjustments in medication regimens. For example, leukopenia with associated neutropenia among SOT recipients occurs commonly. It is estimated that more than 50% of SOT recipients experience leukopenia at some time point during their post-transplant course, most commonly during the first year [4–7]. Thoracic organ transplantation portends the highest risk, likely related to the higher doses of immunosuppressive therapy needed to maintain allograft function [8]. Alternatively, as a result of the conditioning regimen, HSCT recipients are profoundly pancytopenic at the time of their transplant and remain so until engraftment. As such, the threshold to investigate and treat cytopenias is usually determined on an individual patient basis with consideration of the underlying transplant type, severity, and timing post-transplant. It is crucial to consider the diagnostic possibilities in the post-transplant setting, both infectious and non-infectious, in order to promptly intervene to avoid complications.

Table 1 Clinical syndromes (other than drug reactions) associated with post-transplant cytopenias, classified by the hematopoietic lineage(s) affected, typical timing post-transplant, clinical manifestations, and diagnostic approach

Etiology	Hematologic findings	Timing after transplant	Other clinical/lab features	Diagnosis confirmation
Infections				
Cytomegalovirus (CMV)	Pancytopenia, especially leukopenia Atypical lymphocytosis	Early Usually in first 6 mos or after withdrawal of prophylaxis Periods of enhanced immunosuppression	Constitutional symptoms End-organ involvement of GI tract, liver, lung, eye	Blood CMV PCR Tissue biopsy demonstrating cytopathic effect, CMV IHC Serology poor
Parvovirus B19	RBC aplasia May have accompanying TCP and leukopenia	Early Periods of enhanced immunosuppression	Constitutional symptoms Symptoms of profound anemia Occasional ↑ LFTs	Blood parvovirus PCR Serology to confirm prior infection Bone marrow biopsy demonstrating giant pronormoblasts
Adenovirus	Pancytopenia	Early Usually in first 3 mos	Constitutional symptoms End-organ involvement of GI tract, liver, lung, brain, urinary tract	Blood adenovirus PCR Adenovirus PCR of other body fluids Tissue biopsy with IHC Serology poor

(continued)

Table 1 (continued)

Etiology	Hematologic findings	Timing after transplant	Other clinical/lab features	Diagnosis confirmation
Human herpesvirus (HHV) 6, 7, 8	Pancytopenia Delayed engraftment	Early	Encephalitis Rare hepatitis	Compatible clinical syndrome Blood/CSF PCR Tissue biopsy (HHV8)
Histoplasmosis	Pancytopenia	Variable Most in first year	Subacute, multisystem illness End-organ involvement of GI tract, lung, skin, reticuloendothelial system	Serum/urine antigen EIA Blood/tissue biopsy and culture Serology poor
Other syndromes				
Hemophagocytic Lymphohistiocytosis syndrome (HLH)	≥2 cell lines	Most cases within 2 mos, but variable over years	↑↑ ferritin ↑ LFTs, LDH, triglycerides ↑↑ soluble IL-2 receptor alpha [sIL-2R]	Compatible clinical syndrome Bone marrow biopsy
Thrombotic microangiopathy	Anemia, TCP	Early Usually in first 3 mos	Hypertension, mental status changes, CNI use ↑ LDH, bilirubin, Cr, and urine free HB, ↓ haptoglobin Schistocytes on blood smear	Compatible clinical syndrome Kidney biopsy

Autoimmune cytopenias	Hemolytic anemia Anemia> TCP> all lineages	Variable	↑ LDH, bilirubin, and urine free HB, ↓ haptoglobin Symptoms are associated with lineage affected Multiple potential triggers	Positive DAT, spherocytes on PBS, reticulocytosis No direct diagnostic tests
Passenger lymphocyte syndrome	Hemolytic anemia	Early First 1–3 weeks	Primarily occurs in SOT Lab findings consistent with hemolysis	Compatible clinical syndrome Self-limiting within 3 mos
Post-transplant lymphoproliferative disease (PTLD)/EBV	Pancytopenia May present as HLH	Variable Early PTLD: usually polyclonal Late PTLD: usually monoclonal	Lymphadenopathy, visceral/soft tissue masses B symptoms	PET-CT scan Tissue biopsy Blood EBV viral load
Graft-versus-host disease (SOT)	Pancytopenia	Early	Rash, diarrhea, sparing of the allograft	Tissue biopsy, often skin, bowel Assessment for chimerism
Graft failure (HSCT)	≥2 cell lines	Early: primary graft failure Late: secondary graft failure	Symptoms are associated with the lineage(s) affected	Bone marrow biopsy Assessment for chimerism

PCR polymerase chain reaction, *IHC* immunohistochemistry, *TCP* thrombocytopenia, *LFTs* liver function tests, *CSF* cerebrospinal fluid, *EIA* enzyme immunoassay, *CNI* calcineurin inhibitor, *LDH* lactate dehydrogenase, *Cr* creatinine, *HB* hemoglobin, *DAT* direct antiglobulin testing, *PBS* peripheral blood smear, *PET-CT* positron emission tomography-computed tomography, *EBV* Epstein-Barr virus, *SOT* solid organ transplant, *HSCT* hematopoietic stem cell transplant, *HB* hemoglobin, *RBC* red blood cell

Etiologies of Transplant-Associated Cytopenias

Etiologies Impacting Both SOT and HSCT

Infections

Infectious etiologies are a major consideration in the evaluation of cytopenias. Transplant recipients are susceptible not only to common infections but also to opportunistic infections, which may manifest with one or more cytopenias by a variety of mechanisms. As a group, viral pathogens are the most frequently encountered, particularly those within the *Herpesviridae* family. While acute bacterial sepsis is often transiently associated with cytopenias, there are specific bacterial infections in which cytopenias manifest as a more prominent feature. Likewise, parasitic infections due to Leishmania, Toxoplasma, Babesia, and malaria may all cause cytopenias. Fungal infections, aside from histoplasmosis, infrequently manifest with cytopenias. The most common infections associated with cytopenias are discussed below, with a more comprehensive list of etiologies outlined in Table 2.

Cytomegalovirus

Cytomegalovirus (CMV) is a ubiquitous herpesvirus which infects the majority of humans, with an estimated seroprevalence of 30–97%. The seroprevalance varies based on geography and socioeconomic status and increases with age [9]. Primary infection typically manifests as asymptomatic infection or a self-limited febrile illness in immunocompetent host, after which the virus establishes latency in monocytes and various other cell types. These cells serve as a reservoir for reactivation infection or a vehicle to transmit CMV infection to susceptible hosts via blood transfusion, SOT, or HSCT. CMV infection is of particular importance as an opportunistic infection in the post HSCT and SOT transplant setting [10–12]. Pancytopenia, especially leukopenia, is a common finding, often associated with atypical lymphocytes on peripheral blood smear. Direct inhibition of hematopoiesis due to virus-induced damage to bone marrow stroma and reduced regeneration of marrow repopulating pluripotent stem cells has been implicated in the pathogenesis of cytopenias [13]. Associated clinical findings range from asymptomatic infection to a flu-like illness to life-threatening invasive tissue disease. CMV infection may also contribute to delayed engraftment in HSCT recipients. Broadly, risk factors for post-transplant CMV include donor/recipient sero-mismatch and increased depth of immunosuppression. CMV infection classically manifests in the early post-transplant period, specifically in the first 6 months. However, post-transplant antiviral prophylaxis regimens have become standard of care which result in postponement or prevention of CMV infection, altering the traditionally observed time course [11].

The diagnosis of post-transplant CMV infection/disease relies on detection of CMV viremia by polymerase chain reaction (PCR) assay and/or demonstration of cytopathic effect and viral inclusions on tissue biopsy [14, 15]. In most instances, the diagnosis of CMV-associated pancytopenia is inferred from identification of CMV viremia in the appropriate clinical context. In SOT-associated CMV infection, ganciclovir or valganciclovir are the initial treatments of choice. Though pancytopenia, particularly leukopenia, is a well-established side effect of this agent, blood

counts typically improve despite use of this agent in the setting of active CMV infection [11]. In HSCT recipients, foscarnet is more frequently used as first-line CMV therapy in the early post-transplant period to avoid ganciclovir-associated toxicity to the bone marrow graft [16].

For a more extensive discussion of CMV management, refer to ▶ Chaps. 24, "Cytomegalovirus in Solid Organ Transplant Recipients: Prevention, Diagnosis, and Treatment" and ▶ 25, "Cytomegalovirus in Hematopoietic Stem Cell Transplant Recipients: Prevention, Diagnosis, and Treatment."

Parvovirus

Human parvovirus B19 infection is a common illness of childhood, with approximately half of the population demonstrating seropositivity by age 15 [17, 18].

Infection in transplant recipients may be through primary infection, reactivation from latent virus, or donor transmission [19, 20]. Despite the high seropositivity among adults, the incidence of symptomatic infection among transplant recipients is estimated to be <5%. The virus has a particular tropism for human erythroid progenitor cells expressing the P antigen [21]. The P antigen facilitates viral entry into the cell with subsequent viral replication leading to cellular lysis and resultant red blood cell aplasia. The pathogenesis of this finding is speculated to be non-specific cytopathic effects in the bone marrow or restricted nonstructural protein expression in megakaryocytes, leading to cytotoxicity but not viral progeny.

The clinical manifestations of human parvovirus B19 in transplant recipients reflect this pathogenesis, in that the most common manifestation is severe and/or persistent anemia without accompanying reticulocytosis or response to erythropoietin. A subset of transplant recipients will manifest concomitant leukopenia (38%), thrombocytopenia (21%), or both with the anemia [22, 23]. Organ invasive diseases, including carditis, hepatitis, pneumonitis, glomerulonephropathy, vasculitis, and neurologic diseases, have been described among both HSCT and SOT recipients, though these are distinctly less common than the hematological manifestations [19, 23]. In the SOT setting, direct involvement of the allograft may lead to graft failure. Rash and arthropathy are seen commonly in parvovirus infection among immunocompetent children and adults, respectively. However, these findings are infrequent among transplant recipients, which are postulated to be due to impaired formation of antigen-antibody complexes. Clinically apparent infection is more common in the early months following transplant, typically during the period of more intense immunosuppression. However, relapsing or persistent anemia associated with viremia is a common occurrence, in some cases lasting months to years [19].

Published guidelines recommend the initial diagnostic approach for suspected active parvovirus B19 infection should be based around a serum/whole blood PCR assay and potentially also include serology [19]. The positive predictive value of parvovirus viremia is high in the transplant recipient with a compatible clinical syndrome, especially red blood cell aplasia. A higher viral load correlates with symptomatic disease. Serology can also be obtained, though the interpretation is problematic in this patient population and it should not serve as the sole diagnostic test. Serology may be unreliable to diagnose primary infection due to blunted antibody production in the setting of immunosuppression. Additionally, background parvovirus seroprevalence is estimated to be 60–90% in adults, and thus serologic distinction between primary, remote, or reactivation infection is challenging. Eid and colleagues detail the variation in parvovirus IgG and IgM serology results among 98 transplant recipients with confirmed parvovirus disease [22]. When serology and serum/blood PCR results are inconclusive, bone marrow examination with concomitant in situ hybridization or immunohistochemistry (IHC) staining should be performed [19]. Pathognomonic bone marrow biopsy findings include giant pronormoblasts with prominent intranuclear inclusions and cytoplasmic vacuolations and absent late normoblasts [22, 24]. Unlike many chronic viral infections, a strong humoral immune response is required to control and clear the infection. Accordingly, immunoglobulin (IVIG) therapy has historically been the primary approach to

parvovirus treatment in transplant recipients [19, 20]. However, the optimal dose and duration have not been established. Relapsed and recurrent infections occur in an estimated 23% of transplant recipients, with or without IVIG therapy [22]. There are no known effective antiviral drugs recommended for the treatment of parvovirus B19 infection. As such, a reduction in immunosuppression should be attempted if possible. Successful resolution of the clinical syndrome and viremia is prolonged, typically taking weeks to months.

Adenovirus

Adenoviruses remain an important clinical pathogen in the setting of transplantation. There are over 50 serotypes that cause human infection with worldwide endemicity [25]. The virus establishes latency primarily in T-lymphocyte populations in various tissues, including lung, intestine, CNS, tonsils, and adenoids [26]. These sites can harbor small quantities of replicating and nonreplicating viral DNA in the absence of symptoms [25]. During latency, the virus evades immune surveillance. Adenovirus infections are more frequently encountered in children than adults, both in the immunocompetent and immunocompromised patient populations. The highest incidence is in children under the age of 5 years and decreases toward adolescence. Among SOT recipients, the incidence depends on the allograft type and degree of immunosuppression: 11% for kidney recipients; 3.5–38% for liver recipients; 7–50% for heart, lung, and heart-lung recipients; and 4.3–57.1% for intestinal and multivisceral recipients [26]. The incidence of adenovirus infections in allogeneic HSCT recipient ranges from 2.5% to 20%, with higher rates reported among the pediatric and T cell-depleted HSCT recipients [20]. Most clinically significant infections occur within the first 3 months post-transplant, though given the ubiquitous nature of the virus, adenovirus infections may occur anytime in the post-transplant period [27]. Early adenovirus disease post-transplantation suggests either endogenous adenovirus reactivation of latent virus or donor-derived infection. Serologic testing for adenovirus in donors and recipients as a risk stratification strategy is not routinely performed in clinical practice, as this is unlikely to alter patient management. Sporadic adenovirus infections occurring later in the post-transplant period are generally presumed to be primary infections. In general, distinguishing between primary and reactivation infection is not thought to be clinically relevant.

Clinical manifestations among transplant recipients demonstrate a spectrum from asymptomatic viral shedding to severe, disseminated disease. The gastrointestinal tract is the most common site affected, typically manifesting with fever (53%) and diarrhea (68%) [20, 26]. End-organ involvement may also manifest as respiratory disease with pneumonitis (21%), hepatitis, encephalitis, and/or hemorrhagic cystitis. Disseminated disease is defined as the involvement of two or more organ systems. Pancytopenia, particularly leukopenia, and thrombocytopenia are common, though rarely manifest as an isolated clinical finding. In allogeneic HSCT recipients, with the exception of hemorrhagic cystitis and gastroenteritis, end-organ disease is associated with a mortality rate of 20–44% [28–30]. There are isolated case reports of mortality associated with adenovirus infections among SOT recipients, suggesting a lower mortality rate as compared to HSCT recipients. However, localized allograft

infection in SOT may have a direct impact on immediate and long-term allograft function, particularly among lung transplant recipients [26].

Adenovirus disease is defined by the presence of attributable signs and symptoms combined with one or more positive adenovirus diagnostic assays. Diagnostic tests include the detection of adenovirus in tissue biopsy specimens by immunohistochemistry or culture, demonstration of viremia by blood PCR, and/or detection of adenovirus DNA or antigen from other body fluids such as cerebrospinal fluid (CSF), bronchoalveolar lavage (BAL) fluid, urine, or stool [26]. It is challenging to differentiate true adenovirus disease from asymptomatic viral shedding, which may occur for prolonged periods before and after clinical infection. Serology is of limited utility in the post-transplant setting due the prevention of antibody production in the immunosuppressed state. The primary approach to treatment is supportive care and a reduction in immunosuppression. Cidofovir is an option for the most critically ill, and a number of experimental therapies are in various stages of clinical development. Currently, there are no randomized clinical trials to guide an approach to adjunctive antiviral or immunoglobulin therapy [20, 26].

For a more extensive discussion of adenovirus epidemiology and management, refer to ▶ Chap. 32, "Transplant Adenovirus Infection: Clinical Syndromes, Diagnosis, and Management."

Human Herpesviruses 6 and 7

Human herpesviruses (HHV) 6 and 7 are closely related Betaherpesviruses that are typically acquired early in life, with the establishment of lifelong latency following primary infection. By adulthood, nearly 90% of individuals are seropositive for both viruses [31]. Latent HHV-6 is found in monocytes and macrophages, as well as bronchial, oropharyngeal, and salivary epithelial cells [27]. HHV-7 primarily infects CD4+ T cells [32]. Viral reactivation with associated lytic infection may occur in the setting of immunosuppression, usually within the first 1–2 months post-transplant [31, 32].

The majority of reactivation events in transplant recipients are asymptomatic. However, clinical syndromes, particularly for HHV-6, have been well described [31, 32]. In both HSCT and SOT recipients, HHV-6 reactivation manifests most commonly as a febrile illness associated with bone marrow suppression [33]. HHV-6 in HSCT recipients has also been implicated in delayed engraftment, graft loss, and the development of acute GVHD [34, 35]. The most concerning syndrome, typically only seen in heavily immunosuppressed HSCT recipients, is HHV-6-associated limbic encephalitis [36–38]. Clinical manifestations often include seizures, acute delirium, and memory deficits. MRI imaging characteristically shows medial temporal lobe enhancement with hippocampal area encephalitis. CSF can reveal a lymphocytic pleocytosis, and typically by this point the recipient is either viremic or has HHV6 detected in the CSF, or both. Encephalitis is a well-described entity in the HSCT population, but less common in the SOT setting. Hepatitis, enteritis, and pneumonitis have also been reported, although causality is hard to prove in these cases [31, 39, 40]. Clinically relevant HHV-7 disease is infrequently encountered in HSCT and SOT recipients, but has been reported to cause a nonspecific febrile illness

associated with thrombocytopenia and bone marrow suppression, particularly in children [41, 42].

The preferred diagnostic assay for both HHV-6 and HHV-7 is quantitative PCR of serum or plasma [43, 44]. PCR may also be used to quantify viral DNA from tissue, CSF, and BAL fluid specimens. While available through reference laboratories in North America and Europe, their availability elsewhere is limited. Interpretation is limited by the lack of assay standardization and validation, which prohibits the establishment of a threshold value for clinical significance [45]. Likewise, finding HHV-6/HHV-7 DNA in any specimen does not confirm causality, particularly since the majority of reactivation events in transplant recipients are not associated with symptoms [46, 47]. An infrequent but well-described phenomenon of chromosomally integrated HHV-6 should also be considered when interpreting HHV-6 viral loads. Suspicion for chromosomally integrated HHV-6 should be raised in the setting of extremely and persistently elevated HHV-6 viral loads that show minimal fluctuation over time, even with the administration of antiviral therapy [48, 49]. Recognition of this phenomenon is important in order to avoid unnecessary antiviral therapy in individuals who have persistently elevated HHV-6 viral loads but no clearly attributable symptoms. Hence, HHV-6 and HHV-7 PCR assays must be always be interpreted in the clinical context.

Antiviral treatment with ganciclovir, foscarnet, or cidofovir should be initiated in the setting of HHV-6 encephalitis. The evidence for administering antiviral treatment for other HHV-6 and HHV-7 syndromes such as bone marrow suppression is weak, but may be considered in the setting of viremia where symptomatic infection is plausible or failure of allo-HSCT engraftment is feared. The majority of reactivation events do not require treatment. For all cases of HHV-6 and HHV-7 viral reactivation, an adjunctive reduction in immunosuppression should be considered [31, 32].

Human Herpesvirus 8

HHV-8 is a DNA gammaherpesvirus that exhibits both latent and lytic phases. The virus primarily infects B cells and establishes lifelong latency. There is varied geographic prevalence of the virus with the highest seroprevalence in individuals from sub-Saharan Africa (>30–40%), followed by the Mediterranean (10–20%) and Asia/United States (<10%) [32, 50, 51]. Clinically apparent post-transplant HHV-8 infections are rare. For SOT recipients, incidence estimates range from <1% in nonendemic regions to 3–5% in endemic regions [31]. For HSCT recipients, data are more limited, but incidence estimates are <1%, with higher risk for allogeneic versus autologous transplants [52]. The majority of clinical HHV-8 infections in the post-transplant setting are presumed due to viral reactivation, though donor-transmitted infection through the solid organ has been observed [53–55]. A clear understanding of the epidemiology of HHV-8 infections in the transplant setting is limited due to the lack of routine pre-transplant serologic screening among donors and recipients, both in the SOT and HSCT populations. Individuals with HHV-8 infection may present with both infectious and neoplastic manifestations. Relevant to cytopenias, both HSCT and SOT recipients may present with cytopenias

concomitant with a spectrum of illness characterized by fever, maculopapular rash, splenomegaly, and hepatitis [31, 52]. In more severe cases, HHV-8 may progress to lymphoproliferative B-cell disorders, bone marrow failure, and hemophagocytic syndrome. Another HHV-8-associated syndrome, multicentric Castleman disease, is characterized by B-cell transformation to plasmablasts and associated with fevers, hepatosplenomegaly, and cytopenias [56, 57]. Kaposi's sarcoma is the most common HHV-8-associated neoplasm, and cytopenias are a less common clinical feature with this disease than with the aforementioned syndromes.

Transplant recipients and their donors who are living with HIV infection may be a unique population at risk for HHV-8 reactivation and disease. Higher rates of HHV-8 seropositivity occur in men with male sexual partners, individuals who are also at higher risk for HIV infection. Consequently as organ donation and transplantation among individuals living with HIV infection become increasingly accepted, clinicians should be mindful of the risks of HHV-8 syndromes, especially early in the post-transplant period when immunosuppression is greatest.

The diagnosis of HHV-8 syndromes is most definitively made with tissue biopsy of the involved site, with corresponding immunohistochemistry staining, in situ hybridization, and viral PCR [58]. Quantitative PCR of plasma and peripheral blood mononuclear cells can also be performed. Test interpretation is challenging due to lack of interlaboratory standardization and varying testing modalities, but may be helpful when interpreted within the clinical context.

As there are no controlled studies assessing the utility of antiviral therapy for HHV-8, these agents are not recommended in treatment. Management recommendations call for judicious reduction or cessation of immunosuppression [31, 52]. In the setting of Kaposi's sarcoma, early data indicate that the use of the mammalian target of rapamycin inhibitors (MTORi), sirolimus and everolimus, may also provide therapeutic benefit. In addition to the immunosuppressive properties of these agents, MTORi inhibit the growth of certain vascularized tumors. The mechanism is likely multifaceted, but presumed related in part to the drug's action of disrupting vascular endothelial growth factor production and activity, as well as impacting HHV-8-associated oncogenesis [59]. This approach may be particularly beneficial in the setting of transplant-associated Kaposi's sarcoma where preservation of allograft function is desired. In general, Kaposi's sarcoma treatment requires oncology consultation.

Epstein-Barr Virus (EBV) and Post-Transplant Lymphoproliferative Disorder

Post-transplant lymphoproliferative disorder (PTLD), a heterogeneous group of polyclonal and monoclonal lymphoid proliferations, is a well-recognized EBV-associated complication of both SOT and allogeneic HSCT [32, 60, 61]. Cytopenias of one or multiple cell lines may be a manifestation of PTLD as a consequence of marrow infiltration with monoclonal B cells, hypersplenism, and/or immune destruction. In addition, cytopenias result as a consequence of PTLD treatment.

Although the most feared EBV-associated disease after transplantation is PTLD, non-PTLD manifestations can also occur. Clinical features include an infectious mononucleosis type syndrome, organ-specific diseases such as hepatitis,

pneumonitis, and gastrointestinal symptoms and hematological abnormalities [60]. Specific hematologic findings include leukopenia, thrombocytopenia, hemolytic anemia, as well as hemophagocytosis. In severe cases, hemophagocytic lymphohistiocytosis (HLH) and macrophage activation syndrome may occur (discussed below). Clinical EBV-associated syndromes most commonly manifest in the early post-transplant period, often in the setting of enhanced immunosuppression. However, the timing of PTLD is more variable, spanning the entire post-transplant period [62].

Diagnosis of post-transplant EBV-related syndromes, including PTLD, includes interpreting EBV-specific diagnostic tests in the clinical context [60, 63]. Obtaining an EBV viral load in the blood is often the initial screening assay. This assay is most predictive of the risk of developing or having PTLD in individuals at highest risk, specifically EBV sero-mismatched recipients and possibly all intestinal transplant recipients. The diagnostic utility of EBV viral load testing is less established in adult SOT recipients who were EBV-seropositive pre-transplant, as elevated and often sustained viral load elevations have been observed and appear to be a poor marker of future PTLD risk [60]. Furthermore, serial EBV viral load measurements are of unclear value in tracking treatment success. The optimal assay type, interpretive diagnostic criteria, and monitoring algorithms remain uncertain. Interpretation of EBV viral load measurements in BAL fluid and CSF are even less well established. Serology is of limited utility except as a means to risk stratify and inform prevention strategies. Ultimately, diagnosis of EBV-associated PTLD requires biopsy of involved tissues and histopathologic evaluation, typically including RNA in situ hybridization targeting Epstein-Barr-encoded small nuclear RNA (EBER) [63]. Positron emission tomography-computerized tomography (PET-CT) is a useful adjunct for disease staging and assessment of treatment response [64].

Management of post-transplant EBV-related syndromes is multifaceted and depends on the specific clinical manifestations [60]. For non-PTLD EBV syndromes, the recommended initial intervention is a reduction in immunosuppression [65]. Many cases will resolve with this intervention alone. While this approach is also recommended in PTLD, it is combined with rituximab or cytotoxic chemotherapy and/or surgical resection [60, 66]. Adoptive immunotherapy using donor-derived or third-party EBV-specific cytotoxic T cells has been used successfully for the treatment of PTLD in allogeneic HSCT recipients, but experience is limited in SOT [67]. As there are no antiviral agents effective against EBV, their use is not recommended [68].

For a more extensive discussion of EBV epidemiology and management, refer to ► Chap. 27, "Epstein-Barr Virus and Posttransplant Lymphoproliferative Disorders."

Histoplasma capsulatum

Histoplasmosis is caused by the dimorphic fungus, *Histoplasma capsulatum*, which occurs in unique geographic niches in several areas worldwide. In the United States, the organism is endemic to the Ohio and Mississippi River valleys. The clinical spectrum of illness ranges from a self-limited febrile illness to severe multi-organ dysfunction, depending on the size of the host inoculum and immune status of the

host. Estimated incidence of histoplasmosis after SOT is <1%, with post-HSCT histoplasmosis limited to case reports and small case series [69–71].

The infection commonly presents in an occult, subacute manner among transplant recipients and is often disseminated at the time of diagnosis [69, 71–74]. Pancytopenia is a frequent manifestation due to decreased hematopoiesis and/or marrow infiltration and may be an important early clue to diagnosis (Fig. 1). Other associated findings include fever/constitutional symptoms, pulmonary infection, hepatosplenomegaly, liver function abnormalities, and gastrointestinal involvement. Confirmatory diagnosis can be made with direct visualization of *H. capsulatum* yeast forms in involved tissues and/or culture growth. Bone marrow aspirate cultures are often positive. However, cultures may take up to 4 weeks to demonstrate growth. A more rapid diagnosis is often made by antigen detection enzyme immunoassays. In the setting of disseminated disease, the newer-generation assays have a sensitivity of 97% and 89% in urine and blood specimens, respectively [73–75]. Lower sensitivity is observed in isolated pulmonary infection. Test specificity is limited by its cross-reactivity with other endemic fungi, notably 90% with *Blastomyces*. Cross-reactivity has also been reported with *Coccidioides* spp., *Paracoccidioides brasiliensis*, *Talaromyces marneffei*, and *Sporothrix schenckii* [75]. Serology has limited value in the post-transplant setting due to blunting of the serologic response in the setting of immunosuppression.

Despite the severity of illness upon presentation, treatment efficacy with systemic antifungal therapy is 80–100% among infected transplant recipients [72]. A concomitant reduction in immunosuppression is a typically employed adjunctive treatment approach.

Arrows highlighting multiple yeast forms demonstrating a central basophilic body, refractile capsule, and perinuclear clear zone (halo). (**b**) Grocott methenamine silver stain (50X) showing multiple densely staining yeast forms with rare budding and the characteristic "clusters of grapes" morphology

Mycobacteria

Mycobacterial infections are uncommon in SOT and HSCT recipients, but are associated with significant morbidity and mortality [76–80]. The true incidence of infection varies by geographic region and transplant type. For both *M. tuberculosis* and nontuberculous mycobacteria, disseminated infection occurs with higher frequency in transplant recipients than in their non-immunosuppressed counterparts. The timing of post-transplant mycobacterial infections is variable and reflects the intensity of the environmental exposure/inoculum and the underlying immunosuppression. Infections typically present subacutely, frequently with slowly progressive pulmonary and/or cutaneous manifestations. When the bone marrow is involved in disseminated infection, pancytopenia can result due to marrow infiltration with granulomas and decreased hematopoiesis. Bone marrow biopsy typically shows granulomas with acid-fast bacilli. Bone marrow and/or peripheral blood culture may be positive in disseminated disease. Cultures may take as long as 6–8 weeks before turning positive, and identification of the specific agent may take additional days [76]. There are limited data spanning over two decades on the performance of PCR and other molecular assays for the diagnosis of mycobacterial infections on bone marrow specimens [81–83]. However, among the multiple assays studied, the assays demonstrate variable sensitivity and specificity depending on the patient population, incidence of the disease, and specimen type (bone marrow aspirate versus core biopsy) tested. These factors, in addition to the cost and logistics of test validation, have limited their more widespread development to date. This is a promising area of investigation, however, as newer-generation molecular assays to diagnose mycobacterial infections become more mainstream. Treatment courses require multiple antimicrobial agents for a prolonged period, which are often poorly tolerated.

For a more extensive discussion of mycobacteria and their management, refer to ▶ Chaps. 18, "*Mycobacterium tuberculosis* in Transplantation"; ▶ 19, "Rapidly Growing Mycobacterial Infections in Transplant: Evolving Epidemiology and Treatment Options" and ▶ 20, "Slow-Growing Nontuberculous Mycobacteria in Transplant."

Drugs

Drugs are an important cause of cytopenias that can influence one or more cell lineages, with drugs accounting for 20–40% of all instances of cytopenias [84]. The proportion may be even higher in transplant recipients, particularly in the early post-transplant period, due to induction immunosuppressive therapy and intense maintenance immunosuppression. There are multiple mechanisms by which drugs may cause cytopenias, some of which are discussed in the sections of this chapter on thrombotic microangiopathy (TMA) and autoimmune disorders. However, the most common mechanisms in the transplant setting are cytopenias due to marrow suppression (decreased production) and/or increased destruction directly from the targeted cytotoxic agents. Identifying the culprit drug for a drug-induced hematological cytopenia lacks an evidence-based approach. Often, individuals are receiving multiple cytopenia-inducing agents that may potentiate the toxicity of any one drug. Most management decisions are based on clinical experience and the relative thresholds/risks of dose modification and/or drug discontinuation. In most instances,

cytopenias resolve with drug discontinuation. A summary of drugs commonly associated with cytopenias in the post-transplant setting is outlined in Table 3, with the more clinically significant drugs discussed below.

Immunosuppressive agents used in transplantation are commonly associated with hematologic derangements. Though antibody therapies have defined targets for their use as induction agents or for treatment of rejection, they are well known to be associated with collateral cytopenias. For example, rituximab, a chimeric anti-CD20 monoclonal antibody leading to B-cell depletion, has been associated with grade 3 or 4 cytopenias in 48% of patients (lymphopenia> neutropenia> anemia> thrombocytopenia) [85]. Likewise, alemtuzumab, a humanized monoclonal IgG1 antibody directed against CD52, is associated with a combined incidence of leukopenia and neutropenia of 47% and thrombocytopenia of 14% [85]. Antithymocyte globulin is less specific in its target, as despite its name the antibodies are directed against and cross-react with multiple blood cell types, resulting in a broad range of cytopenias of varying degrees based on the dose and duration of therapy. For HSCT recipients, the chemotherapeutic agents, methotrexate and/or cyclophosphamide, may be used in the early post-transplant setting for prevention of graft-versus-host disease (GVHD). Both drugs have known marrow suppressive effects. However, cyclophosphamide has a unique mechanism of action such that it can prevent GVHD without impairing engraftment [86]. Regarding methotrexate, doses administered in this setting are variable, but are generally lower than those standardly used for treatment of the underlying malignancy with less associated toxicity and minimal effect on engraftment [87, 88].

Agents typically used for longer term immunosuppression in both SOT and HSCT also are commonly associated with cytopenias and are frequently dose related [85]. Though the antimetabolites mycophenolate mofetil and azathioprine can lead to marrow suppression of all three cell lineages, leukopenia is the most common and pronounced. Dose reduction is a frequent management approach, particularly when use of other marrow suppression agents are more pressing from a clinical standpoint. The calcineurin inhibitors, tacrolimus and cyclosporine, have also been associated with cytopenias of all lineages. Tacrolimus, however, has been more frequently implicated for its hematologic (and other) adverse effects. Bone marrow toxicity associated with the two most commonly used MTORi, sirolimus and everolimus, is a well-known phenomenon. Anemia is the most common cytopenia and typically the most pronounced, but leukopenia and thrombocytopenia occur in 10–17%. Generally these occur within the first month of initiating therapy and are potentiated with concomitant use of other marrow suppressive drugs.

Several antimicrobial agents used routinely in transplantation for prophylaxis and treatment of infection are associated with cytopenias. The most pronounced toxicity among these agents is leukopenia, which can occur with ganciclovir/valganciclovir and trimethoprim-sulfamethoxazole (TMP-SMX), though multi-lineage suppression can occur with higher doses [10, 85, 89]. Linezolid is associated with bone marrow suppression, particularly thrombocytopenia, with longer durations of therapy (>10 days). The risk with tedizolid, the newer agent in the oxazolidinone class, appears to be less [90]. This is frequently a therapy-limiting issue in transplant recipients and a

DIHA drug-induced hemolytic anemia, *DIITP* drug-induced immune thrombocytopenic purpura, *HITT* heparin-induced thrombocytopenia with thrombosis, *WBC* white blood cell, *PCN* penicillin, *TCP* thrombocytopenia, *CTX* ceftriaxone, *MMF* mycophenolate mofetil, *AZA* azathioprine
[a]Includes alkylating agents, antitumor antibiotics, topoisomerase inhibitors, antimetabolites, and mitotic inhibitors

reason to avoid use of these agents early after HSCT. Dapsone-induced neutropenia has been reported, occasionally severe enough to result in agranulocytosis. Dapsone can also result in acquired methemoglobinemia. Beta-lactam antibiotics and TMP-SMX can cause hemolytic anemia [91]. Although vancomycin triggers drug-induced immune thrombocytopenic purpura or granulocytopenia infrequently per dose or per course, the cumulative and widespread use of vancomycin leads to many cases. It rarely occurs after the first dose, rather later in a prolonged treatment course.

While a comprehensive list of all drugs associated with cytopenias that are used post-transplant is beyond the scope of this review, and idiosyncratic reactions are possible with many drugs, other drugs to consider in the differential diagnosis of cytopenias include antineoplastic agents (multi-lineage cytopenias), colchicine (thrombocytopenia), and ACE inhibitors (anemia) [92–94].

Hemophagocytic Lymphohistiocytosis

Acquired hemophagocytic syndrome, also referred to as hemophagocytic lymphohistiocytosis (HLH), is an uncommon but life-threatening condition in the post-transplant setting typically associated with progressive and profound cytopenias. Mechanistically, HLH is characterized by an aberrant immune response of abnormal T-cell activation in response to a precipitating cause. As a result, the release of macrophage-activating, proinflammatory cytokines leads to uncontrolled proliferation of hemophagocytic monocytes/macrophages/histiocytes that ingest and destroy cellular blood elements within the bone marrow and reticuloendothelial system (Fig. 2) [95]. In the post-transplant setting, HLH is typically triggered in association with viral infections, such as EBV, CMV, adenovirus, HHV-8, and parvovirus B19. However, HLH associated with several bacterial, fungal, and protozoan infections has also been reported [95, 96].

The true incidence of post-transplant HLH remains unknown due to variable diagnostic criteria reported through the literature, overlap with other clinical syndromes, and underreporting of the disease. This is particularly true in the post-HSCT setting where conditions such as capillary leak syndrome, engraftment syndrome, cytokine release syndrome, and TMA may occur concomitantly [97]. Among the SOT population, the incidence is estimated to be <1%. For both the HSCT and SOT

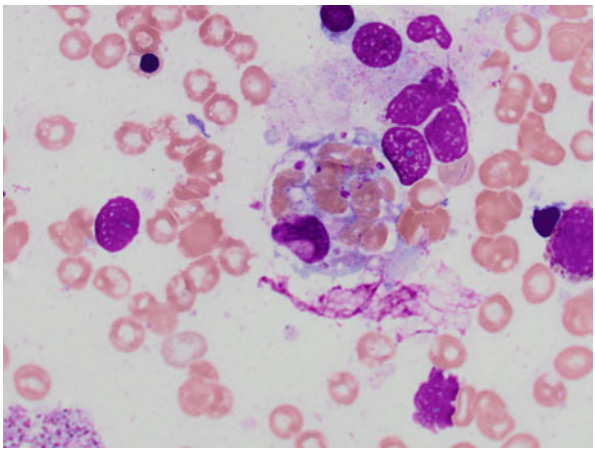

Fig. 2 Bone marrow aspirate (Wright stain, 100X) depicting an activated macrophage engulfing cellular blood components characteristically observed with hemophagocytic lymphohistiocytosis

populations, most cases of HLH occur within 2 months post-transplant, though cases occurring many years later have been reported [96–98]. The clinical features include fever, sweats, weight loss, hepatosplenomegaly, rash, jaundice with characteristic laboratory aberrancies including cytopenias (of two or more cell lineages), hyperferritinemia (>500 ug/L), hypertriglyceridemia, elevated lactate dehydrogenase (LDH), abnormal liver function tests, and hypofibrinogenemia [99]. Characteristically, soluble CD25 receptor (soluble IL-2 receptor alpha [sIL-2R]) is markedly elevated and now forms the backbone of diagnostic criteria, although this test is not widely available. Bone marrow aspiration and biopsy reveal large macrophages with intracytoplasmic erythrocytes, platelets, and leukocytes.

The primary approach to HLH management is the identification and treatment of the underlying driver of the uncontrolled hemophagocytic response, with targeted antimicrobial therapy and/or reduction of immunosuppression [96]. An array of adjunctive treatment approaches has been reported with varying success, but none have been subjected to randomized trials. Despite treatment, the mortality rate is approximately 50% in case reports and series among SOT recipients, with even higher mortality in HSCT recipients [97, 100].

Thrombotic Microangiopathy

Thrombotic microangiopathy (TMA) following SOT and HSCT is a well-recognized complication characterized by intravascular platelet aggregation, leading to thrombosis in the microcirculation with resultant thrombocytopenia and microangiopathic hemolytic anemia. Several risk factors have been identified for developing TMA. In HSCT recipients, risk factors include endothelial damaging conditioning regimens (including irradiation), GVHD, HLA mismatch, and angioinvasive viral and fungal infections [96, 101–103]. In SOT recipients, risk factors include antibody-mediated allograft rejection, severe renal ischemia (renal transplantation), and viral infections [96, 104]. For both populations, calcineurin inhibitors and/or sirolimus may exert a

direct toxic effect on the vasculature and lead to TMA independently, or potentiate established TMA precipitated by other causes. TMA typically manifests in the early post-transplant period, usually within the first 3 months. The incidence is variable, estimated in up to 35% of post-HSCT recipients, with a higher incidence among allogeneic versus autologous HSCT recipients [101].

There are no specific clinical features or laboratory abnormalities that define post-transplant TMA. The identified risk factors, proposed pathophysiologic processes, and clinical presentation are heterogeneous, which lead to a common end result of anemia, thrombocytopenia, and peripheral blood schistocytes (Fig. 3) [102]. Early in the clinical course, individuals often demonstrate hypertension, with neurologic abnormalities in more severe cases. Additional laboratory abnormalities may include elevated serum creatinine, LDH, bilirubin, and serum/urine free hemoglobin. Haptoglobin is usually decreased. These laboratory findings are typically used for diagnosis, as the history and exam manifestations are often nonspecific. Renal biopsy may help to confirm the diagnosis histologically, but renal involvement is not always present. Given the potential bleeding risk of the procedure and the lack of correlation between the laboratory and pathological findings, renal biopsy to diagnose TMA is rarely performed in clinical practice [101].

Management of post-transplant TMA primarily includes the withdrawal of suspected immunosuppressive agents if possible and assessment for a contributing infection. In severe cases, plasma exchange, rituximab, and eculizumab have been deployed with varying success [96].

Autoimmune Cytopenias

Autoimmune disorders, of which autoimmune cytopenias are the most common, are a challenging complication in the post-transplant setting. All cell lineages may be affected, either individually or in combination, with the most common being autoimmune hemolytic anemia, followed by immune thrombocytopenia. In HSCT

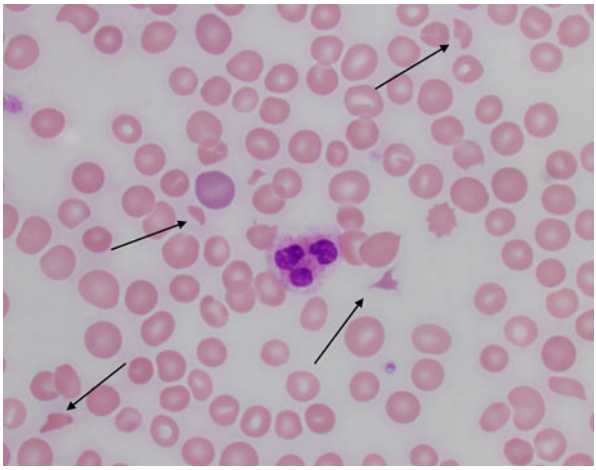

Fig. 3 Peripheral blood smear (Wright stain, 100X). Arrows highlight schistocytes as typically found in thrombotic microangiopathy

recipients, the incidence is estimated to be ~1–6% [101, 105, 106]. The strongest risk factors for the development of autoimmune hemolytic anemia (AIHA) include unrelated donor status, nonmalignant underlying disease, and chronic GVHD [107]. Among SOT recipients, immune cytopenias have been reported following liver, intestinal, heart, pancreas, and kidney transplants. Based on a single center review of 764 SOT recipients, immune cytopenias were found in 19 patients (2.4%), with the highest incidence identified in multivisceral transplant recipients [93].

In both HSCT and SOT populations, the etiology of cytopenias is often multifactorial, such that establishing an autoimmune component is a diagnostic challenge. Adding to the complexity, immune cytopenias may also be triggered by a preceding viral infection or manifest in conjunction with underlying PTLD [106]. Clinical findings range from asymptomatic laboratory abnormalities, to mild symptoms such as fatigue and/or easy bruisability related to the affected cell line, severe bleeding, neutropenic sepsis, and/or anemia. Hemolytic anemia is suspected if anemia is accompanied by an elevated reticulocyte count, LDH, and bilirubin, and unmeasurably low haptoglobin (particularly in the absence of recent RBC transfusion). An autoimmune etiology for the hemolytic anemia can often be confirmed by a positive direct antiglobulin test (DAT) with a broadly reactive RBC eluate. Less commonly, spherocytes are also seen on peripheral blood smear. Diagnosis of autoimmune thrombocytopenia and neutropenia is largely by exclusion of other etiologies in the appropriate clinical context [108]. The disease course is variable, ranging from spontaneous remissions to life-threatening complications. Furthermore, as the pathogenesis of these disorders is poorly understood, the treatment response to traditional first-line therapies and modifications of immunosuppression regimens is variable. In the post-HSCT setting, AIHA is associated with decreased survival [101].

Passenger Lymphocyte Syndrome

Though anemia following organ transplantation is a common finding, passenger lymphocyte syndrome (PLS) is a unique cause of hemolysis in the transplant population [108]. PLS is triggered when viable lymphocytes of donor origin are adoptively transferred as passengers with the allograft. These lymphocytes are then stimulated in the transplant recipient by exposure to recipient or transfused red cell antigens, either by primary or secondary (anamnestic) response, leading to red cell hemolysis.

This syndrome is typically observed in SOT in the setting of minor ABO or other red cell antigen incompatibilities between donor and recipient [95]. The risk and severity of this syndrome is proportional to the volume of lymphoid tissue transplanted, being more frequent in heart-lung transplant (around 70%), followed by liver transplant (~40%) and kidney transplant (~17%) [109]. Though PLS in intestinal transplant is limited to case reports, the association of this syndrome with the volume of transplanted lymphoid tissue suggests these recipients may be at even higher risk [110]. Additional risk factors include (1) blood group O to A transfer, (2) sensitizing events such as pregnancy and/or blood transfusions, (3) cyclosporine use, and (4) infection in the immediate post-transplant period [111]. The onset is typically

abrupt, occurring between 1 and 3 weeks post-transplant. Advances in the understanding of transplant immunology have allowed more successful ABO-mismatched organ transplants over time, thus the necessity of awareness of PLS as a potential complication of this practice. The degree of hemolysis is often mild and resolves spontaneously within a few weeks of SOT. However some cases require transfusion support during this period, and fulminant cases resulting in death have been reported. Diagnosis is made by the development of a positive direct antiglobulin test 7–14 days after transplantation and the presence of anti-A or anti-B in the RBC eluate (as well as in the plasma) [109].

While this syndrome can also be observed in the setting of HSCT, it is less common despite estimates that approximately 40–50% of all HSCTs are performed across the ABO blood group barrier. The introduction of reduced intensity conditioning regimens, however, has led to a higher incidence of PLS, up to 30% [112]. Assessing the independent incidence of PLS as separate from other etiologies of hemolysis and anemia in the post-HSCT setting is challenging, particularly with varying conditioning regimens and GVHD prophylaxis strategies. Immune hemolysis typically begins near the end of the first week or during the second week post HSCT. Manifestations may range from a gradual, mild drop in hemoglobin to abrupt, severe hemolysis with associated renal failure [108]. Graft manipulation to minimize isohemagglutinins prior to infusion can significantly lessen the clinical impact [113].

Laboratory findings are those typical of hemolysis, as described above. Leukocyte and platelet counts are unaffected. The process is usually transient and self-limiting, resolving without major complication in ~3 months due to the finite lifespan of passenger lymphocytes. Treatment is largely supportive with donor compatible transfusion, volume resuscitation, and/or steroids. Exchange transfusion can be considered in severe cases [95, 108–111].

Etiologies Unique to SOT: Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) after SOT results from the engraftment and proliferation of lymphocytes from the organ donor, which in turn attack HLA-disparate tissues in the transplant recipient. As compared to GVHD in the HSCT population, GVHD following SOT is rare. The risk correlates with the quantity of lymphoid tissues transplanted, with small bowel (5.6–19.2%) [114] and liver transplantation (1–2%) [115] posing the highest risk. The risk is additive in the setting of multivisceral transplantation [114, 116]. The lowest risk occurs in lung and kidney transplantation [117]. Other recognized risk factors include recipient age >65 years and a higher degree of HLA matching between donor and recipient. GVHD after SOT is regarded as an early complication with a median onset of 33 d post-transplant in a series of 30 cases [117]. Most cases manifest within the first 90 days after transplant.

The main clinical manifestations are similar to those seen in the more classic form of GVHD in HSCT, with involvement of the skin and GI tract. Unlike HSCT-associated GVHD, bone marrow involvement manifesting as pancytopenia is a

frequent finding [115, 116]. Cutaneous findings are the most common and occur in ~90–100% of reported cases. Skin eruptions appear early in the disease course, with a maculopapular exanthem being most commonly reported [118]. The triad of fever, diarrhea, and pancytopenia, especially when accompanied by a rash, warrants consideration of the diagnosis. The transplant allograft is generally spared given it is perceived as "self" by the offending donor lymphocytes. Diagnosis is often delayed as the findings are often attributed to other diagnoses such as viral infection or drug toxicity. Early skin and/or GI biopsy demonstrating lymphocytic infiltrates of the epithelium, apoptotic bodies, lymphocytic exocytosis, and cellular vacuolization are highly supportive of the diagnosis and can support interventions to mitigate the process. The diagnosis should also be investigated with an analysis for lymphocyte macrochimerism in the peripheral blood, bone marrow, and other affected tissues [115, 116]. Left unchecked, GVHD after SOT is frequently lethal, with mortality most commonly due to sepsis/infection and multi-organ failure in the setting of prolonged marrow aplasia [117]. A trial of high dose steroids has historically been the initial approach to treatment [114, 116]. In recent years, more novel approaches with biologic agents and extracorporeal photopheresis have also been used with varying success [116, 119].

Etiologies Unique to HSCT: Graft Failure

Graft failure as an etiology of cytopenias is an infrequent but often fatal complication of HSCT. Diagnostic criteria are based on established cell count parameters. It can be primary, often defined as the failure to surpass an absolute neutrophil count of 500/mm^3 by day 28 post-graft infusion [120, 121]. Secondary or late graft failure occurs in those individuals who satisfy criteria for initial engraftment but subsequently develop severe cytopenias of at least two cell lineages. Cytopenias of one cell lineage or milder cytopenias which are clinically significant following engraftment may be a sign of poor graft function. These may ultimately resolve with time or progress to late graft failure. Late graft failure is more commonly associated with allogeneic HSCT than with autologous transplantation [122]. The reported incidence of graft failure varies and is clearly dependent on the quality and quantity of transplanted cells. Among autologous HSCT recipients, graft failure approximates 1–3% [123]. Conversely, depending on the specifics of the transplant, graft failure among allogeneic HSCT recipients occurs in 2–20% [124–126]. Risk factors include host- and donor-related immune factors, increased donor and/or recipient age, recipient disease-related factors including previous treatment, pre-transplant conditioning regimen, post-transplant infections, post-transplant immune suppression regimens, nature of any HLA mismatch, and graft source/cell numbers infused [120, 121]. Additionally, graft failure may result from relapse of the primary disease for which HSCT was indicated, with acute leukemias and myelodysplastic syndromes portending the highest risk [120]. Mortality ultimately arises secondary to bleeding and/or infection.

Even when an allograft HSCT does engraft, and the overall leukocyte count normalizes, it is important to recognize that individual cell lines may normalize at

vastly different rates. For example, typically neutrophil recovery is comparatively early, whereas individual lymphocyte subsets can take many months to recover. Consequently, there are implications for the infection risk over time, with the recovery of granulocytes corresponding to a reduction in bacteremia and candida infections, whereas the ongoing functional lymphopenia results in persistent complex fungal and viral infection risk.

Overall, establishing the etiology of graft failure is complex as it is very frequently multifactorial [120]. Chimerism studies can be performed for monitoring in individuals at risk for allogeneic graft failure. The kinetic change of the proportion of donor cells over time is central to projecting subsequent graft function. Successful management of graft failure centers around preventive measures and early identification/treatment of potential reversible causes [121, 127]. In select individuals, lymphocyte infusion from the original stem cell donor, use of a CD34+ cell selected graft from the same donor without additional conditioning chemotherapy, or a second allogeneic HSCT can be offered [121, 128].

Approach to Diagnosis of Transplant-Associated Cytopenias

The differential diagnosis of cytopenias involving one or multiple lineages is broad. Transplantation introduces additional considerations for determining an etiology, particularly since the etiology of pancytopenia is often multifactorial in the post-transplant setting. As launching a workup for all possible causes in the transplant population is not feasible, it is important to consider key variables that will serve to guide the diagnostic workup.

Characterization of the abnormality: When cytopenias are discovered, it is important to confirm a true result to rule out laboratory error, hemodilution, or other exogenous event as an explanation for the finding. Once confirmed, review of the patient's complete blood count is needed to determine which cell lineage(s) are involved. In addition to reviewing the absolute leukocyte, hemoglobin, and platelet values, it is important to clinically assess the severity of the abnormality and the urgency with which intervention is required. Active and/or significant bleeding may be manifested with clinical findings such as tachycardia, pallor, petechiae, ecchymoses, and mucosal bleeding involving the GI, respiratory, and reproductive tracts. Leukopenia, especially with associated severe neutropenia, may be accompanied by fever, mouth ulcers, gingivitis, and sepsis.

Timing: An important aspect in determining the etiology of cytopenias is identifying the time of onset and the trajectory over time. Exposures, symptoms, and medication changes that occurred around the time of onset of the lab abnormalities can assist with prioritizing the differential diagnosis. The development of cytopenias in relation to the date of transplantation is similarly helpful (Table 1).

Associated clinical findings: A thorough assessment for additional history, physical examination, and laboratory findings can further refine the differential diagnosis. Important points from the patient history include medication use (including prescribed medications, obtained over-the-counter medications, and herbal

preparations), weight loss, seasonal association, travel, environmental exposures, and ill contacts. Adjunctive exam findings to note include skin rashes or lesions, hepatosplenomegaly, lymphadenopathy, and jaundice. The WBC differential and peripheral blood smear may provide useful clues with findings of atypical lymphocytosis, visualization of intracellular pathogens, malignant-appearing cells, and/or spherocytes or schistocytes associated with hemolysis. In addition, abnormalities of liver function tests, creatinine, ferritin, LDH, and/or triglycerides may aid with diagnosis.

Consideration for adverse drug effects: As drug-associated cytopenias are very common in the post-transplant setting, it is important to consider whether a drug effect may be causing potentiation of a nondrug etiology of cytopenia rather than the drug solely causing the abnormalities. For example, CMV can cause cytopenia directly, as can its first-line treatment, ganciclovir. As such, this provides an opportunity to manipulate the medication regimen through dose reduction or discontinuation to help clarify the clinical findings.

If, based on an assessment of the above factors, an infectious etiology of the cytopenia remains a consideration, the most important starting point is a detailed history and physical examination. This should include gathering detailed information about the patient's zoonotic, geographic, and other environmental exposures that may have been overlooked previously. Based on this information, opportunities for additional targeted diagnostic testing may become apparent. For example, obtaining a history of recent international travel in the setting of cytopenias and fever raises the possibilities of dengue fever, typhoid fever, malaria, and viral hepatitis. Seasonality is an important factor when considering the likelihood of tickborne infections such as Ehrlichia/Anaplasma and viral infections such as adenovirus, parainfluenza virus, and enteroviruses. Environmental exposure to excavated soil or construction sites located within the Ohio River Valley increases the possibility of histoplasmosis.

In cases where the preliminary workup is negative, the cytopenia(s) persist despite reducing or discontinuing marrow suppressive drugs, and/or a more expedient/aggressive workup is indicated, a hematology evaluation is recommended. Often a bone marrow examination will follow as the next diagnostic step to assess for marrow infiltrating lesions including neoplastic processes, hyper- or hypo-proliferative cytopenic states, and infection [129]. For HSCT recipients with pancytopenia, there is a low threshold to perform a bone marrow examination to assess for relapsed primary disease as an etiology for graft failure. There are limited data to assess the utility of bone marrow examination in SOT recipients. Two studies of 85 sequential kidney and 44 sequential liver transplant recipients undergoing bone marrow biopsy primarily for workup of cytopenias at a single center demonstrated nonspecific findings of normo/hypocellular marrow in 67% and 82%, respectively [130, 131]. Malignancy was diagnosed in 6/85 (7.1%) of renal and 1/44 (2.3%) of liver transplant recipients, and no infections were diagnosed. Aside from diagnosing relapsed primary disease in the setting of HSCT, unfortunately, the bone marrow examination is often inconclusive for determining the underlying cause of cytopenias in transplant recipients. However, it remains an important diagnostic step in the evaluation of challenging cases.

General Approach to Management of Transplant-Associated Cytopenias

The most important initial step in management of transplant-associated cytopenias is recognizing those conditions that are life-threatening and initiating prompt, aggressive interventions. The most important of these include life-threatening bleeding or hemolysis, HLH, and neutropenia-associated bacterial or fungal sepsis. Additionally, any of the aforementioned infections and/or autoimmune cytopenias may lead to acute complications requiring urgent interventions.

Life-threatening bleeding requires prompt intervention to control the bleeding source and provide supportive transfusion with red blood cells, platelets, and coagulation factors as the clinical picture dictates. In the absence of life-threatening bleeding, red blood cell transfusions are generally recommended when the patient is symptomatic from lack of adequate tissue oxygenation, which often but not always occurs when hemoglobin concentrations decrease to <7.0 g/dl [132]. In the setting of myocardial ischemia, severe hypoxemia or acute hemorrhage the actionable hemoglobin level for RBC transfusion is higher in order to minimize the risk of end-organ injury. Prophylactic platelet transfusion is indicated for platelet counts $\leq 10 \times 10^9$/L for stable patients, in the absence of acute bleeding. For the patient awaiting high-risk interventions such as tissue biopsy or surgery, higher targets are typically sought, for example, $>50 \times 10^9$/L [132]. In the setting of drug-induced or autoimmune hemolysis, life-threatening hemolysis in the acute setting can be managed with transfusion of incompatible blood, provided that the presence of underlying alloantibodies has been excluded. Whole blood exchange transfusion can also be considered in centers providing this service.

In the setting of leukopenia/neutropenia and suspected sepsis, expedient antimicrobial therapy and supportive care are paramount. Though there is no evidence that sepsis and septic shock require different treatment in neutropenic vs. non-neutropenic individuals, count recovery has historically been considered to be an important component of infection cure.

Granulocyte transfusions have a long history of usage in neutropenic patients with severe infections [133, 134]. In the 1960 and 1970s, granulocyte transfusions were limited by low cell collection yields and challenging cell storage issues. With the availability of granulocyte colony-stimulating factor (G-CSF) in the 1990s, larger granulocyte quantities were able to be mobilized from stimulated donors with increased ex vivo cell longevity [133]. Further, G-CSF-stimulated granulocytes demonstrate enhanced functional activity [135]. The utility of granulocyte transfusions has been studied in a variety of patient populations, predominantly those with neutropenia related to chemotherapy and/or stem cell transplantation. Despite demonstrated benefit in uncontrolled studies, the logistical challenges in procuring cells has meant this approach is infrequently used in clinical practice in adults [133]. Adverse recipient and donor reactions may contribute to the limited use, as do the logistics of the procedure and the relatively low granulocyte dose administered. Conversely, granulocyte transfusions present a better therapeutic option for children due their smaller size and the relative

higher granulocyte dose achieved with transfusion. Current guidelines for granulocyte transfusion include those individuals with temporary neutropenia ($<0.2–0.5 \times 10^9$/L) who have severe infections unresponsive to aggressive antibiotic treatment for >48 h [133]. In our experience in adult patients, granulocyte transfusions should be restricted to neutropenic patients with proven or suspected invasive infections, such as *Mucorales*, where standard therapies are poor and mortality is high. Overall, the quality of evidence to support routine granulocyte transfusions to reduce mortality and other adverse outcomes related to infection in individuals with neutropenia is low [136].

The use of the hematopoietic growth factors, granulocyte colony-stimulating factor (G-CSF), and granulocyte monocyte colony-stimulating factor (GM-CSF) for treatment of leukopenia in transplantation provides a more feasible option [137]. Among individuals with chemotherapy-induced neutropenia, numerous randomized controlled trials demonstrate that administration of these agents effectively reduces the time to neutrophil recovery and length of hospitalization [138]. G-CSF may also be administered in HSCT recipients in the setting of marginal graft function related to marrow suppression from a necessary medication, such as an antimicrobial or immunosuppressive agent. Although the routine use of these factors in the absence of infection is generally well tolerated in this population, respiratory deterioration with associated ARDS has been described with G-CSF−/GM-CSF-induced neutrophil recovery [132]. As leukopenia with associated neutropenia among SOT recipients is also a common occurrence, G-CSF treatment is often considered as a management option in this setting; however, data to support this approach are limited and conflicting. The exact immunomodulatory effects of G-CSF on the adaptive immune response and T-cell activity are not known. Specifically, there is concern its use will trigger allograft acute cellular rejection (ACR) [139–141]. Collective data indicate there is minimal risk of ACR in the liver and kidney transplant populations, but there are conflicting findings in heart and lung recipients [4, 5, 8, 139–142]. The majority of studies are retrospective, with differing patient populations, definitions of leukopenia/neutropenia, and G-CSF dosage regimens which limit comparisons across studies. In addition, concurrent medication adjustments, particularly with immunosuppressive regimens, are frequent and confound the findings. Despite data limitations, G-CSF is widely used in SOT recipients to allow for continuation and full dosing of myelosuppressive agents as deemed necessary for individual drug regimens.

There are varying thresholds for interventions to manage cytopenias based on the underlying transplant type and timing post-transplant. For cytopenia cases requiring less urgent intervention, a more methodical management approach is prudent. Particularly among transplant recipients, the underlying cause is often multifactorial and potentiated by concomitant medications which can often be modified as an initial approach. Quantitative or qualitative immune suppression modification, where the net state of immune suppression is enhanced, reduced, or the agent changed, is a common intervention. This step may be critical for determining an individual patient's subsequent course and requires careful consideration in a multidisciplinary context.

Conclusion

Cytopenias are a common occurrence in both HSCT and SOT recipients, particularly in the early post-transplant time period. The etiology is frequently multifactorial and potentiated by medications. Thorough evaluation of patient history, physical exam, and preliminary laboratory values can assist with prioritizing the differential diagnosis and focusing the diagnostic workup. Treatment approaches are commonly multifaceted, often requiring manipulation of immune suppression.

Key Points

- Transplant-associated cytopenias of variable spectrum and severity occur commonly among HSCT and SOT recipients. The etiology is frequently multifactorial.
- Both primary and reactivation infections, the most common of which are viral, may cause transplant-associated cytopenias due to bone marrow suppression and/or infiltration.
- Immune-mediated processes causing cytopenias, including those precipitated directly by host-graft interactions, present a diagnostic and therapeutic challenge in the transplant population.
- Medications often cause cytopenias alone or potentiate cytopenias due to other etiologies in transplant recipients. A patient's drug regimen provides a modifiable variable for intervention.
- Important factors which assist with prioritizing the differential diagnosis of an individual's cytopenia include the characterization of the abnormality, evaluation of associated clinical findings, post-transplant timing, and identification of potential environmental/drug exposures.
- The management of transplant-associated cytopenias foremost requires recognition of conditions that are life-threatening in order to facilitate prompt intervention. All cases are best managed in a multidisciplinary context.

Introduction

Pediatric transplant recipients have unique infectious risks compared to adult transplant recipients. Distinct challenges to pediatric providers include incomplete or missed primary immunizations, lack of primary immunity to common illnesses, inability to definitively determine infectious serostatus in infants, and recognition of pediatric-specific disease states. Further, the lack of pediatric indications and dosing data for antimicrobials as well as variations in pediatric pharmacokinetics and drug exposure target levels complicate treatment of infectious diseases in pediatric patients.

Vaccine-Preventable Diseases

As part of the pretransplant evaluation, vaccination history should always be reviewed. In the pediatric population, this is particularly important. Studies have shown that pediatric transplant recipients, particularly those less than 2 years of age, have a high rate of incomplete vaccination [1]. Pediatric recipients may be incompletely vaccinated pretransplant for a variety of reasons, including immunosuppressive therapy for primary illness, young age, and prolonged hospitalizations. Ideally, vaccines should be given at least 4 weeks, and no less than 2 weeks, prior to transplantation [2]. Vaccination schedules in the United States are updated yearly and can be found on the Advisory Committee on Immunization Practice (ACIP) website. Pediatric transplant recipients, especially those who have not completed their primary series of vaccinations, should be vaccinated using an expedited schedule to ensure they are fully vaccinated prior to transplantation. Because many transplant recipients may not be able to be vaccinated fully pretransplant, all healthcare workers and close contacts of transplant recipients should be fully vaccinated. All live-attenuated vaccines are safe for close contacts except for smallpox and oral polio vaccination [3].

Special Considerations in Pediatric Vaccination

Rotavirus

Rotavirus vaccine, a live attenuated vaccine, is typically started at 2 months of age; the first dose of vaccine cannot be given after 15 weeks of age and the final dose must be given by 8 months of age. Some infant transplant candidates may

miss the eligible window due to chronic illness. Those who require prolonged hospitalization after birth also typically miss out on rotavirus vaccination with concerns for active viral shedding 10–14 days after vaccination and theoretical risk for nosocomial transmission [4]; administration within a healthcare facility is typically avoided. However, newer data suggest that although viral shedding occurs, transmission in the hospital setting is unlikely, and this could be considered for hospitalized infants [5]. As children born with primary immunodeficiency who require hematopoietic cell transplant (HSCT) are not candidates for any live-attenuated vaccines, the rotavirus vaccination would be deferred for this patient population.

Measles

Measles, mumps, and rubella vaccine (MMR), another live-attenuated viral vaccine, is also currently not routinely recommended after solid-organ transplantation [2], although newer studies have shown that live-attenuated vaccines may be safe and effective in specific posttransplant populations [6]. The ability to safely pursue posttransplant immunization with live-attenuated vaccines is important because young children undergoing transplantation may not have received primary immunization with MMR prior to transplantation despite efforts to ensure accelerated vaccination schedules pretransplantation. Due to the increasing proportion of unvaccinated individuals that has resulted in decreased herd immunity, measles is reemerging globally in areas where it was previously determined eradicated. During outbreaks, it is best for transplant recipients to avoid high volume areas, particularly those who did not receive the MMR vaccination.

Varicella

Varicella remains a common cause of infection in pediatric patients posttransplant [7]. Live-attenuated varicella vaccination is approved as early as 9 months of age, but many infants are still unable to receive this vaccination pretransplant [3]. A recombinant, adjuvated zoster vaccine (Shingrix, GSK, Philadelphia, PA) has been approved for people over 50 year of age, but no studies have been performed in pediatrics.

Human Papillomavirus

Many pediatric transplant recipients are too young to receive adolescent vaccinations such as the human papillomavirus (HPV) vaccination pretransplantation. One in four Americans will be infected with HPV within their lifetime, causing an increase risk cervical, anal, penile, and oropharyngeal malignancies. Transplant recipients have a significantly increased incidence of HPV-related malignancy making vaccination a

priority in these patients [8]. Although a two-dose series is acceptable in many children ages 9–14 years, a three-dose series is recommended for all children with immunocompromising conditions, regardless of the age. A study in 50 adult recipients vaccinated with four-valent HPV vaccine posttransplantation showed a lower vaccination response compared to healthy controls [9]. However, another study in 20 adolescent liver and kidney recipients vaccinated similarly showed no difference in vaccine response compared to controls [10]. More studies are needed to understand variations in immunogenicity in transplant patients. Given concern of possible decrease immunogenicity of vaccine and increasing risk of malignant transformation, the American Society of Transplantation recommends regular screening, including annual cervical and anal Papanicolaou (pap) smear, starting at 21 years of age [11].

Influenza

Influenza is another important infection in patients posttransplantation. In a study of pediatric liver transplant recipients, influenza was the most common vaccine preventable disease that causes hospitalization [12]. Data suggest that influenza vaccine has decreased immunogenicity in posttransplant recipients compared to healthy controls [13, 14]. The optimal influenza vaccination dosing strategy in pediatric HSCT recipients posttransplant is uncertain. All children under 9 years of age who have not received prior influenza vaccination are recommended to receive a two-dose series. A repeat of the two-dose series in the first season after HSCT in pediatric recipients under 9 years of age may be considered with potential loss of imprinting during the HSCT process. Some experts also consider giving a second dose of influenza vaccine outside this age range [15]. If pediatric SOT recipients might benefit from multiple doses is unknown.

Additional Age-Specific Considerations

Age-specific vaccine requirements may prevent administration of vaccines pretransplant when children are likely to have the best immune response. Posttransplantation, children may not be able to receive vaccines that protect against diseases for which they are at increased risk. For example, children undergoing solid organ transplant are at increased risk for *S. pneumoniae* infections [12]. Currently two vaccinations are on the market for *S. pneumoniae*, including 23-valent polysaccharide vaccine (PPSV23), which elicits a T-cell independent response and 13-valent protein-conjugated vaccine (PCV13), which induces a T-cell dependent response. In general, PCV13 tends to have a higher response; PPSV23 covers 10 additional strains of *S. pneumoniae* and therefore both are recommended for protection. However, currently the 23-valent polysaccharide pneumococcal vaccination (PPSV23) is only approved for children >2 years of age.

Hepatitis A vaccine is recommended for children with chronic liver disease but only licensed for children >12 months of age, so infants with chronic liver disease

(e.g., biliary atresia) awaiting transplant remain unvaccinated. Increasing use of eculizumab, a monoclonal antibody directed against C5 in the complement cascade, as an immune modulator in transplant recipients increases the risk of encapsulated organisms including meningococcal disease. Meningococcal vaccines are recommended for patients receiving eculizumab; meningococcal ACWY vaccine should be given down to 2 months of age in all high-risk individuals, however, the current meningococcal B vaccines are not licensed in the United States in children <10 years of age. Canadian and European labeling demonstrate safety and immunogenicity data down to 2 months of age for Bexsero (GSK).

Common, Non-Vaccine-Preventable Infections

Many children undergoing transplantation lack primary immunity to common, non-vaccine-preventable pathogens. By adulthood, immunity to such pathogens, including non-influenza respiratory viruses, cytomegalovirus (CMV), and Epstein-Barr virus (EBV), is common. Thus, compared with adults, children have increased susceptibility to these pathogens since primary infection typically occurs after, rather than before, transplantation. When primary infection occurs, children are on immunosuppressive therapies that not only limit their ability to respond to the current infection but also inhibit development of memory responses that protect against future infections. Although primary infection with respiratory viruses typically occurs in the first 2 years of life, many infants undergoing transplantation, e.g., those with cardiomyopathy or liver disease, have been frequently or chronically hospitalized since birth, thus limiting their exposure to pathogens. Young children and adolescents who are CMV and EBV negative are at high risk of primary infection both from donor positive grafts and community exposures in daycare and school. The unique aspects of these infections, including aspects of preventative measures in pediatrics, are discussed in further detail.

Respiratory Viral Infections

Solid Organ Transplants

The burden of respiratory viral infections (RVI) in the pediatric solid organ transplant (SOT) population is significant. A retrospective study, which including 1,096 children at 9 pediatric hospitals, reported that 149 (14.5%) children had ≥ 1 RVI in the first year posttransplant. Rhinovirus (RV) (51.6%) was the most commonly detected virus, followed by respiratory syncytial virus (RSV) (25.2%), parainfluenza virus (PIV) (18.2%), human metapneumovirus (HMPV) (12.6%), and influenza (11.9%). RVI rates varied based on the graft: multivisceral (45.5%), intestine (30%), heart (18.3%), lung (16.7%), liver (15.6%), and kidney (5.5%). Although children were followed for 1 year post-SOT, the majority of initial RVI occurred during the first 100 days. Children with RVI were significantly younger than those without an RVI (median age 1.7 years vs. 7.9 years, $p < 0.001$), highlighting the

increased susceptibility in infants and toddlers. Children with RSV and RV required respiratory support in 33% and 30% of cases, respectively, and children with these viruses also had the highest rates of ICU admission (RV: 33% and RSV: 28%). Lower respiratory tract infection (LRTI) at initial presentation occurred in 56 (35%) children. Mortality within 3 months post-RVI was uncommon, 4.4%. Of the seven deaths, one was likely attributed to RSV and one was possibly attributed to PIV. Rates of subsequent pulmonary complications occurred in nine (5.7%) patients [16].

In a cohort of pediatric lung transplant recipients, 28 (51%) developed an RVI, with 41% of infections occurring in the first 90 days. RV was the most commonly detected virus, and young age was identified as a risk factor for any RVI. Three (5.5%) children died secondary to RVI (two with adenovirus and one with RSV). Interestingly, RVI was not associated with chronic rejection or death, unlike adult literature [17].

Although rates of influenza infection were among the lowest hospitalized RVI, solid organ transplant patients remain at high-risk for complications. In a cohort of pediatric liver transplant patients, influenza-related hospitalizations occurred in 5.6% of patients, with 16.1% occurring during the transplant hospitalization and 63.6% occurring in the first year posttransplant. One-quarter of influenza-infected patients required intensive care unit management, and three deaths occurred (case-fatality rate 2%). In the same cohort, RSV was more common than influenza with 6.2% of all patients. Over 50% required intensive care unit management, and the case fatality rate was 4.4% [7].

Hematopoietic Cell Transplants

Pediatric HSCT patients have higher rates of RVI than pediatric SOT patients. In a retrospective cohort of 9 centers, 259/1560 (16.6%) children who underwent HSCT developed 307 RVI within the first year post-HSCT. Similar to children undergoing SOT, children with an RVI were younger than those without an RVI (4.8 vs. 7.1 years, $p < 0.001$). Interestingly, the overall incidence of RVI was not significantly different between autologous (14.2%) and allogeneic (17.4%) HSCT. Initial RVI occurred a median of 56 days post-HSCT, and RV was the most common pathogen identified. Pathogen epidemiology in this population was similar to pediatric SOT: RV ($n = 162$, 62.5%), PIV ($n = 53$, 20.5%), RSV ($n = 40$, 15.4%), influenza ($n = 29$, 11.2%), and HMPV ($n = 17$, 6.6%). Although most patients (72%) had upper respiratory tract infection, some pathogens, particularly HMPV, were more associated with LRTI, which was identified in 59% of HMPV-infected children. Although need for respiratory support (14%) and ICU management (5%) were less common than in pediatric SOT patients, HMPV was associated with significant morbidity with 35% and 12% of HMPV cases required respiratory support and ICU admission, respectively. Twenty-eight (11%) of children died within the first year post-HSCT, and 50% of those cases were considered to be likely or possibly attributable to the RVI event. The majority (82%) of deaths occurred within the first 60 days after the RVI event. The highest all-cause fatality rate (24%) occurred in children with HMPV, highlighting the significant morbidity and mortality associated with this pathogen

in pediatric HSCT patients [18]. Other studies have highlighted the morbidity associated with RSV in pediatric HSCT patients.

Detection of respiratory viruses pre-HSCT is problematic. In a large cohort of pediatric and adult HSCT patients, children were more likely to have a respiratory virus detected prior to HSCT (46% vs. 23%, $p < 0.001$). HSCT delay is typically pursued when RVI pre-HSCT occurs. Children have higher rates of asymptomatic respiratory virus detection pre-HSCT compared with adults (31% vs. 6%). Although symptomatic RVI pre-HSCT has been associated with worse outcomes, with deaths described in two children, one each with pre-HSCT adenovirus and HMPV, the role of asymptomatic shedding remains unclear. Asymptomatic shedding of respiratory viruses pre-HSCT may be associated with decreased time out of the hospital but not increased mortality or need for bronchoscopy although this is extrapolated from primarily adult data [19].

Preventative Strategies

Despite the burden of RVI in both pediatric HSCT and SOT patients, limited prophylactic and therapeutic agents are available. The use of palivizumab, an RSV monoclonal antibody targeting the fusion protein, is licensed for children at high-risk of hospitalization due to RSV infection. Currently, the American Academy of Pediatrics recommends consideration for the use of palivizumab for children <2 years of age undergoing cardiac transplantation during the RSV season. Consideration for use is also recommended for others of the same age who are "profoundly immunocompromised during the RSV season." [20] Further specifications regarding the degree of immune suppression are not available, and therefore, palivizumab use if highly variable in the transplant setting. A survey of pediatric SOT centers from 2005 to 2006 highlighted this variation, and 10% of respondents noted that they extended prophylaxis in children >24 months. Additionally, some centers reported administering prophylaxis to transplant candidates. Importantly, only about 65% of transplant centers reported receiving third-party reimbursement or medical assistance for palivizumab, which highlights the significant cost burden associated with prophylaxis. Centers reported a decreased rate of RSV infection in children who received prophylaxis compared with those who did not receive prophylaxis (4% vs. 11%), $p = 0.03$ [21]. Similarly, wide variation was noted in a survey of pediatric lung transplant centers: 10/17 offered prophylaxis to transplant candidates while 9/17 offered it to recipients. While all centers used palivizumab for prophylaxis, the specific criteria varied widely based on age with some centers following national guidelines and others using local and institution guidelines [22].

Recent data suggest that the morbidity associated with RSV in both the SOT and HSCT population may not be as high as previously suspected. In a retrospective single-center study of 10 SOT and 7 HSCT pediatric patients with RSV detected as an outpatient, 20% and 40%, respectively, required hospitalization. However, overall disease was not severe with no child requiring ICU admission [23]. A survey of Canadian pediatric transplant centers reported that 25% of RSV cases were managed in the outpatient setting although 29% of children did require ICU management. Interestingly, 43% of cases were nosocomial, suggesting that improvement in

infection control practices, as opposed to palivizumab, may be the most favorable, and cost-beneficial, to prevent RSV disease in transplant patients [24]. Identification of select risk factors may be beneficial to targeting prophylaxis. In a cohort of pediatric liver transplant patients, both age < 2 years and multivisceral transplants were significantly associated with RSV-related hospitalizations [7]. One hospital which instituted restrictive criteria for palivizumab use in pediatric HSCT patients (i.e., children <12 months with need for chronic oxygen children with severe combined immunodeficiency pre-HSCT or within the first 100 days post-HSCT), did not note an increased risk of RSV disease [25]. Thus the target population for palivizumab and the cost-efficacy remain unclear.

Cytomegalovirus

Primary CMV infection typically occurs in childhood, so children undergoing transplant are often CMV-negative recipients. Thus, they are at risk for development of primary disease posttransplant, either from the graft or typical exposures, including daycare. CMV-negative children undergoing HSCT are at risk of primary CMV infection after transplant. CMV-positive children undergoing HSCT are at risk for CMV reactivation, particularly those who receive CMV-negative grafts or grafts with T-cell depletion. Cord blood transplants are more commonly used in pediatric transplants compared with adults, and these grafts lack CMV-specific T-cells.

For CMV-negative children undergoing SOT, those that receive CMV positive grafts are at highest risk for the development of subsequent DNAemia and potentially disease. CMV negative children who receive CMV negative grafts remain at risk for primary infection. In one study, 6.6% of pediatric SOT recipients (D−/R-) developed primary CMV infection within the first year post-SOT [26]. Primary infection often occurs during childhood, so CMV negative children are at high risk for primary acquisition of the virus, even if a negative donor is used. Lastly, the correct designation of recipient status is difficult in children <12–18 months of age as antibody positivity may be reflective of maternal status. In these cases, recipient status is typically not known and should be assigned to the highest risk class based on the donor, as discussed further in the diagnostics section.

CMV can be a devastating disease in children. In a cohort of pediatric small bowel transplant recipients, 7/98 (7%) developed CMV disease despite prophylaxis. Those with disease had an 11-fold increased risk of death although only 1/7 deaths was attributed to CMV [27]. Interestingly, CMV negative children undergoing HSCT from a CMV negative donor had an increased risk of relapse (3.15, 95%CI 1.46–6.76) [28].

Although CMV has been associated with graft function decline in pediatric renal transplant recipients, the association of CMV with other infections, rejection, and graft dysfunction in the pediatric population is lacking compared with adults. Pediatric dosing of valganciclovir is complex. Traditional weight-based dosing is no longer recommended outside of congenitally infected infants. The more complex body surface area dosing is suggested including for prevention of CMV down to

4 months of age and may more accurately represent adult pharmacokinetics [29]. Compared with adults, the duration of recommended CMV prophylaxis, either with ganciclovir or valganciclovir, in children is slightly shorter with recommendations for close monitoring of DNAemia and disease [30].

New pharmacologic agents are being studied for the prevention of CMV and treatment of resistant disease. However, pediatric data for these agents is limited. In particular, letermovir, which is increasingly being studied and used prophylactically in adults undergoing HSCT and SOT, has a lack of pediatric dosing data. Similarly, the use of maribavir, for CMV-resistant infections, has not been not well studied in the pediatric population. Thus, pediatric practitioners rely on preemptive surveillance or prophylaxis with older, and often more toxic, agents to prevent CMV infection. Identification of CMV resistant disease often results in the use of multiple agents with significant toxicities.

Epstein-Barr Virus

Many children undergoing transplantation have not had exposure to primary EBV, and rates of seroconversion during childhood are higher than CMV. In a large cohort of children from Minnesota, only 31% of children ages 1–5 years were EBV positive, but by age 15–19 years, 71% of children were seropositive. Importantly, significant variations in EBV antibody seropositivity by race and ethnicity occurred. White, non-Hispanic children were less commonly (26%) antibody positive compared with Black children (74%) [31]. The differing rates of antibody positivity suggest that the risk of primary infection is significantly higher in some groups, which is important to acknowledge in children undergoing transplant. Similar to CMV, antibody status in children <12–18 months may reflect maternal serostatus, rather than pediatric immunity, so expert opinion recommends considering seropositive children <18 months to be seronegative for risk stratification purposes.

EBV seronegative children are at high risk for primary infection posttransplant. In a cohort of EBV seronegative children undergoing renal transplant, 50/103 (48.5%) developed primary EBV compared with 40/201 (19.9%) of seropositive children. Both EBV seropositivity and age > 14 years at the time of transplant were associated with lower risk of developing EBV infection, highlighting primary disease risk in young, seronegative children [32]. Seroconversion in EBV negative kidney transplant recipients occurred a median of 7.3 months posttransplant, suggesting that primary infection occurs in the early posttransplant period [33]. Primary EBV infection may be asymptomatic, and in a cohort of pediatric renal transplant patients, 42% of children <5 years with primary EBV infection were asymptomatic compared with 26% of children ≥12 years [34]. Therefore, intermittent screening for EBV DNAemia may be important in seronegative children.

Posttransplant lymphoproliferative disorder (PTLD) is one of the major causes of EBV-associated morbidity and mortality. Children have higher rates PTLD than adults, likely related to higher rates of EBV seronegativity and risk of primary infection posttransplant. The highest rates of pediatric PTLD occur in children

undergoing lung/heart-lung transplant (4% in the first year and 16% by 5 years) and small bowel transplant (14%) in all children, regardless of EBV serostatus [35]. The relationship between EBV serostatus and development of PTLD has been well described, and EBV seronegativity is a well-described risk factor for development of PTLD [35]. In a cohort of pediatric renal transplant patients, 7/10 (70%) patients who developed PTLD were seronegative at the time of transplant [32]. Among pediatric heart transplant recipients, EBV seronegative patients were also at high risk, with up to 25% developing PTLD [36].

Age at the time of transplant, likely related to the development of primary EBV infection, is another important factor when evaluating PTLD risk. In a multivariate analysis of a cohort of pediatric renal transplant patients, those $\leq$5 years and EBV D+/R- were more likely to develop PTLD (relative hazard: 3.2, $p = 0.03$ and 7.7, $p = 0.01$, respectively) [37]. However, another study of pediatric renal transplant patients with primary EBV infection demonstrated that the highest rate, 63.6%, of PTLD occurred in adolescents $\geq$12 compared with an overall rate of 24% in all children [34]. Among children undergoing liver transplant, age $<$ 1 year and EBV seronegative status at the time of transplant were risk factors for PTLD (relative risk 13.3, $p = 0.002$) [38]. In pediatric heart transplant recipients, the highest rates of PTLD occurred in children transplanted at 1–10 years of age [36]. Interestingly, data from pediatric renal and liver transplant patients identified that EBV seronegative children were more likely to have chronically high viral loads than their seropositive counterparts, but the presence of high viral loads did not correlate with subsequent development of PTLD [39, 40].

Emerging Infections

Transplant patients may be the "canary in a coal mine" for emerging infections due to their immunosuppressed status. Similarly, pediatric patients are a unique cohort in whom many emerging diseases are initially identified. Providers who care for pediatric transplant patients need to recognize diseases that are unique or have unusual manifestations in pediatric patients, which may have an exacerbated presentation in pediatric transplant patients. Herein, we provide a few select examples of such diseases.

Enterovirus D68

Enterovirus D68 (EV-D68) is an emerging virus that can cause significant disease in the pediatric population. The majority of patients are previously healthy, but children can present with significant respiratory distress. It is not known whether the virus may be exacerbated in transplant patients. In a large cohort of 614 patients, of whom $>$90% were children, only 2% of patients were noted to be immunocompromised [41]. In a cohort of adult HSCT patients, symptoms associated with EV-D68 ranged from mild disease managed in the outpatient setting to death associated with

respiratory failure [42]. Given the significant respiratory distress described during EV-D68 epidemics, this may be a severe pathogen in pediatric lung transplant patients, which given the predilection for school-aged children, may be more commonly seen in pediatric patients than adults. No specific treatment is available, but aggressive management of bronchospasm may be needed.

Acute Flaccid Myelitis

Acute flaccid myelitis (AFM) is an emerging disease with increasing rates biennially [43]. The majority of cases are reported in pediatric patients. In a large study of 120 cases in patients $\leq$21 years, only one patient had a transplant history (cardiac) [44]. At least two cases adult transplant patients with AFM have been reported, including one HSCT and one renal transplant patient. EV-D68 was identified from both patients, one from a respiratory specimen and one from CSF [45, 46]. Although the relationship between AFM and EV-D68 remains unclear, it is possible that persons who are immune suppressed may be more likely to have unusual manifestations of EV-D68. Both AFM and EV-D68 represent examples of diseases in which pediatric transplant practitioners may identify new diseases prior to the emergence in adults.

Arboviruses

Emerging diseases, such as arboviruses, have been described in the general pediatrics population although pediatric transplant data are limited and often extrapolated from adult transplant data. However, these infections may have distinctive presentations in pediatrics that have unique implications for transplant patients. For example, Zika virus was initially identified due to congenital abnormalities in newborns because only a mild illness occurred in adults. Although cohorts of adult transplant patients with Zika infection have been described, the implications of transplanting infants and children with Zika virus are not known. Similarly, less data are available for emerging arboviruses in pediatric transplant patients. Existing literature suggests that dengue can be severe in the pediatric transplant patients although there is a paucity of literature for other viruses, e.g., chikungunya and West Nile Virus [47].

Diagnostic Testing

Determination of Serostatus

Diagnostic testing in pediatric patients presents additional issues compared to adults. Infants present a unique problem when determining presence of prior infection and risk for future infection. During the third trimester of pregnancy, infants receive

passive transfer of maternal antibodies that provide protection for the infant in the early antenatal phase. These antibodies can be detectable for up to 15–18 months after birth, although a recent study suggests that maternal cytomegalovirus (CMV) antibodies clear by 12 months of age [48]. Assigning pretransplant serostatus to predict risk of posttransplant events, specifically for EBV and CMV, is therefore complicated by confounding by maternal antibody [30, 49]. This ambiguity can complicate the interpretation of serology from both the transplant candidate and the potential donor if they are under 12 months of age. For CMV, serostatus positivity can be confirmed by detection of viral shedding in the urine, blood, or oral secretions. Recently, Burton et al. showed that 30–50% of infants with positive serology also had positive viral culture or PCR with increasing positivity correlating to increasing age; thus confirming CMV infection in a significant proportion of transplant candidates [48]. However, a negative test does not exclude prior infection as shedding can be intermittent in candidates, and CMV viral PCR testing is not routinely performed in potential donors. Additionally, attempts have been made to assess CMV status through detection of CMV-specific T-cells but testing under 12 months of age has not been reliable [50]. Due to this specific difficulty in ascertainment of CMV serostatus in infant donors and recipients, it is currently recommended that risk assessment in this age group should assume the highest risk level for purposes of CMV prevention [30]. Infant serology for Epstein-Barr virus (EBV) also suffers from similar issues; however, limited information of EBV PCR testing and EBV-specific cellular immunity in this infant transplant candidates exists.

Clostridioides Difficile

A second issue with diagnostic testing in pediatric patients concerns assessment of *Clostridioides difficile* (previously *Clostridium difficile*) infection (CDI). The incidence of hospitalizations in children secondary to CDI infection has increased over the past two decades [51], and pediatric SOT recipients are increased risk for CDI infection compared to immunocompetent children [52]. Additionally, up to 24% of pediatric SOT with diarrhea will have positive testing for CDI [53]. With the increased utilization of nucleic acid amplification testing (NAAT) that detects genes encoding *C difficile* toxins, the sensitivity of testing has increased [54]. The primary issue is that *C difficile* including toxigenic strains are normal commensal organisms excreted by infants. The proportion of infants excreting toxigenic organisms decreases from 35–40% in the first month of life to approximately 10% by 12 months of age. Further, resolution of diarrhea in a cohort of children under 2 years of age occurred independent of whether the children received therapy or did not underscoring the likelihood that positive testing in this age group does not accurately predict active invasive infection [55]. The increased incidence of loose stools in infants coupled with the impact of certain immunosuppressive medications such as mycophenolate mofetil further complicates the interpretation of testing. In fact, the 2017 Infectious Diseases Society of America Guidelines on CDI recommend against testing for CDI for infants under 2 years of age unless other infectious and noninfectious etiologies have been excluded [54]. Therefore, pediatric-

specific understanding to interpret infectious-disease related testing is essential in the transplant population.

Unique Aspects of Antimicrobial Therapy for Pediatric Transplant Patients

Lack of Antimicrobial Dosing Data and Indication in Pediatrics

Although new antimicrobial agents are on the market for multidrug-resistant organisms (MDRO), a paucity of pediatric literature exists despite the fact that children are susceptible to multidrug-resistant pathogens. Since these drugs are generally not studied in pediatrics, limited pharmacokinetic (PK) and adverse effect data are available in the pediatric population. Pediatric exclusivity (PE), which provides financial incentives through market protection to drug companies for performing pediatric specific studies, encourages clinical trials to obtain some additional PK and safety data that may not otherwise be obtained. Of the 25 infectious diseases drugs that underwent pediatric trials for PE, 7 had dosing changes and 6 had new or enhanced safety concerns identified, highlighting the importance of studying antimicrobial agents in pediatrics [56]. Despite these incentives, pediatric trials are generally performed well after the completion of adult trials.

Although children remain at risk for MDRO, newer drugs that target these pathogens have limited pediatric data. Population PK analyses have provided suggested dosing data for ceftolozane/tazobactam [57] and ceftazidime/avibactam [58], the latter of which has a labeled indication for intra-abdominal infections and complicated urinary tract infections in children $\geq$3 months. Fidaxomicin has a similar PK profile in children and adults and may be efficacious but does not have a pediatric indication at this time [59]. Pediatric data for letermovir is not yet available.

Additionally, the lack of medications approved may affect the ability to accept organs for some pediatric patients while awaiting information about dosing and side effects specific to pediatric patients. One example relates to the use of HCV positive organs which is expanding rapidly in adult solid organ transplantation [60, 61]. With the approval of direct acting antiviral therapy for HCV (DAA) including pan-genotypic agents, cure of HCV in solid organ transplant recipients is possible allowing for the use of HCV+ organs to expand the donor pool and decrease wait-list mortality. DAA are currently only approved as young as 12 years of age with approval received in May 2019 for pan-genotypic agents. This prohibits many pediatric transplant recipients from potential access to these organs as appropriate DAA dosing and documentation of HCV cure is uncertain.

Variations in Pediatric Pharmacokinetics

The importance of obtaining pediatric PK data is highlighted by both variation in PK from children to adults but also within the pediatric population. Children require

higher doses of voriconazole in order to meet recommended troughs, and significant interindividual variability occurs, particularly in younger children [62]. Similarly, daptomycin is cleared rapidly in young children [63], and higher doses are recommended in children <12 years. Glomerular filtration maturation throughout childhood influences vancomycin dosing, and attainment of recommended goal troughs can be difficult in young children. Higher vancomycin dosing (15 mg/kg/dose every 6 h) is recommended in children with invasive methicillin-resistant *Staphylococcus aureus* infections in order to achieve a target trough concentration of 15–20 μg/mL. In adults, this target trough, which correlated with an area under the curve (AUC)/minimum inhibitory concentration (MIC) of ≥400 in adults, has been associated with better outcomes [64]. However, the association of improved outcomes in children with achievement of goal trough doses is not as robust as in the adult population. Modeling data in children suggest that a target trough of 7–10 μg/mL may actually achieve an AUC/MIC >400 in children receiving vancomycin doses of 15 mg/kg/dose q6 [65]. Thus, dosing strategies of many commonly used drugs in the pediatric transplant population remain complicated. The use of adult troughs and outcomes may not be fully applicable, and a better understanding of drug-specific pediatric PK is important in order to limit associated toxicities.

Limitations in Route of Drug Administration

The route of drug administration in pediatric transplant patients is important to consider, particularly in young children who cannot swallow tablets or capsules. For example, oral posaconazole suspension must be given multiple times per day, is best absorbed with fatty food, and may not be well absorbed. The delayed-release tablet is an excellent alternative, with once daily administration. However, the delayed-released tablet cannot be crushed or chewed for children who are unable to swallow tablets. Early pediatric data from a small number of patients are available to guide dosing recommendations for intravenous posaconazole [66]. Therefore, in children requiring posaconazole therapy, options are limited.

Limitations in Adverse Event Assessment in Pediatrics

Although many drugs have pediatric dosing available, these drugs are often used off-label in the pediatric population. In particular, the fluoroquinolones provide an oral, broad-spectrum antimicrobial option for treatment of pediatric infections, despite limited pediatric indications. Adverse events observed in the adult population may not occur in pediatrics. For example, Achilles tendon rupture, which has been well described in adults taking fluoroquinolones, has not been reported in pediatrics. Children do develop arthropathy at rates of <2%, which is typically reversible with cessation of the drug. Similarly, fluoroquinolone-associated risks of cardiac death and glucose abnormalities are largely uncommon in children compared with adults. Differences in the rates of adverse effects may be related to overall less

comorbidities in the pediatric populations; however, prescribers should be aware that other adverse effects, related to the use of these drugs in children with developing organs, may occur. Due to decreased frequency of use in the pediatric population, uncommon events may not be detected.

Summary

In conclusion, practitioners caring for pediatric transplant patients face unique issues compared with adult transplant providers. As the field of pediatric transplantation continues to expand, additional pediatric data will guide best practices in the field, and pediatric-specific recommendations will increase. Future studies to better define antimicrobial dosing and adverse effects will be crucial for children undergoing pediatric transplantation.

Trichomonas, 1524
Trichophyton rubrum, 1519
Trichuris trichiura, 1431–1433
Trimethoprim-sulfamethoxazole (TMP-SMX), 64, 158, 490, 491, 1190, 1197, 1258, 1265, 1272, 1464, 1499, 1586, 1617
Tropheryma whipplei, 1607
Trophozoite(s), 1185, 1454
Trypanosoma cruzi (*T. cruzi*), 166, 184, 1294
  amastigotes, 1323
  blood donors, 1298
  Chagas disease (ChD) reactivation, 1310, 1314–1317
  conventional serologic assays, 1306
  discrete typing units (DTUs), 1308
  donor-to-recipient transmission, 1294
  myocardial infection, 1301
  oral transmission, 1297
  parasite life cycle, 1299
  peripheral blood samples, 1308
  polymerase chain reaction (PCR) tests, 1308
  prevalence, 1296, 1297
  prophylaxis, 1324
  solid organ transplant (SOT) recipients, 1312
  strains, 1299
  transmission rates, 1312
  triatomine species, 1295
  trypamastigotes, 1314
  vector transmission, 1296
Trypomastigote(s), 1299
Trypomastigote excretory-secretory antigen (TESA), 1306
T-SPOT.CMV, 554
T-Track CMV assay, 554
Tuberculin skin test (TST), 177
Tuberculosis (TB), 177–178, 1607
  active, 414–416
  diagnosis, 412
  epidemiology, 410–411
  latent, 416–418
  mortality, 411
  screening, 412–414
  symptoms of, 411
  urine and serum tests, 414
Tumor necrosis factor α (TNF-α), 1208
Typical bacteria, 1606

U
Umbilical cord blood (UCB), 48
Umbilical cord blood transplantation (UCBT), 48, 49
Umbilical cord transplant, 686
Upper airways infection, 1516
Upper respiratory tract infection (URTI), 733
Ureaplasma infections, *see Mycoplasma* infections
Urinary antigen detection, 1088
Urinary tract infections (UTI), 143–145, 158, 345
Urogenital infections, 506
Urothelial cancers, 823–824
US Acute Liver Failure (US ALF) Study Group, 886

US stem cell transplant recipients, 4
US TRANSNET surveillance study, 1111
Uterine transplants, 1517, 1524

V
Vaccination, 7, 69, 114, 115, 118, 119, 241
  cytomegalovirus (CMV), 604–605
  hepatitis B virus (HBV), 936
  yellow fever (YF), 1014–1018
Vaginal infection, 1518–1519
Valacyclovir, 163, 596–597, 632
Valganciclovir, 595–596
Valganciclovir prophylaxis, 693
Valley fever, 1208
Value, 5–8
Vancomycin, 140, 291, 1656
  febrile Neutropenia, 142
Vancomycin resistant *Enterococcus* (VRE), 52, 111, 288–289
Varicella vaccination, 1711
Varicella zoster virus (VZV), 64, 66, 118, 188, 1521, 1580, 1581, 1599
  acyclovir shortage, 647
  antiviral prophylaxis after transplant, 642
  clinical impact in transplant, 624–625
  clinical issues and risk factors for infections in transplant patients, 624
  disease diagnostics and clinical evaluation, 628–630
  disease epidemiology, 621–623
  immunization in seronegative SOT and HSCT, 637, 644
  infection control, 646
  laboratory methods for diagnosis of, 629–630
  post-transplant post-exposure prophylaxis, 639–640
  in pregnant transplant recipients, 647
  prevention of reactivation, 640
  primary, 269
  primary infection prevention, 636–637
  reactivation, 625
  recommendations for treatment in transplant patients, 634
  recurrent, 270
  treatment, 634
  vaccination, 643
  vaccination against, 269–271
Vascular anastomoses, 347
Vascularized composite allograft (VCA) transplants
  environmental exposures, 1527
  graft preparation, 1515, 1516
  immunosuppression, 1514–1515
  organ-specific infections, 1522–1524
  perioperative antibiotics, 1515
  rejection, 1515
  safe living practices, 1527
  systemic infections, 1525–1526
  tissue-specific infection, 1516–1522
  vaccinations, 1526
VCA transplants, *see* Vascularized composite allograft (VCA) transplants
Vector-borne disease, 1385
Vector-borne infections, 980
Veno-arterial extracorporeal membrane oxygenator, 1476
Ventilator-associated pneumonia (VAP), 379
Ventricular assist device (VAD), 174, 1477
  cerebrovascular accident, 1489
  clinical outcomes, 1485–1486
  incidence of infections, 1480–1481
  infection definitions, 1479
  management of infection, 1486–1488
  microbiology, 1481
  post-heart transplant infection, 1489
  prevention strategies for infecion, 1484–1485
  risk factors for infections, 1482–1484
Verigene enteric pathogens (Verigene EP), 1643
Verigene GN assay, 1542, 1547
Verigene GP assay, 1541, 1547
Verigene gram-negative blood culture (BC-GN) assay, 354
Verona integron-encoded metallo-β-lactamase, 317
Viral infections
  adenovirus (AdV), 67, 68
  BK virus, 68
  cytomegalovirus (CMV), 65–67
  Epstein-Barr virus (EBV), 67
  herpes simplex virus (HSV), 64
  varicella zoster virus (VZV), 64
Viral prophylaxis, 557
Viremia, 581, 1655
Visceral leishmaniasis (VL)
  diagnosis, 1353, 1354, 1356
  disease endemicity, 1344
  disease epidemiology, 1343, 1344
  donor transmission, 1355, 1356
  geographical distribution, 1344
  haematological parameters, 1359
  hematopoietic stem cell transplantation (HSCT) recipients, 1344, 1359
  recipient infection and reactivation, 1356, 1357
  secondary prophylaxis, 1358

Visceral leishmaniasis (VL) (*cont.*)
serological techniques, 1354
solid organ transplant (SOT) recipients, 1344, 1359
transplant recipients, 1345–1347, 1349, 1351, 1352
treatment, 1357, 1358
Volatile organic compounds, 1088
Voriconazole, 63, 1060, 1065, 1080, 1081, 1090–1096, 1098–1103, 1145–1149, 1232, 1464, 1580, 1587

W
Waterborne pathogens, 107, 108, 110, 111
Water safety, 245–247
Western blot, 1259, 1269
West Nile virus (WNV), 190
West Nile virus infection
blood donor screening, 979
diagnostic considerations and laboratory testing, 975–977
disease manifestation, 977–978
environmental prevention, 981
epidemiology, 971–974
management, 977–978
organ donor screening, 979–981
preventive strategies, 978–981
Whipple's disease, 1607
Whole genome next-generation sequencing (NGS) technologies, 472
World Health Organization (WHO), 1294, 1343
malaria terminology, 1388
Wound infections, 506–508

X
Xenodiagnosis, 1306, 1309
Xpert MRSA/SA blood culture assay, 1538

Y
Yeasts
blood cultures, 58
C. auris-specific diagnostics, 59
diagnosis, 58–59
disease epidemiology, 57, 58
fungal antigen testing, 58
management, 59–60
nanodiagnostics, 58
Yellow fever (YF), 1016
clinical manifestations, 1012–1013
diagnosis, 1013–1014
epidemiology, 1011–1012
hematological malignancies and HSCT candidates, 1017–1018
kidney transplant candidates, 1018
liver transplantation, 1019–1020
liver transplant candidates, 1018–1019
prevention, 1014–1016

Z
Zanamivir, 715
Ziehl-Neelsen staining, 1649
Zika virus (ZIKV), 191
blood supply safety, 1001
clinical impact on transplantation, 995
diagnosis, 996–997
disease epidemiology, 991–992
management, 998
nucleic acid tests (NAT) screening policy, 1001
vaccine, 1000
vector control, 999
Zoster ophthalmicus, 1600
Zygomycosis, 1110
