EBV-specific CTL	Unproven – Not recommended	Effective but limited availability
Rituximab	Unproven – Not recommended	Not shown to be superior to preemptive rituximab – Not recommended
Preemptive therapy		
Reduction of immune suppression	Appears effective and recommended	Ineffective alone – Recommended in combination with rituximab
		Unproven – Not recommended
Antiviral	Unproven – Not recommended	Effective and recommended
Rituximab	Limited data – Not recommended	Effective and recommended IF available
EBV-specific CTL	Unproven – Not recommended	

to these strategies, the use of leukocyte-reduced blood products also serves as an important barrier to the spread of EBV in both patient populations since the virus is typically carried in B lymphocytes which are eliminated through the process of leukoreduction.

Immunoprophylaxis. Immunoprophylaxis can be categorized as active or passive. Active immunoprophylaxis would be accomplished through the use of an EBV vaccine. While a number of investigators have worked to develop a vaccine against EBV in both the transplant and non-transplant setting, no vaccine is currently available or likely to be approved for use in the foreseeable future. Passive immunoprophylaxis is accomplished by providing anti-EBV antibodies through the infusion of IVIG or through infusion of EBV-specific cytotoxic T lymphocytes (CTL).

Initial interest in the use of IVIG to prevent EBV-associated PTLD was supported by the protective effect of IVIG on the development of EBV disease in a SCID mouse model [57]. The potential benefit of IVIG was further supported by a retrospective analysis of SOT recipients receiving anti-CMV immunoglobulins for CMV prophylaxis which found that PTLD did not develop in patients while receiving immune globulin during their first year posttransplant [12]. However, this benefit was not confirmed in a multicenter, randomized controlled trial using anti-CMV immunoglobulin prophylaxis vs. placebo in pediatric liver transplant recipients although a trend toward less EBV disease and PTLD was observed in patients receiving CMV IVIG [12, 58]. Similarly, the use of IVIG had no impact on time free from any EBV viral load, mean viral load, time free from achieving a "high" EBV viral load, or development of EBV-associated PTLD in a prospective study of IVIG versus placebo in EBV mismatched (donor EBV seropositive/recipient EBV seronegative) adult and pediatric organ recipients, all of whom received 12 months of a combination of IV and oral antiviral therapy (IV ganciclovir followed by oral acyclovir or ganciclovir) [59]. Evidence on the protective effect of IVIG in HSCT recipients against EBV is lacking.

The use of EBV-specific cytotoxic T lymphocytes (CTL) for treatment for EBV-associated PTLD has been proven to be efficacious in stem cell transplant recipients [60] though the limited availability and access to CTL therapy impacts the extent of its use. This approach has been primarily used preemptively (see below) in response to an elevated EBV load in the blood and not as prophylaxis. There are no studies describing the prophylactic use of EBV-specific CTLs in SOT recipients.

Another potential strategy is the use of prophylactic rituximab for those at increased risk of developing EBV disease including PTLD. This is exemplified by a study by Schachtner et al. which gave a single dose of rituximab to five EBV-negative kidney candidates 1 month prior to scheduled transplants from EBV-positive living donors [56]. None of these recipients developed a positive EBV load or PTLD, but the study was too small to confirm benefit or to assess the potential risks associated with the use of rituximab in this setting [60]. Larger trials comparing outcomes including both progression to EBV disease and PTLD but also documenting potential adverse events related to the use of rituximab are necessary to define the utility of this approach. Based on the absence of adequate data, the section

on EBV in the AST ID Guidelines neither recommends for or against the use of preemptive rituximab [3]. The potential use of prophylactic rituximab was addressed in ECIL Guidelines [2]. While the Guidelines recognize the potential beneficial effect of this approach for those at increased risk for developing EBV disease including PTLD, they concluded that available evidence did not demonstrate better outcomes compared to preemptive use of rituximab for those with a documented elevated or rising EBV load and favored its preemptive use over prophylaxis.

Chemoprophylaxis. Chemoprophylaxis using antiviral agents, such as acyclovir and ganciclovir, represents another possible approach to preventing EBV infection and disease including PTLD. Theoretically, ganciclovir or its prodrug valganciclovir may be the preferred drug for EBV prophylaxis because of its higher in vitro antiviral activity compared to acyclovir. However, these drugs are only effective against the lytic forms of EBV. This might translate into inefficiency in preventing latently driven disease (e.g., PTLD), providing a potential explanation for the lack of clear evidence of benefit for the use of antivirals to prevent EBV infection and development of disease.

Initial enthusiasm for the role of antiviral therapy was derived from several single-center retrospective studies that appeared supportive for a role for antiviral therapy, but these studies suffered from methodologic concerns including the lack of appropriate controls or concomitant changes in clinical practice that could have impacted the development of EBV and PTLD [61–63]. A US case-controlled study reported that the use of ganciclovir given for CMV prophylaxis reduced the PTLD incidence in kidney transplant recipients [64], but analysis of data from a similar European registry did not confirmed the efficacy of ganciclovir, valganciclovir, or acyclovir against EBV/PTLD in SOT recipients [58]. A randomized prospective trial of 2 weeks of ganciclovir compared to 2 weeks of ganciclovir followed by 50 weeks of oral acyclovir in EBV seronegative pediatric liver transplant patients did not establish any benefit to the extended use of antiviral therapy to prevent EBV disease [65]. Similarly, the previously described study of IVG and antiviral therapy with ganciclovir and or acyclovir also failed to show benefit of these therapies [59]. A small sub-analysis of a prospective trial in pediatric renal transplant recipients observed a significant reduction of the 1-year incidence of EBV primary infection in 20 EBV D+/R patients on ganciclovir or valganciclovir prophylaxis compared with 8 patients without prophylaxis [66]. However, one patient each developed monomorphic PTLD in both the treated and untreated cohorts, and the authors concluded that no significant impact of ganciclovir or valganciclovir prophylaxis on PTLD occurrence could be derived from this study. More recently, a 2016 meta-analysis showed that the use of antiviral drugs (ganciclovir, valganciclovir, acyclovir, and valacyclovir) in mismatched EBV transplant recipients (D+/R) had no effect on PTLD incidence [67]. No significant differences were seen across all types of solid organ transplants, age groups, or antiviral use as prophylaxis or preemptive strategy. The use of antivirals for the prevention of EBV disease and PTLD was not recommended at the IPTA EBV Consensus Conference and is also not currently recommended in the AST ID Guidelines [3]. While clinical evidence assessing the potential impact of antiviral therapy on preventing EBV disease and PTLD is drawn

from the SOT population, there is no reason to believe that its impact would be substantially different in HSCT recipients in whom the bone marrow suppression of these agents can have substantial impact on successful engraftment. Consistent with this, the ECIL Guidelines specifically state that there is no evidence to support effectiveness of antiviral in this population and accordingly do not recommend the use of these agents for this purpose [2]. While there are some antiviral agents in development that may have activity against EBV in vitro, these drugs have not been systematically studied in the treatment or prevention of EBV related-disease and will also suffer from the limitation of not impacting proliferation of EBV-transformed B cells driven by human replicative enzymes.

Finally, since transmission of EBV from the donor to the EBV-naïve recipient is a major risk factor for EBV disease and PTLD, the role of antiviral chemoprophylaxis given to the donor to limit transmission has also been recently explored. A small pilot study of randomized treatment of living kidney donors with 2 weeks of valganciclovir provides encouraging preliminary results that treatment of the donor or recipient pretransplant might impact EBV transmission and potentially PTLD [68]. Additional studies are necessary to fully evaluate this novel approach to prevent EBV-associated disease.

Viral load monitoring and preemptive strategies of prevention. Despite limited published data, surveillance monitoring of EBV loads to inform a preemptive intervention has been widely implemented for both SOT and HSCT recipients. Among SOT recipients, the use of monitoring the EBV load in the peripheral blood to inform reductions in immune suppression in patients who have developed primary EBV after SOT has resulted in a decreased incidence of EBV/PTLD compared to historical controls. McDiarmid reported a decreased incidence of PTLD from 10% to 5% using EB viral load monitoring to guide the combined use of reduced immune suppression and intravenous ganciclovir in pediatric liver transplant recipients with rising EBV loads [69]. Two other studies demonstrated decreased incidences of PTLD using decreased immunosuppression alone without ganciclovir in response to elevated EBV loads [70, 71]. An important limitation of this approach is that the development of a detectable load does not necessarily predict progression to EBV disease, and additional risk factors that enhance the predictive value of an elevated load as a marker of risk of developing EBV disease including PTLD have not been identified. Patients experiencing initial recognition of a positive load in the setting of primary EBV infection after SOT may both be at increased risk and represent an opportunity for the newly infected recipient to optimize their chance to develop an appropriate immune response. However, even in this setting, many such patients may not progress to EBV disease or PTLD at this time or in the future. Assigning the risk of progression to symptomatic EBV disease in patients who develop recurrent or persistent asymptomatic elevations in their EBV viral loads remains challenging at best. Specific criteria relating to a specific height or rate of rise of EBV load are not available, in part due to the heterogeneity of available EBV load assays and differences in compartments of blood (e.g., whole blood or serum) being sampled. Accordingly, reductions in immune suppression in both published studies and clinical practice have been carried out based on elevated

load alone. Due to the risk of rejection, these reductions have been done carefully with ongoing attention for the presence of findings suggestive of early rejection. For HSCT recipients who develop an elevated EBV load early transplant, the absence of donor T-cell engraftment and function is the source of immune impairment predisposing to progression to EBV disease. Accordingly, reduction of immune suppression is more likely to play a therapeutic role for those presenting later after transplant with some T-cell engraftment receiving prophylaxis or treatment against GVHD. Despite the less clear impact of reduction of immune suppression in HSCT, the ECIL Guidelines do recommend this but in combination with preemptive rituximab or CTL therapy.

The anti-CD20 monoclonal antibody rituximab has been considered as preemptive therapy in both SOT and HSCT recipients. Little data is available to inform the use of rituximab for SOT recipients. Martin reported encouraging results using EBV load monitoring to inform the preemptive use of rituximab in EBV D+/R− adult kidney transplant recipients [72]. However, the majority of treated patients actually had clinical evidence of EBV disease at the time of treatment. Accordingly, these data speak more to the use of rituximab for early treatment and not prevention of EBV disease. Additional experience is needed to confirm efficacy and long-term safety of rituximab in a prevention/preemption model against EBV in the SOT setting. While its potential use as preemptive therapy was discussed at both the IPTA Consensus Conference and in the EBV section of the AST ID Guidelines, neither of these recommended general use of preemptive rituximab in SOT recipients at this time.

Among HSCT recipients, rituximab is more often employed than among SOT recipients. Because HSCT recipients at high risk for PTLD often develop EBV infection prior to reestablishment of adequate cell-mediated immunity, reduction of immune suppression is frequently not an option. Since the period of risk is much more predictable and relative early after HSCT, monitoring with EBV viral load PCR and preemptive therapy with rituximab appears to reduce the incidence of PTLD [73]. Although no randomized trials have been published to date, this approach of serially monitoring high-risk patients (e.g., patients that receive TCD) by weekly EBV blood PCR and giving rituximab for patients with elevated EBV DNA levels or persistently increasing levels has become standard of care at many institutions, especially for centers without access to adoptive immunotherapy against EBV (see above). Consistent with this, the ECIL Guidelines strongly recommend the preemptive use of rituximab along with reduction of immune suppression where possible. Rituximab is given as a weekly dose of 350 mg/m^2 until the load is no longer detectable (typically 1–4 doses) [2]. While preemptive use of CTL therapy is likely efficacious and may actually be the preferred therapy (see below), its limited availability makes rituximab the most frequently used preventive strategy in the HSCT population.

Finally, the preemptive use of EBV-specific CTL from either the allograft donor or an HLA partially matched third-party donor has been shown to be highly effective in HSCT recipients. Rates of prevention approaching 100% have been reported by centers with access to EBV-specific T-cell therapy [74]. Unfortunately, at present,

access to EBV-specific CTL for preemptive therapy is limited to a relatively small number of centers limiting its impact in this patient population. However, if available, the ECIL Guidelines recommended their use in this setting. In contrast to the successful use of this approach in HSCT recipients, efforts to translate these benefits to the prevention of EBV/PTLD in SOT recipients have been limited, and clear evidence of efficacy for preemptive use in SOT recipients is lacking at this time [75].

To summarize the approach to SOT recipients, available data supports the use of the strategy of using EBV load monitoring for patients who are EBV negative prior to transplant from an EBV-positive donor, to inform preemptive reduction in immune suppression to prevent EBV/PTLD as the optimal currently available preventive strategy. This approach was endorsed by the IPTA Guidelines and is supported in the EBV section of the AST ID Guidelines. With few exceptions (i.e., intestinal transplant recipients, those retransplanted for history of PTLD), this should be limited to the patients who is EBV seronegative prior to transplant, and this approach should not be used for those who were EBV seropositive prior to transplant. For HSCT recipients, consistent with the ECIL Guidelines, preemptive use of rituximab combined with reduction of immune suppression where feasible is strongly recommended. However, centers with access to EBV-specific CTL for preemptive therapy should consider this as a potentially preferred option.

Conclusion

Epstein-Barr virus is an important potential cause of morbidity and mortality in children and adults undergoing SOT and HSCT. These immunocompromised patients are at risk for uncontrolled lymphoproliferation because of the EBV virus' ability transform and immortalize B lymphocytes leading to viral-driven proliferation of infected B cells causing a wide spectrum of disease including true malignancies. Careful observations and sustained research over the last 30 years have led to an understanding of key risk factors associated with development of these complications as well as enhanced diagnostic studies to optimize early diagnosis and even inform preventative and preemptive interventions. Individual and collaborative efforts have identified potential options that differ for SOT HSCT recipients leading to improved outcomes. Evidence-based guidelines now provide recommendations on their use for both prevention and treatment of the complications of EBV. Going forward, larger, prospective, and ideally randomized trials are necessary to define the best treatment strategies for the varying clinical scenarios seen in both the SOT and HSCT patient populations.

Key Points

1. EBV (Epstein-Barr virus) impacts morbidity and mortality in children and adults after solid organ transplantation (SOT) and hematopoietic stem cell transplantation (HSCT).

2. EBV is the most important pathogen causing posttransplant lymphoproliferative disorder (PTLD).
3. Pretransplant EBV serology, type of organ, and age differentiate the risks for EBV-associated PTLD in SOT.
4. PTLD in HSCT is of donor origin, and the risk increases with T-cell depletion therapy.
5. Antivirals do not prevent PTLD.
6. EBV viral load monitoring is useful to monitor the EBV activity after SOT and HSCT though limitations with both sensitivity and specificity must be considered in interpreting results.
7. EBV load monitoring to inform reduction of immunosuppressants appears to be a generally effective strategy to prevent PTLD in SOT recipients.
8. Prophylactic rituximab in response to elevated or rising EBV load has been effective in the prevention of EBV-associated PTLD in HSCT but controversial in SOT.
9. EBV-specific CTL therapy in response to elevated or rising EBV load is also effective for prevention of EBV-associated PTLD in HSCT but not SOT; this strategy is limited by its availability.
10. Tissue diagnosis is required and determines the characteristics of PTLD and the prognosis.
11. Non-B-cell PTLD has worse outcome.
12. For SOT recipients, a stepwise approach to the treatment of EBV+ PTLD is generally recommended with initial reduction of immunosuppressants followed by rituximab for those who do not respond or develop rejection.
13. Chemotherapy is required if the PTLD does not respond to the first- or second-line therapies.
14. For recipients of HSCT, adoptive T-cell therapy is effective for PTLD if available though rituximab might be used if not. Chemotherapy is poorly tolerated in the HSCT setting.

Introduction

Human herpesviruses (HHV)-6, HHV-7, and HHV-8 are DNA viruses that have been recognized as pathogens among solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients for nearly three decades. However, despite advances in our understanding of their biology and natural history, the

precise roles of HHV-6 and HHV-7 in causing posttransplant infection and immune modulation remain incompletely defined. In contrast, and perhaps due its recognition as the cause of Kaposi sarcoma (KS) during the human immunodeficiency virus (HIV) epidemic in the 1980s, HHV-8-related syndromes after transplantation are well-described though they are much less common after HSCT compared to SOT. Herein, the biology, risk factors, clinical features, and management of HHV-6, HHV-7, and HHV-8 infections after transplantation are discussed, with an emphasis on knowledge gaps that require further investigation.

Human Herpesvirus-6

Overview

Background

HHV-6 was first isolated from patients with lymphoproliferative disorders in 1986 [1]. It belongs to the subfamily β-herpesviridae in the genus *Roseolovirus* and is most closely related to HHV-7 and cytomegalovirus (CMV) [2]. There are two HHV-6 variants, HHV-6A and HHV-6B, which share approximately 90% amino acid identity but are nonetheless classified as two HHV-6 species due to their distinct epidemiology, biology, genomes, cell tropism, and growth and antigenic properties [3]. HHV-6B causes most documented primary infections and reactivation events [4]. Little is known about HHV-6A, though both HHV-6A and HHV-6B have been recovered from peripheral blood mononuclear cells (PBMCs) of immunocompromised patients. For the purposes of this review, HHV-6A and HHV-6B will be collectively referred to as HHV-6 unless otherwise indicated.

Following acute infection, HHV-6 establishes latency in a wide variety of host cells, although it replicates most efficiently in CD4+ T lymphocytes by binding to its cell surface receptor CD134 [5, 6]. It has also been recovered from lymph nodes, PBMCs, CD8+ T lymphocytes, natural killer (NK) cells, renal tubular cells, salivary glands, and the central nervous system (CNS) [7]. HHV-6 is believed to have immunomodulatory characteristics and can impair cellular proliferation of infected PBMCs in vitro. It is transmitted via saliva and is the most common cause of roseola infantum in infants. Over 90% of adults are seropositive for HHV-6, with infection after HSCT or SOT almost always representing reactivation of latent disease, though donor transmission can occur as discussed below [2].

Chromosomally Integrated HHV-6

Population-based studies have estimated that vertical germ line inheritance of HHV-6 occurs in about 1% of the population [8]. This phenomenon is referred to as chromosomally integrated HHV-6 (ciHHV-6). These individuals are completely healthy, but the genome of HHV-6 is integrated into the telomere regions of a single chromosome in every nucleated cell of their body. They are therefore able to

pass this HHV-6 genome to their children. Since HHV-6 can essentially be thought of as being part of these individuals' genetic makeup as humans, patients with ciHHV-6 always exhibit sustained levels of extremely high HHV-6 viral loads (generally $>10^{5.5}$ copies/mL, though the exact threshold is unclear) that are stable over time and unaffected by any intervention [3, 9].

Since ciHHV-6 is not a pathological state, it almost never requires any specific treatment, even in transplant recipients. Proving the presence of ciHHV-6 is however difficult, as current laboratory testing cannot reliably differentiate between innocuous ciHHV-6 viremia and viremia due to HHV-6 reactivation. Therefore, detection of high HHV-6 viral loads in clinical specimens of transplant patients can confuse clinicians, who may not be able to prove that this is ciHHIV-6, resulting in the administration of antiviral therapy when none is warranted. The presence of ciHHV-6 should however be suspected in any patient with extremely elevated and stable viremia. Viral loads measured in whole blood are typically higher than those measured in plasma [3]. Polymerase chain reaction (PCR) or fluorescent in situ hybridization (FISH) testing of hair follicles or nails can confirm the diagnosis, but these are labor-intensive and impractical [3]. A novel technology called droplet digital PCR can assist with the diagnosis by determining the ratio of HHV-6 to cellular DNA, which is expected to be 1:1 in patients with ciHHV-6 due to the presence of HHV-6 DNA in every single nucleated cell [10].

Diagnosis and Antivirals

In the current era, PCR of peripheral blood or cerebrospinal fluid (CSF) is the diagnostic modality of choice [3]. These assays are however limited by lack of standardization and validation. Immunohistochemistry can also detect viral antigens from clinical specimens. While HHV-6 causes a self-limited illness in healthy children and its direct role as a pathogen after transplantation is debated, some situations – specifically in transplant recipients with encephalitis – often warrant antiviral therapy. Unfortunately, no antiviral is licensed for the treatment of HHV-6. Ganciclovir, foscarnet, cidofovir, and brincidofovir (which is not currently in development) all possess in vitro activity and have all been used to treat patients with HHV-6-related syndromes, with varying degrees of success [3]. Acyclovir appears to be inactive. Adoptive immunotherapy for HHV-6 infections is an area of active investigation [11].

HHV-6 Infection in HSCT Recipients

Epidemiology and Risk Factors

HHV-6 reactivation occurs in 30–80% of HSCT recipients within the first 2–6 weeks after transplant and is associated with significant morbidity and mortality [12–15]. The wide discrepancy in incidence rates is due to the pitfalls inherent to single-center retrospective studies, which have accounted for most of the published data evaluating HHV-6 infections. These studies have used different modalities to establish the presence of HHV-6 infection (such as various PCR assays

performed on whole blood, plasma, or other tissue fluid or brain imaging findings alone) and have inconsistently evaluated for the presence of ciHHV-6. While generally thought of as reactivation of latent infection, primary HHV-6 infection has also been described, potentially due to either donor stem cells or HHV6-positive blood products [13, 16].

A major risk factor for HHV-6 infection is the type of HSCT, with umbilical cord transplant recipients experiencing the highest rates (up to 92%), followed by allogeneic (bone marrow, peripheral blood) and autologous HSCT recipients (30–50% and 9%, respectively) [5, 13, 17, 18]. Peak plasma viral loads are also higher after umbilical cord HSCT compared to other types of transplants [5]. The increased incidence of HHV-6-related syndromes after umbilical cord transplantation is hypothesized to be due to the absence of primed HHV-6-specific memory T cells in cord blood and the immunologic immaturity after umbilical cord blood transplantation [13, 19]. Other risk factors for HHV-6 infection include receipt of human leukocyte antigen (HLA) or sex-mismatched HSCT, younger recipient age, CD4+-rich and NK cell-poor grafts, delayed CD8+ reconstitution, myeloablative conditioning, use of anti-CD3 monoclonal antibodies, and acute graft-versus-host disease (GVHD) [5, 13, 15, 17, 20]. Naïve T-cell depletion (which is performed to reduce the risk of GVHD) may be an emerging risk factor for HHV-6-related syndromes, though this warrants further investigation [21]. T-cell reconstitution has been shown to confer protection against HHV-6 infections [22].

Association with Infectious Syndromes

Clinical data regarding HHV-6 infection after HSCT are mostly limited to case reports, case series, and single-center retrospective observational studies. The literature suggests that HHV-6 infection should be considered in cord blood, allogeneic, or autologous HSCT recipients with sustained and unexplained rashes and fevers, diarrhea, pneumonia, and confusion, particularly in the early posttransplant period [14, 18, 23]. However, the ubiquitous and often self-limited nature of most post-engraftment fevers and rashes after HSCT calls into question the true role of HHV-6 in these patients. HHV-6 causes bone marrow suppression by infecting hematological progenitor cells, leading to a reduction in colony formation [24, 25]. In a recent study, HHV-6 infection was implicated in the pathogenesis of the idiopathic pneumonia syndrome, where HHV-6 DNA was found in 55% of BAL samples [26]. The authors speculated that the presence of HHV-6 in the lungs of HSCT recipients precipitated lung injury, predisposing to the idiopathic pneumonia syndrome through dysregulated host and alloimmune responses. HHV-6 viremia can precede or occur simultaneously with CMV infection and has been associated with BK virus infections, suggesting that it is a marker of overall immunosuppression [20, 27].

Encephalitis is one of the most well-described, debilitating, and potentially fatal syndromes attributed to HHV-6. It is associated with increased 100-day mortality and can lead to long-term neuropsychiatric sequela in up to 57% of patients [17]. Data from the Center for International Blood and Marrow Transplant

Research Database evaluating over 27,000 patients demonstrated that HHV-6 was the most common virus isolated from the CSF of HSCT recipients with encephalitis (52% of cases) and that HHV-6 encephalitis occurred earlier in the posttransplant course than did encephalitis caused by other viruses (median of 28 vs. 80 days, respectively) [28]. A well-recognized HHV-6-related CNS syndrome is posttransplant acute limbic encephalitis (HHV-6-PALE), which presents with altered mental status, anterograde amnesia, marked deficit in short-term memory recall, intermittent agitation, lethargy, mild CSF pleocytosis, temporal electroencephalogram abnormalities, and MRI changes in the limbic system [5]. Half of the patients in this study died, and most survivors unfortunately had residual fatigue and episodic memory impairment despite receiving foscarnet. Other HHV-6-related CNS syndromes after HSCT include hippocampal atrophy and optic neuritis [29, 30].

Overall, it remains uncertain whether HHV-6 causes these syndromes or whether it is merely incidentally detected in patients with fevers, rash, diarrhea, and confusion resulting from other causes.

Association with Transplant-Related Events

In addition to infectious syndromes, HHV-6 has also been implicated in the pathogenesis of adverse graft-related and immunological phenomena after HSCT. These include delayed monocyte and platelet engraftment, GVHD (which is also a risk factor for HHV-6 infection), and disease relapse [5, 15]. It is hypothesized that HHV-6 can trigger or exacerbate GVHD by interacting with and upregulating CD134, which is the HHV-6 cell entry receptor. CD134 is an immunomodulatory molecule that blocks regulatory T-cell (Treg) activity, which when activated releases anti-inflammatory cytokines such as interleukin-10, thereby reducing the functional activity of autoreactive cells and ultimately preventing the development of acute GVHD [31]. By upregulating CD134 expression, HHV-6B infection prevents Treg-mediated anti-inflammatory cascade, increases alloreactivity, and ultimately leads to GVHD. An alternative explanation for this observation is that by directly infecting and depleting CD4+ cells, HHV-6 may have detrimental effects on early T-cell reconstitution, resulting in uncontrolled alloreactivity secondary to Treg depletion and eventually leading to acute GVHD [32].

Despite these observations, detection of HHV-6 viremia may simply be an epiphenomenon. Indeed, whether HHV-6 is causative in the pathogenesis of GVHD, or whether its detection is simply a marker of immune dysregulation heralding the development of acute GVHD, is not currently known. Thus, based on current data, it cannot be recommended to screen patients for HHV-6 viremia as a marker for future GVHD, nor can it be recommended to treat asymptomatic HHV-6 viremia after HSCT. Further studies (which must evaluate for the presence of ciHHV-6) are required to fully understand the complex interplay between HHV-6 viremia and graft-related outcomes.

Chromosomally Integrated HHV-6 After HSCT

Roughly 2% of HSCT donors and/or recipients have ciHHV-6, which confounds molecular testing for HHV-6 viremia [12, 33]. Though data are limited, the rate of

ciHHV-6 among patients with syndromes that may be attributed to HHV-6 was around 4% in one study [20]. As previously mentioned, all patients (including transplant patients) with ciHHV-6 have persistently elevated viral loads (usually $>10^{5.5}$ copies/ml) in blood and CSF specimens, with no dynamic change on serial testing [5]. In contrast, transplant recipients with HHV-6 reactivation usually have transiently detectable HHV-6 DNA, typically at $<10^5$ copies/ml in blood samples. Only a few studies have investigated the role of ciHHV-6 after HSCT. In one study, seven patients diagnosed with HHV-6-PALE had plasma viral loads $>10^{5.5}$ copies/ml, suggesting that the HHV-6-PALE possibly occurred in the context of ciHHV-6 [5]. The presence of ciHHV-6 has also been described in patients with other CNS as well as pulmonary syndromes typically attributed to HHV-6 infections [12]. In addition, one study showed that acute GVHD and CMV viremia were more frequent when recipients or donors had ciHHV-6, though this did not confer an increased risk for chronic GVHD, delayed engraftment, or mortality [33]. Patients with ciHHV-6 viremia have been shown to clear their viremia after engraftment from a donor without ciHHV-6, and conversely, HSCT recipients with transplants from donors with ciHHV-6 develop HHV-6 viremia after engraftment, consistent with donor chimerism [20, 34]. Further studies are required to understand the complex biology of this phenomenon. The benefit of screening for ciHHV-6 to guide donor selection and post-HSCT risk stratification warrants additional investigation.

Utility of Treating HHV-6 After HSCT

Whether HHV-6 is even a treatable virus remains controversial, as antivirals with in vitro activity have never been conclusively shown to improve outcomes, and many patients with HHV-6-related syndromes after HSCT improve with no specific intervention [35, 36]. In addition, antivirals given to prevent CMV do not have an impact on the incidence of HHV-6 viremia [13]. Nonetheless, the use of antivirals (ganciclovir, foscarnet, or cidofovir) has been shown to result in successful eradication of HHV-6 viremia in some patients, though this practice had no impact on survival in one study [37]. In contrast, another study found that all haploidentical HSCT recipients with an HHV-6-related encephalitis improved after receiving foscarnet [38]. However, in a randomized trial of umbilical cord HSCT recipients evaluating the efficacy of foscarnet for treating HHV-6 viremia compared to historical controls who received no treatment, foscarnet significantly suppressed HHV-6 reactivation but did not prevent the development of HHV-6 encephalitis or GVHD [39]. There have even been reports of viremia attributed to ciHHV-6 that ostensibly responded to antivirals, which calls into question whether this was truly ciHHV-6 viremia [20].

While the data are conflicting, they demonstrate that in a subset of patients, HHV-6 may truly cause disease and respond to antivirals. It is difficult to justify withholding antivirals for patients with encephalitis who have evidence of HHV-6 infection. In this setting, treatment is warranted. However, a well-designed randomized trial of antivirals for the treatment of HHV-6-related syndromes needs to be conducted, with standardized HHV-6 monitoring and testing for the presence of ciHHV-6.

HHV-6 Infection in SOT Recipients

Epidemiology and Risk Factors

While initially reported in 1989 after a seronegative liver transplant recipient developed primary HHV-6 infection from a seropositive donor [40], there is a dearth of contemporary data describing HHV-6-related syndromes after SOT, with most published reports clustered between the 1990s and early 2000s. Nonetheless, the central concepts surrounding HHV-6 infection in SOT recipients appear to mirror those of HSCT recipients. HHV-6 infection occurs within the first few weeks after SOT, at a median of 36 days in one study [41]. Incidence rates vary by testing modality and the type of organ transplanted but have ranged from 25 to 82% in liver, 20 to 79% in kidney, 26 to 91% in lung, and up to 73% in heart transplant recipients [41–46]. Cases after pancreas and intestinal transplantation have also been described [34, 47]. Given the near universal seropositivity of adults, post-SOT HHV-6 infection usually represents viral reactivation, though primary infection (particularly after pediatric transplantation) has been described [48]. Antiviral prophylaxis (e.g., with ganciclovir) for other viruses like CMV does not appear to affect the incidence of HHV-6 viremia [45].

Risk factors for HHV-6 infection after SOT have not been fully defined. Receipt of OKT3 may increase the risk, though this agent is no longer clinically available in the United States [49]. Whether thymoglobulin, alemtuzumab, or basiliximab increase the rates of HHV-6 viremia or HHV-6-related syndromes is not known. Acute rejection has been inconsistently found to be a risk factor [2]. In pediatric liver transplant recipients, younger age and severity of liver failure were associated with higher rates of HHV-6 infection [50].

Association with Infectious Syndromes

As with HSCT recipients, it is unclear if the infectious syndromes that have been linked to HHV-6 after SOT are truly caused by HHV-6 or if HHV-6 is merely a bystander. While most patients with viremia are asymptomatic, HHV-6-related syndromes have included rashes, diarrhea, cytopenias, pneumonitis, confusion, and even shock. About 50% of cases of fever of unknown origin after liver transplant were attributed to HHV-6 [51]. In addition, 84% of kidney transplant recipients with HHV-6 reactivation developed fever of unknown origin in one study, compared to 30% of patients without HHV-6 viremia [52]. It is unknown if these findings would be replicated in the current era, given the improved diagnostics of fever of unknown origin. Some have called these early observations into question. For example, in a longitudinal study of kidney, liver, and kidney-liver transplant recipients, HHV-6 was detected in 31% of patients after transplant, but clinical syndromes were observed only in patients who had concomitant CMV infection [53].

More fulminant manifestations of HHV-6 infection have been described. For instance, HHV-6A was thought to be the cause of a severe disseminated donor-derived syndrome of colitis, fever, and cytopenias in two kidney transplant recipients and resulted in the death of one of them [54]. In addition, a case report

by Singh et al. describes an acute febrile illness characterized by life-threatening thrombocytopenia, progressive encephalopathy, and skin rash, which developed in association with invasive HHV-6 infection in a liver transplant recipient [55]. HHV-6 was isolated from blood and bone marrow, and the patient responded to ganciclovir.

CNS dysfunction of undetermined etiology remains the most well-recognized syndrome attributed to HHV-6 infection after SOT. The clinical presentation is nonspecific and variable but is generally characterized by confusion, involuntary movements, amnesia, decreased responsiveness, seizures, and visual hallucinations, often with fevers and rashes [47, 56]. The reported onset in the literature is between 17 days and 3 months after transplant, with a median of 25 days. Brain imaging can be normal or reveal abnormalities in the medial temporal lobes or hippocampus [24, 47]. CSF pleocytosis and elevated protein are inconsistently reported. Most patients with encephalitis occurring in the setting of detection of HHV-6 DNA have been treated with ganciclovir or foscarnet, though it is unclear if improvement or survival is related to antiviral therapy.

HHV-6 has been implicated in increasing the predisposition to and severity of other infections after SOT, including CMV, hepatitis C virus, and opportunistic fungi, though detection of HHV-6 in these patients may simply represent a heightened state of immunosuppression [57]. HHV-6 viremia has been frequently identified concurrently with or immediately preceding CMV viremia [45, 58]. Indeed, the presence of HHV-6 viremia heralded the development of CMV viremia in high-risk (CMV donor positive, recipient negative) kidney transplant recipients, all of whom were HHV-6 seropositive [42]. It is speculated that subclinical CMV infection may have led to immune dysregulation resulting in HHV-6 viremia prior to overt CMV viremia. Alternatively, a heightened state of immunosuppression may have led to viremia with both viruses, with the timing of viremia seen in these studies being a spurious observation. Whether HHV-6 viremia occurring prior to or concurrently with CMV viremia portends more severe CMV infections is unknown.

Association with Transplant-Related Events

The potentially immunomodulatory and immunosuppressive properties of HHV-6 have been described in the SOT population, in whom it is thought to facilitate allograft rejection and graft loss. However, these may simply be parallel phenomena, as the literature is rife with conflicting data. For instance, the presence of HHV-6 viremia was not associated with bronchiolitis obliterans syndrome (BOS) after lung transplantation in one study [44] but did predict stage 1 or greater BOS in another [59]. Some studies have found that HHV-6 viremia was associated with decreased liver allograft survival and the development of chronic allograft nephropathy [60, 61]. However, another study found no correlation between graft rejection and HHV-6 infection after kidney, liver, or liver-kidney transplant [53]. In addition, in one of the only randomized trials comparing preemptive monitoring of HHV-6 viremia (with reduction of immunosuppression and antiviral therapy upon the detection of viremia) to usual care with no monitoring

among 129 adult liver transplant recipients, no cases of symptomatic HHV-6 viremia were detected, nor did viremia have any impact on graft function or mortality [41]. The authors concluded that preemptive monitoring of HHV-6 viremia confers no benefit after liver transplant.

Chromosomally Integrated HHV-6 After SOT

Chromosomally integrated HHV-6 has rarely been reported after SOT and is estimated to occur in about 0.9% of patients [62]. A single-center study described the outcomes of seven liver transplant recipients with suspected ciHHV-6 (defined as persistent viremia of $>10^6$ genomes/mL of whole blood) in addition to nine SOT recipients from the literature (five liver, two liver-kidney, one small bowel, and one kidney transplant) [34]. None of the patients had fever, rash, or organ-invasive clinical syndromes that were attributed to HHV-6 by their clinicians. Notably, HHV-6 DNA was even detected at high levels in the CSF of the small bowel transplant recipient, though this was not believed to be pathogenic. Five patients unnecessarily received antivirals (ganciclovir, valganciclovir, or foscarnet), which had no effect on viremia, consistent with the notion that HHV-6 is integrated in every nucleated cell.

The phenomenon of donor-derived ciHHV-6 after SOT has not been thoroughly investigated. A case of fatal transmission of ciHHV-6A from donor to recipient through liver transplantation was recently reported, with HHV-6 DNA isolated from multiple compartments (CSF, liver tissue, saliva, respiratory fluid). This ultimately resulted in the recipient's death despite ganciclovir and foscarnet [63]. However, routine screening for ciHHV-6 cannot currently be recommended. Nonetheless, clinicians should be cognizant of this phenomenon to avoid the unnecessary use of antiviral drugs in SOT recipients with ciHHV-6, in whom antivirals may be safely discontinued.

HHV-6 in HSCT and SOT: Challenges and Future Directions

A major problem with interpreting studies of patients with HHV-6 viremia after transplantation is that testing for HHV-6 is imprecise, and the presence of viremia does not prove that HHV-6 is causing the patient's syndrome. Indeed, fevers, rashes, pneumonia, diarrhea, and confusion are extremely common after both HSCT and SOT due to polypharmacy (immunosuppression, antimicrobials, other medications), GVHD, mucositis, engraftment, rejection, and other infections. Thus, patients who are found to have HHV-6 viremia in the presence of these syndromes may be falsely labelled as having HHV-6 disease, when in fact the HHV-6 may simply be present in a complex background of unrelated events. The inconsistent efficacy of antivirals in published studies supports the notion that HHV-6 viremia on its own may not always be pathogenic. Indeed, the apparent response to antiviral therapy in some studies may be coincidental, representing the natural history of the underlying disease as opposed to cure of a viral infection. Nonetheless, there does appear to be a subset of patients in whom HHV-6 is truly pathogenic, particularly those with CNS infection or fulminant disease.

Taken together, the abundance of reports providing completely disparate points of view on the pathogenicity of HHV-6 suggests that both scenarios may be true: HHV-6 is a true pathogen capable of leading to significant morbidity and mortality in some patients but is also an innocent bystander in others. The immunologic milieu dictating the emergence of one phenotype over the other is unknown. Future studies must focus on host-pathogen signatures in syndromes thought to be caused by HHV-6, as well as the complex interactions between CMV and HHV-6. It is imperative that we better define the role of HHV-6 in posttransplant infectious and graft-related outcomes, to help us identify which patients would benefit from monitoring and therapy.

Human Herpesvirus-7

Overview

HHV-7 was first isolated from activated CD4+ T cells of a healthy individual in 1990 [64]. It belongs to the *Roseolovirus* family and bears genetic and antigenic resemblance to HHV-6. It is a lymphotropic virus that replicates in CD4+ T cells but has a much narrower host-cell range compared to HHV-6, which includes cord blood mononuclear cells and macrophages [65]. Unlike HHV-6, it utilizes CD4 as a cellular receptor for cell entry. It is ubiquitous, sheds through saliva, and leads to latent infection in adults, with seroprevalence rates of over 95% [2]. Chromosomal integration is not thought to occur. Primary infection in infants usually leads to a nonspecific febrile illness, including roseola. Antiviral agents with in vitro activity against HHV-7 are less well-defined than those for HHV-6. Foscarnet and cidofovir appear to be active; reports on the activity of ganciclovir are conflicting [2, 66, 67]. Acyclovir has no activity.

There is a dearth of literature describing HHV-7 after either HSCT or SOT, with most of the published studies limited to case reports, case series, or small, single-center retrospective reviews. While it does have cytopathic and immunomodulatory effects, no study has definitively proven that HHV-7 causes any syndrome, nor has any study shown that administering antivirals for syndromes attributed to HHV-7 affects outcomes. Therefore, even more so than HHV-6, the presence of HHV-7 in clinical specimens of transplant patients may simply be a marker of immune dysregulation.

HHV-7 Infection in HSCT Recipients

HHV-7 viremia has been described in 6–56% of HSCT recipients, occurring at a median of 18–21 days after HSCT [68–71]. HHV-7 viremia has been detected in patients with fever of unknown origin, rash, hepatitis, pneumonitis, and CNS infection [68–70, 72]. GVHD was associated with HHV-7 infection in a few studies [69, 71]. Allogeneic transplant was a risk factor in one study [71], though others

have surprisingly found a greater incidence of HHV-7 viremia in autologous compared to allogeneic HSCT and in peripheral blood HSCT compared to cord blood HSCT [70, 73]. These data are biologically implausible and appear to contradict the HHV-6 literature, which has established cord blood and allogeneic HSCT as the major risk factors for HHV-6 infections. Most patients in the literature have not received any specific treatment for HHV-7 viremia [69]. However, a case report of encephalitis attributed to HHV-7 after allogeneic HSCT described clinical improvement with foscarnet but not ganciclovir [74].

A few studies have evaluated the dynamics of CMV and HHV-7 infection. One such study found that HHV-7 viremia occurred simultaneously with CMV viremia in 26% of patients and may have contributed to increasing the severity of CMV disease [75]. In addition, patients with HHV-7 viremia had higher CMV viral loads compared to those without viremia (1986 vs. 432 copies/mL, respectively), though the duration of CMV was similar across both groups. In an older study, HSCT recipients with CMV disease were more likely to have concurrent HHV-7 DNA viremia prior to onset of disease than were patients with asymptomatic CMV infection, suggesting that HHV-7 may be a cofactor in the progression from CMV infection to CMV disease [76]. HHV-7 viremia has also been described in patients with other viral infections (adenovirus, parainfluenza) and bacterial and fungal opportunistic infections. Whether this is due to ill-defined HHV-7-related immune modulation, or whether the simultaneous occurrence of these infections is an indirect marker of the net state of immune dysfunction, is not currently known.

HHV-7 Infection in SOT Recipients

As is the case with HHV-7 after HSCT, most studies in the SOT population are limited to case reports, case series, and retrospective studies from the 1990s and early 2000s. Viremia has been reported in 6–88%, 41–48%, and 50% of kidney, liver, and lung or heart-lung transplant recipients, respectively [45, 77–81]. Valganciclovir prophylaxis for CMV has no impact on the incidence of HHV-7 viremia, which occurs within the first month after SOT. Most cases have described incidental asymptomatic viremia with absolutely no clinical consequences [45, 77, 79, 80], though HHV-7 may have been the cause of hepatitis and fever in some liver transplant recipients in one study [77].

HHV-7 viremia after SOT has been postulated to be a cofactor in the pathogenesis of CMV infection in a few limited studies [45, 58, 77, 82, 83]. In a study of 52 kidney transplant recipients, there was a significant increase in CMV disease occurring in patients with CMV and HHV-7 coinfection compared to those with CMV infection alone [81]. The risk of progression to CMV disease after kidney transplant was more pronounced in patients with CMV, HHV-6, and HHV-7 viremia detected simultaneously and in patients with CMV and HHV-7 together, but not in those with only CMV and HHV-6 [84].

Some studies have investigated the role of HHV-7 in graft-related outcomes. HHV-7 DNA was found in 9% of transbronchial samples of lung

transplant recipients and was implicated in the pathogenesis of ischemia reperfusion injury [85]. In addition, all lung transplant recipients with bronchiolitis obliterans with organizing pneumonia (BOOP) were found to have HHV-7 DNA in their bronchoalveolar lavage samples [86]. It has also been linked to acute rejection and chronic allograft nephropathy after kidney transplant [61, 81].

Unfortunately, the veracity of these observations has not been duplicated in larger, prospective, and more contemporary studies. Indeed, a randomized trial of 129 liver transplant recipients with HHV-7 viremia found no association between viremia and clinical disease, nor did it find any benefit of HHV-7-specific intervention (e.g., antivirals or reduction of immunosuppression) [41].

HHV-7 in HSCT and SOT: Challenges and Future Directions

Contemporary prospective studies are required to better understand the true risk factors, biology, host-pathogen interface, and clinical consequences of HHV-7 viremia after transplant. As is the case with detection of HHV-6 DNA in bodily fluids, the presence of HHV-7 after transplant is unlikely to represent true infection but rather a state of immune dysregulation. With the explosion of molecular diagnostics, clinicians need to be judicious in testing for HHV-7 DNA and consider refraining from such testing until additional data are available to elucidate the biology of this virus and the complex interplay between HHV-7, the graft, and other infections.

Human Herpesvirus-8

Overview

Biology

Until the HIV epidemic in the 1980s, Kaposi sarcoma (KS) had largely been a rare skin tumor of older Mediterranean or Ashkenazi Jewish men [87]. HHV-8 itself (also known as Kaposi sarcoma herpes virus (KSHV)), was not identified as the causative agent of KS until 1994, when it was isolated from KS lesions. It is a member of the subfamily *Gammaherpesvirinae* and belongs to the genus *Rhadinovirus* [2].

HHV-8 infects a wide variety of cell types, including B cells, endothelial cells (spindle cells in KS lesions), macrophages, and epithelial cells [88]. As with any herpesvirus, it leads to both lytic and latent infection and has evolved mechanisms to evade the immune system. Cytotoxic T lymphocytes are required for viral control, as evidenced by the increased incidence of KS in transplant patients and those with advanced HIV and by the regression of KS lesions upon immune reconstitution. HHV-8 also contains viral oncogenes that are important in the pathogenesis of tumor formation. For instance, it can transform primary human endothelial cells, which are the cells affected in KS. HHV-8 is unique in that it contains an unprecedented number of genes that were transduced from host

cellular genomes during its evolution, a phenomenon known as molecular piracy [89]. These genes encode for cellular homologs that induce angiogenesis, regulate antiviral immunity, and alter cellular growth. HHV-8 is also a potent inducer of angiogenic cytokines, such as interleukin-6, basic fibroblastic growth factor, and interferon gamma [2].

Overview of Well-Known Manifestations

While KS it the most well-described entity related to HHV-8, it can also cause multicentric Castleman disease and primary effusion lymphoma. Castleman disease is an uncommon lymphoproliferative disorder characterized by fever, splenomegaly, hepatomegaly, and massive lymphadenopathy. Primary effusion lymphoma is a rare subclass of non-Hodgkin lymphoma (NHL) associated with HHV-8 infection and principally seen in persons living with HIV [90]. Other transplant-specific manifestations are discussed in greater detail below. A full discussion of these syndromes is beyond the scope of this chapter.

Epidemiology

The incidence of HHV-8-related disease mirrors its seroprevalence rates, which are highest in sub-Saharan Africa, intermediate in Italy and other Mediterranean areas, and lowest in the United States, Northern Europe, and Asia [91]. Transmission is believed to be via saliva, though it has also been transmitted through sex, blood transfusion, and SOT. It is a predominantly male disease, with the male-to-female ratio of KS in different endemic populations ranging from 3:1 to 15:1 [92].

Diagnosis and Antiviral Therapy

As with HHV-6 and HHV-7, PCR is the gold standard for diagnosis of HHV-8 viremia [3]. KS and other associated syndromes can be diagnosed pathologically. Serology is useful for epidemiologic purposes, particularly donor-recipient risk stratification after SOT (see below). There are extremely limited reports evaluating the activity of antivirals against HHV-8. Ganciclovir, foscarnet, and cidofovir (but not acyclovir) are all active [93], as is the HIV protease inhibitor nelfinavir [94]. However, no clinical report has unequivocally shown the efficacy of antivirals. Mammalian target of rapamycin (mTOR) inhibitors such as everolimus and sirolimus have also been used. The efficacy of these agents is thought to be a result of the constitutive activation of the mTOR signaling pathway in KS and HHV-8-associated primary effusion lymphoma [95]. As discussed below, the mainstay of management is reduction of immunosuppression, often with chemotherapy for visceral KS and for other manifestations.

HHV-8 Infection in SOT Recipients

The first cases of KS occurring as complication of SOT were reported in the 1990s [96]. Since then, post-SOT HHV-8-related syndromes have been extensively described and include not only KS but also Castleman disease (aptly termed

iatrogenic Castleman disease in the post-SOT setting), primary effusion lymphoma, and severe non-neoplastic complications such as bone marrow failure or multiorgan dysfunction [97–100]. Most of these studies have been conducted in areas of the world in which HHV-8 is endemic, such as Italy, the Mediterranean, and the Middle East.

Epidemiology, Risk Factors, and Clinical Manifestations

HHV-8 infection after SOT represents either reactivation of latent infection or donor-derived transmission [96, 98, 101, 102]. Seroprevalence studies have suggested that primary infection from an exogenous source can also occur [103]. Risk factors other than the presence of HHV-8 antibodies include male gender, African or Middle Eastern origin, older age at transplant, and use of lymphocyte depleting induction therapy [104, 105]. HHV-8 usually presents within the first year of transplant [99], though late cases occurring nearly a decade later have been reported [90]. It is most common in adults and rarely occurs in the pediatric population [106].

Overall, KS after SOT is relatively uncommon, with incidence rates of 0.5% in the United States, 0.6% in France, 1.6% in Italy, 2.4% in Israel, 4% in South Africa, and 5.3% in Saudi Arabia [2]. KS represented 16% of all transplant malignancies in a registry of kidney transplant patients from Greece [107]. Cutaneous disease predominates, with visceral and lymph node involvement being less common. Allograft involvement with KS tumors has been described, particularly in donor-derived cases [108–110]. Prognosis of cutaneous disease is excellent, with lesions typically regressing simply with reduction of immunosuppression. Visceral involvement however is associated with a high risk of mortality. HIV infection does not impact the natural history of post-SOT KS [111], which is not surprising given the good graft, patient, and infection-related outcomes of HIV-infected SOT recipients in the current era [112]. Valganciclovir prophylaxis to prevent CMV is ineffective in preventing HHV-8 infections [113].

Some very late cases of HHV-8 infection have been described, such as a patient who succumbed to HHV-8-related primary effusion lymphoma 10 years after undergoing a liver transplant [90]. Other atypical cases have also been reported, such as a heart transplant recipient with both multicentric Castleman disease and KS [114], hemophagocytic lymphohistiocytosis (HLH) [115], Castleman disease occurring concurrently with Epstein-Barr virus-associated posttransplant lymphoproliferative disease [116], and a fatal case of a liver transplant recipient with three distinct donor-derived HHV-8-related entities occurring simultaneously: KS, multicentric Castleman disease, and HLH [117].

An emerging entity after SOT is the Kaposi sarcoma-associated inflammatory cytokine syndrome (KICS) [118]. First reported in HIV-infected individuals, it was recently described in a liver-kidney transplant recipient. This is a severe, non-neoplastic complication driven by lytic HHV-8 reactivation and the ensuing hyper-inflammatory host responses. KICS is characterized by markedly elevated fevers, high HHV-8 viral loads, elevated levels of pro-inflammatory cytokines, cytopenia, and organ failure. A high index of suspicion is required to establish the diagnosis and test for HHV-8 DNA in the blood. In this case, the patient survived after being

managed by reduction of immunosuppression followed by a switch from calcineurin to mammalian target of rapamycin (mTOR) inhibitors, weekly cidofovir followed by foscarnet, as well as rituximab, dexamethasone, and intravenous immunoglobulin.

In summary, HHV-8-related illness should be suspected not only in transplant patients with characteristic KS lesions but also in those who present with an acute febrile illness, systemic symptoms, lymphadenopathy, and/or multiorgan failure.

Donor and Recipient Screening

Whether organ donors and recipients residing in endemic areas would benefit from (a) screening for HHV-8 antibodies prior to transplant and (b) preemptive monitoring of HHV-8 viral loads (with reduction of immunosuppression at the onset of viremia) is unknown but is an area of active investigation. This is not yet standard of care in part because whether this strategy will improve outcomes is unclear and because no reliable HHV-8 screening antibody test exists [119]. In one study from Italy, HHV-8 seroprevalence was 4% and 18% in SOT donors and recipient, respectively [98]. After transplant, 3 (25%) of 12 HHV-8-mismatched SOT recipients developed primary HHV-8 infection, one of whom developed a lethal non-malignant illness characterized by cytopenias and multiorgan system failure. Two of 93 HHV-8-seropositive recipients (2.1%) had evidence of HHV-8 viremia after transplant, but only one of these patients developed KS. None of the 20 HHV-8 low-risk (donor negative, recipient negative) patients developed any HHV-8-related syndrome. In another study, only 4 out of 89 liver transplant recipients developed HHV-8 viremia, with KS lesions developing in only 2 liver recipients and 1 kidney transplant recipient [101].

Thus, even though HHV-8 transmission, reactivation, and attributable morbidity and mortality after SOT are infrequent, HHV-8 infection can be dramatic and life-threatening in some patients. Indeed, it may be inadvisable to wait for clinical manifestations of HHV-8 to emerge, as some patients with visceral KS or KICS can rapidly succumb to their illness. In addition, HHV-8 viremia may precede overt KS after kidney and liver transplant [120, 121]. However, systematic monitoring of HHV8 viremia may lead to increased cost with no added clinical benefit, as the optimal threshold of viremia at which to intervene (e.g., reduce immunosuppression, switch to an mTOR inhibitor, etc.) and the frequency and duration of monitoring have not been defined. Additional work is needed in the form of a randomized trial comparing preemptive HHV-8 monitoring and watchful waiting, particularly in endemic areas.

Management

Reduction of immunosuppression is the mainstay of treatment, though this can result in graft rejection. In this setting, salvage chemotherapy (e.g., with doxorubicin) has been used [108]. A switch to an mTOR inhibitor may be a reasonable option for patients in whom reduction of immunosuppression is unsafe, though primary effusion lymphoma has been described in patients already receiving rapamycin [95]. Cidofovir and foscarnet have been used [98, 118, 122], but their efficacy is questionable, especially given their toxic side effect profiles.

Castleman disease and primary effusion lymphoma should be managed as per standard of care for these entities in non-SOT recipients (e.g., rituximab, chemotherapy) [123]. A kidney transplant recipient with multicentric Castleman disease experienced complete remission after only graft nephrectomy, with no other intervention required [124].

HHV-8 Infection in HSCT Recipients

There are only a handful of case reports of HHV-8-related syndromes after HSCT. Most of these have described KS or a syndrome of fever and bone marrow failure, though atypical presentations such as gingival and respiratory tract disease have also occurred [125]. Post-HSCT KS is thought to represent reactivation of latent disease after HSCT, which develops when cytotoxic T lymphocytes are unable to respond to HHV-8 proteins as immunodeficiency worsens. It is therefore not surprising that KS coincides with CD4 lymphopenia and iatrogenic immunosuppression to treat GVHD [91, 125–127]. Most cases of KS appear to be cutaneous. In many instances, the KS itself requires no specific intervention, with complete regression of lesions after T-cell recovery and discontinuation of immunosuppression. However, some patients do require KS-specific therapy such as thalidomide, topical retinoids, radiation, and even chemotherapy [91, 128]. A waxing and waning course coinciding with the reintroduction of immunosuppression for GVHD flares has been described [91]. An extensive literature search did not reveal any cases of Castleman syndrome or primary effusion lymphoma after HSCT.

In a comprehensive review of 14 cases of post-HSCT KS, 71% (10/14) of the patients were male (ratio of around 3:1), and the median age at diagnosis was 46 (range 7–69 years) [91]. The median interval from transplant to diagnosis of KS was 8.5 months (range 3–27 months). Forty three percent of patients were of Italian descent ($n = 6$), followed by Spanish (21%, $n = 3$), French, Albanian, Israeli, Jamaican, and Chinese (7%, $n = 1$ each). Underlying diseases were acute myeloid leukemia (36%, $n = 5$), chronic myelogenous leukemia (14%, $n = 2$), multiple myeloma (14%, $n = 2$), sickle cell anemia (14%, $n = 2$), NHL, primary immunodeficiency, and aplastic anemia (7%, $n = 1$ each). All but one patient had undergone allogeneic HSCT, with two patients each having received reduced intensity conditioning or T-cell depleted grafts. Eighty six percent of patients had skin involvement ($n = 12$). Fifty percent of patients had localized disease ($n = 7$ total; 5 with cutaneous disease and 2 with lymph node involvement), and the other 50% had diffuse disease (> 1 site or multiple sites: lymph nodes, oral cavity, gastrointestinal tract, and pulmonary or hepatic involvement). Only 22% of patients had bone marrow failure ($n = 3$). In total, 76% of patients had GVHD ($n = 11$, 2 acute and 9 chronic), and all of these patients were on some form of iatrogenic immunosuppression, which typically included a combination of steroids, calcineurin inhibitors, antimetabolites, and anti-thymocyte globulin. Withdrawal of iatrogenic immunosuppression was the sole initial intervention for six patients and was successful in the three who had localized disease. The other three patients had diffuse disease and

underwent various treatments, including thalidomide with topical retinoids, radiation therapy, and interferon with doxorubicin ($n = 1$ each). Other treatments included interferon with surgery and radiation, interferon with radiation and donor lymphocyte infusion, bleomycin and interferon, surgery alone, and doxorubicin ($n = 1$ each). In one case, KS regressed after the patient was switched from a calcineurin inhibitor to sirolimus [129]. Overall, KS-related mortality was 36% ($n = 5$) and only occurred in patients with diffuse involvement.

A nonmalignant syndrome of HHV-8-related bone marrow failure, rash, and fever has been sporadically described after allogeneic HSCT [102, 130, 131]. This shares some features with KICS, which is encountered after SOT and in persons living with HIV. In one such case, the patient had a progressively deteriorating course and refractory marrow failure, ultimately succumbing to respiratory failure [130]. HHV-8 DNA was documented in her peripheral blood and bone marrow. Another patient who had undergone an allogenic HSCT presented with fever, diarrhea, and pancytopenia and died of related complications [102]. Post-mortem, HHV-8 DNA was detected in serial serum samples. Testing of archived pretransplant blood revealed the presence of anti-HHV-8 antibodies, suggesting that HHV-8 reactivated after HSCT. In addition, HHV-8-infected cells were detected by in situ hybridization and immunohistochemical analysis of the aplastic bone marrow but not in two previous normal bone marrow specimens, supporting the hypothesis that infection of bone marrow cells occurred as a result of viral reactivation. Thus, clinicians need to be cognizant of atypical HHV-8 infection as the cause of irreversible aplasia in HSCT recipients. There are no data however to indicate whether these patients should be managed similarly to cases of post-SOT KICS.

HHV-8 in HSCT and SOT: Challenges and Future Directions

Future research efforts from transplant centers in HHV-8-endemic regions should focus on determining the utility of protocolized donor and recipient screening for HHV-8 antibodies. Given the paucity of data in HSCT recipients, a multicenter study of HHV-8 infection after HSCT is warranted.

Conclusions and Future Directions

Despite advances in our understanding of the biology and clinical impact of HHV-6, HHV-7, and HHV-8, much remains completely unknown. It is imperative that future studies investigate the precise role of HHV-6 and HHV-7 in various direct and indirect clinical syndromes attributed to these viruses after transplantation. Defining the host-pathogen cytokine milieu will be crucial to fully understand the pathogenicity of these viruses, particularly HHV-7, which to this day remains a relatively poorly described pathogen with uncertain clinical significance. The role of these viruses in the pathogenesis of CMV needs to be more properly defined, particularly in the setting of late-onset (post-prophylaxis) CMV infection, as well

as CMV viremia and infection in patients being managed through a preemptive approach. Larger studies are needed to standardize the diagnostic criteria and management of KICS. In transplant centers located in HHV-8 endemic countries, the role of donor and recipient HHV-8 antibody testing needs to be more robustly explored, to help the transplant community formulate evidence-based recommendations for the monitoring and treatment of these patients.

Key Points

- HHV-6 infection after HSCT or SOT typically represents reactivation of latent disease, though donor-derived cases have been described.
- HHV-6 infection occurs early after transplant and has been associated with fever of unknown origin, diarrhea, rash, pneumonitis, and encephalitis.
- Posttransplant encephalitis attributed to HHV-6 typically has a protracted course, with most patients experiencing long-term neurological deficits despite the use of antivirals.
- HHV-6 infection may confer an increased risk of cytomegalovirus infection, allograft rejection, delayed engraftment, and graft-versus-host disease.
- Chromosomally integrated HHV-6 is found in around 1% of the population and may complicate the diagnosis of HHV-6 infection after transplant.
- Chromosomally integrated HHV-6 should be suspected in patients with sustained and markedly elevated viremia, but it may not have any clinical consequences.
- It remains unclear whether HHV-6 actually causes any of the diseases attributed to it, nor is it clear whether HHV-6 leads to immune dysregulation or is simply a marker of immunosuppression.
- Treating HHV-6 is usually not warranted, except in encephalitis or fulminant cases, where ganciclovir, foscarnet, or cidofovir have been used.
- Little is known about HHV-7 after transplant except that it is similar to HHV-6 and reactivates early after transplant.
- HHV-7 is likely not clinically significant, though further data are needed to determine its role in cytomegalovirus infection and graft survival.
- HHV-8 is endemic to sub-Saharan Africa, Italy, the Mediterranean, and the Middle East.
- HHV-8 infection after transplant can either be donor- or recipient-derived.
- HHV-8 infection after SOT causes Kaposi sarcoma, multicentric Castleman disease, primary effusion lymphoma, nonmalignant syndromes of bone marrow failure, and an inflammatory cytokine syndrome.
- Screening organ donors and recipients for HHV-8 antibodies to risk stratify patients for HHV-8 infection after SOT may be considered in endemic regions, though additional data are needed.
- HHV-8 has rarely been described after HSCT and is only known to cause KS and bone marrow failure.
- Increased immunosuppression is a risk factor for KS, and patients with cutaneous lesions recover with reduction in immunosuppression.

- mTOR inhibitors may play a role in treating KS after transplant.
- Antivirals should not be routinely used to treat HHV-8 infection.
- Routine monitoring for HHV-6, HHV-7, or HHV-8 should not be performed.
- Antiviral prophylaxis does not prevent HHV-6, HHV-7, or HHV-8 infection.

Introduction

In past decades, because of advances in surgical technique and development of new immunosuppressive medications, the outcome of solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) has been improved. However, even with development of antimicrobial prophylaxis and infection prevention methods, we still see a high incidence of bacterial, viral, and fungal infections in these immunocompromised hosts. Among the most common posttransplant infections are respiratory viral infections, including influenza virus, respiratory syncytial virus, parainfluenza virus, rhinovirus, adenovirus, and human metapneumovirus. Influenza virus infection causes high morbidity and mortality in this population. Influenza virus is a RNA virus which can cause acute febrile respiratory infection. Influenza virus is in the family of *Orthomyxovidae*. The clinical presentation of influenza infection in immunocompromised hosts varies and frequently differs from manifestations of influenza in the general population. The rate of lower respiratory tract infection is higher in transplant populations due to deficiencies of cellular and humoral immunity and may result in severe disease. Patients with lower respiratory airway disease, more aggressive immunosuppression, and late initiation of antivirals tend to have worse outcomes. Vaccination should be the major strategy to prevent infection, but immunogenicity after influenza vaccination is still suboptimal in transplant recipients.

This chapter focuses on influenza infection in both SOT and HSCT populations and will focus on disease epidemiology, clinical symptoms, treatment, and vaccination.

Influenza Incidence in SOT Recipients

The reported incidence of influenza in SOT recipients varies year to year and between seasonal influenza and pandemic influenza. A recent pandemic A(H1N1) influenza infection occurred in 2009.

For seasonal influenza, there have been several studies in transplant recipients. One single center retrospective study in Brazil demonstrated that the incidence of influenza virus infection in kidney transplant recipients was 26.5 cases/1,000 person-years [1]. A previous large study states the incidence of influenza in kidney, liver,

and lung transplant recipients was 4.3, 2.8, and 41.8 cases/1000 person-years, respectively [2].

During the influenza pandemic, an Australian multicenter retrospective study found a 3% incidence of infection in the lung transplant population in 2009 [3]. A influenza study from Singapore documented an incidence of approximately 20 cases/1000 person-years in kidney or liver transplant and 37 cases/1000 person-years for heart transplantation in 2009 [4]. There should be some reporting bias because the transplant population were more likely to be tested and might therefore have a higher reported incidence as compared to the general population.

The aforementioned reports focus on influenza A virus infection. There are fewer published reports regarding influenza B virus infection in SOT recipients.

Reports confirm that influenza can cause donor-derived infection [5]. Four recipients including two kidney, one liver, and one lung transplant recipient received organs from a single influenza B-positive donor [5]. One kidney and one lung transplant recipient developed influenza B virus infection soon after transplant, which was confirmed by polymerase chain reaction method [5]. Because of the timing early after transplant and infection in two recipients from the same donor, the authors concluded those infections were highly likely to have been donor derived [5].

Influenza Incidence in HSCT Recipients

A recent study from Australia showed that 9/382 recipients developed influenza infection within 100 days after HSCT [6]. Also, within 2 weeks of scheduled HSCT, one report from the USA documented that 10/458 (2%) patients tested positive for influenza virus with qualitative PCR method [7]. All of them had symptoms at the time of detection [6]. One patient out of 10 continued to show positivity even after transplant; influenza was thought to have ultimately contributed to their death [7].

Incidence of Hospital Admission and Intensive Care Unit (ICU) Admission After Influenza Infection in SOT and HSCT Recipients with Influenza Virus Infection

Hospital Admission

One retrospective cohort study done by Katzen et al. showed some benefit in shortened length of hospital stay when oseltamivir therapy was initiated soon after admission in the general population [8]. Oncology patients required longer duration of hospitalization [8]. In this study, around 5% of the study population were SOT recipients [8].

In an SOT population, hospital admission was required in 70% in a multicenter study of the A(H1N1) pandemic in 2009 [9]. For seasonal influenza, among SOT and HSCT recipients with positive influenza polymerase chain reaction (PCR) test, 373/561 (66.5%) were admitted with median of 6 days (interquartile range 3–14 days) in a multicenter prospective study [10].

ICU Admission

ICU admission in SOT recipients was seen in 16% of patients enrolled in a multicenter study of pandemic A(H1N1) in 2009 [9]. Early initiation of antiviral therapy was associated with a reduction in the incidence of ICU admission in SOT recipients [9]. Receipt of antilymphocyte globulin and diabetes were risk factors for ICU admission after multivariate analysis [9].

For seasonal influenza virus, a multicenter study showed that 68 out of 616 (11.0%) SOT and HSCT recipients required ICU admission with median duration of 5 days (interquartile range 2–17 days) [10]. Over the 5-year study period, the ICU admission rates varied from 8.1% to 14.3% [10]. In multivariate analysis, both early antiviral therapy and receipt of influenza vaccine in the same season were statistically significant factors lowering the incidence of ICU admission [10]. In the pediatric group, 3/25 (12.0%) of the recipients required ICU admission [10]. Vaccination and earlier initiation of antiviral agents were associated with reductions in admission to ICU and the need for ventilation for pandemic A(H1N1) [9, 11] in 2009 as well as seasonal influenza infection [10].

Clinical Presentation of Influenza in SOT Recipients

One study showed that the presentation of influenza infection is very similar in SOT and HSCT recipients [10]. This section will explain the clinical profile based on transplant type.

Immunocompromised hosts, including SOT and HSCT recipients, are less likely than the general population to develop symptoms after infection of influenza [12]. Of note, in immunocompromised hosts, symptoms of dry cough, chills, sweats, myalgia, and shortness of breath are less frequent, though they tend to have more severe disease and complications than the general population [12].

Another prospective study from Spain showed that 80% of SOT recipients developed cough at the time of presentation [11]. The biggest multicenter study conducted for pandemic A(H1N1) showed that cough was the most frequent symptom at presentation (91%) [9]. Other accompanying symptoms included myalgia in 51%, rhinorrhea in 43%, sore throat in 43%, and headache in 32% [9].

For seasonal influenza infection, a 5-year multicenter study of SOT recipients showed that more than 80% of the recipients developed cough and around 30–40% of the recipients developed sore throat, rhinorrhea, headache, myalgias, or

gastrointestinal symptoms [10]. Also, in 51 SOT recipients in multicenter prospective study in Spain for pandemic influenza A(H1N1) infection and cough continued for a median of 3 days [11]. Symptoms varied from report to report; the important thing is to suspect influenza infection and have a low threshold for testing in an immunocompromised host with atypical symptoms.

Fever

In a multicenter prospective study conducted in the USA, Canada, and Spain between 2010 and 2015 including 477 SOT and 139 HSCT recipients, 77 percent of the patients developed influenza A [10]. At the time of presentation, fever was absent in 36.2% in total; in SOT recipients around 60% had fever [10]. Fifty-one SOT recipients (including 24 kidney, 11 liver, 8 lung, 5 heart, and 3 combined organs) were identified in a multicenter prospective study in Spain of pandemic influenza A(H1N1) infection, and 94% of the recipients developed fever [11]. Fever lasted a median of 2 days [11]. In hospitalized patients, 80% SOT recipients similarly developed fever with pandemic A(H1N1) infection [13]. In summary, we cannot rule out influenza infection in SOT recipients due to absence of fever.

Lower Respiratory Tract Infection

Lower respiratory tract infection is commonly seen in this population, although the rate varies from study to study and year to year. In a multicenter prospective study of seasonal influenza enrolling 616 SOT and HSCT recipients, lower respiratory tract infection was documented in 22.1% (11.3–35.0% in year to year) [10]. During the A (H1N1) pandemic, lower respiratory tract infection was seen in 32% (73/230) patients in a multicenter study [9]. This study also indicated that the types of imaging abnormalities seen were predominantly either air space consolidation or interstitial infiltrate [9]. In an Australian cohort, lower respiratory tract infection occurred in more than 70% of a lung transplant population with influenza during the A(H1N1) pandemic [3].

In one prospective observational study, statistically significant factors to develop lower respiratory tract infection were older age and mycophenolate usage [10]. Preventive factors were same-season influenza vaccination, calcineurin inhibitor usage, and early antiviral therapy [10].

Only 6% of the recipients had bacterial pathogens identified in respiratory specimen at the time of diagnosis in a multicenter study [9]. Coinfection with other respiratory viruses was rare, and concomitant CMV infection was noted in 3% [9]. In a 5-year multicenter prospective study of seasonal influenza infection, bacterial and viral coinfections were noted in 25/134 (18.7%) and 15/134 (11.2%) of patients with lower respiratory tract infection recipients, respectively [10].

Graft Dysfunction

Especially in lung transplant recipients, we see graft dysfunction after influenza viral infection [11]; that is one of the reasons why it is important in SOT recipients to prevent influenza infection.

Clinical Presentation of Influenza in HSCT Recipients

As noted above, generally speaking, it is less likely to develop fever in immunocompromised hosts with influenza such as HSCT recipients. For seasonal influenza infection, a 5-year multicenter study of 139 HSCT recipients demonstrated that approximately 90% of the recipients developed cough and 30–50% of the recipients developed sore throat, rhinorrhea, headache, myalgias. or gastrointestinal symptoms [10]. In another multicenter prospective cohort study enrolling 289 HSCT recipients, cough was seen in 85% [14].

Fever

One multicenter retrospective cohort study from the UK collected 60 allogeneic HSCT patients with 2009 H1N1 in 2009 [15]. Of note, 35% of the patients did not develop fever [15]. In contrast, in a multicenter prospective cohort study from Europe enrolling 222 allogeneic and 64 autologous HSCT recipients, fever was seen in around 80% [14]. For seasonal influenza infection, fever was identified in 70% of 139 HSCT recipients [10]. In summary, more than 60% of HSCT recipients were febrile at the time of presentation [10, 14, 15].

Lower Respiratory Tract Infection

Several retrospective cohort studies from Jordan and Europe reported that approximately 20–35% of the patients developed lower respiratory disease [14–16]. One study showed that 15% of lower respiratory tract infection patients required ICU admission [15]. Risk factors for lower respiratory tract disease in hematological malignancy and HSCT recipients were a lymphocyte count of less than 200 cells/ml, lack or delay of influenza-directed therapy, and impaired kidney function [17]. A second study showed that older age and lymphocytopenia were independent risk factors for lower respiratory tract disease [14].

As documented above, symptoms may differ from the general population. The European Centre for Disease Prevention and Control provided a modified definition so that it could capture influenza like disease diagnoses earlier and easier [18]. Again, to detect influenza infection in immunocompromised hosts, a lower index of suspicion is necessary especially during influenza season, as they may lack typical symptoms.

Diagnosis

Currently, diagnosis is usually made with nucleic acid amplification testing. This technique is commercially available and has great specificity. Nasopharyngeal swab, wash, or aspirate specimens are widely used on initial presentation because they are easy to obtain. Bronchoalveolar lavage may sometimes provide a better specimen for diagnosis.

One multicenter prospective study showed that the duration of viral shedding was longer in an immunocompromised group [12]. The majority of participants in this study were hematologic malignancy patients [12].

A recent large multicenter prospective observational study of viral shedding in hematologic malignancy patients and SOT recipients showed that by day 3, 24% of all patients achieved viral load negativity and by day 6, more than half of all patients achieved viral load negativity of nasal swab specimens [10]. On the other hand, 25% of the patients at day 11 and 7.1% at day 18 still showed positivity [9]. However, in 4 weeks, no patients tested positive [10]. Interestingly, higher viral load at onset and delayed clearance were correlated with lower respiratory tract disease and ICU admission [10]. Also, this study showed that viral load was higher in the hematologic malignancy group as compared to the SOT group [10]. Although some reports showed resistance to oseltamivir [19, 20], oseltamivir should still be the first choice of treatment in immunocompromised patients. Also, the risk of resistance was correlated with immunosuppression and prior exposure to oseltamivir [21]. Resistance to neuraminidase inhibitors is uncommon in influenza A(H3N2) and influenza B viruses [21]. Guidelines recommend checking for antiviral resistance in recipients on appropriate antiviral therapy with prolonged viral shedding and/or prolonged symptomatic infection [21].

Treatment and Outcomes

Transplant populations are thought to be at higher risk after influenza infection. There are several mostly observational studies published. In some observational, retrospective, or prospective studies in either HSCT or SOT recipients, oseltamivir and zanamivir have been used for treatment [9, 10, 14, 15]. There are currently insufficient data about other antiviral therapies for influenza infection in the immunocompromised host.

The minimum recommended treatment duration is 5, days but therapy may be prolonged based on symptoms [21]. There are several observational studies of treatment duration. Median time of treatment duration in the biggest multicenter study for pandemic A(H1N1) in 2009 was 5 days [9]. This was also noted in another prospective study. The majority of the participants were treated with oseltamivir, either standard, high or low dose, with median of 5 days [10]. About 4% of the patients received more than 10 days [10]. Practically, some doctors recommend to repeat an influenza viral panel at the 5th day of the treatment in symptomatic

patients. If viral shedding is documented, some physicians prolong the therapy up to 10 days with either oseltamivir or zanamivir.

Adjunctive Therapy

Immunosuppression was reduced in 22% of patients in a multicenter study of pandemic A(H1N1) in 2009 [9]. This was also noted in another prospective observational multicenter study in which 17.4% of the patients had reductions in immunosuppressive medications for seasonal influenza [10]. In a multicenter study in Australia, 16/24 recipients received increased corticosteroid (prednisolone 1 mg/kg/day, at most 60 mg), and only 1/24 reduced immunosuppression for pandemic A (H1N1) influenza infection in lung transplant recipients [3]. Currently, there is no consensus about whether to reduce or increase immunosuppression when influenza is diagnosed though reduction of immunosuppressive medications is recommended in a current guideline for SOT recipients [21].

Risk Factors for Mortality and ICU Admission

In a multicenter study of pandemic A(H1N1) in 2009, even after treatment with oseltamivir, the mortality was 4% with death occurring a median of 15 (range 4–88) days after symptom onset [9]. In the other multicenter study for seasonal influenza infection in both HSCT and SOT recipients, death within 30 days after diagnosis was found in 2.9% [10]. In this multicenter study, authors did not perform risk factor analysis for mortality because the mortality was too low to perform the analysis. Vaccination and earlier initiation of antiviral agents were associated with reduced mortality especially in SOT recipients with pandemic A(H1N1) infection [9, 11]. One multicenter prospective observational study showed that neutropenia and older age were the risk factors for death of HSCT recipients with influenza virus infection [14].

Prophylaxis

Chemoprophylaxis

A randomized controlled trial showed approximately 80% efficacy with a good safety profile with oseltamivir prophylaxis in HSCT and SOT recipients [22]. Guidelines recommend postexposure prophylaxis in high-risk SOT patients such as lung transplant recipients, recipients receiving antirejection therapy, and recipients early post-transplant [21]. However, there is very little evidence regarding target population, duration, timing, prophylaxis medication, or dosage for either SOT or HSCT recipients currently.

Vaccination

Vaccination should be one of the best options to prevent influenza infection. However, the response to the vaccine is often insufficient or suboptimal in immunocompromised patients. Also, there is no study identifying a reduced incidence of influenza infection through vaccination though there are some data regarding immunogenicity after vaccination in this specific population. This section will discuss when, how, and what influenza vaccine should be used for SOT and HSCT recipients.

Influenza Vaccination in SOT Recipients

There have been many vaccine trials attempting to achieve better immunogenicity in the SOT population. The vaccine response improves with time after transplantation as the level of immunosuppression decreases; however influenza is a seasonal illness and might require vaccination at a specific time of year, based on the location where patients live. The American Society of Transplantation recommends initiating influenza vaccination as early as 3 months after transplantation in their current updated guideline [23]. In contrast, the Kidney Disease: Improving Global Outcomes (KDIGO) guideline recommends starting 4 weeks after kidney transplantation [24]. There is no study which could determine the exact date to initiate influenza vaccination after SOT; this may even vary by organ transplanted. One report documented that with adjusting confounders, there was no correlation between time from transplant and response to influenza vaccination when compared from 1 month to 6 months after transplant and more than 6 months after transplant [25]. The limitation of this study is that one third of recipients received adjuvanted vaccine and the rest of the recipients received standard vaccine so the groups may not be comparable. In contrast, Baluch et al. documented that vaccine response was more likely to be seen in recipients more than 6 months post-transplant [26].

Two current guidelines state that there is no need to repeat influenza vaccination in the same season if the recipients received vaccination prior to transplant. [22, 23]. This may require further study. In summary, we may be able to initiate influenza vaccination 1 month after transplant, but the reaction to influenza vaccination might be suboptimal especially soon after transplant.

Vaccine Strategy

Previous reports documented insufficient immunogenicity with standard influenza vaccination. To overcome this issue, several methods have been tried to improve outcome.

Repeated Vaccination

There is a randomized controlled trial documenting this method in SOT recipients [27]. Cordero et al. published an open-label, phase 3 randomized controlled clinical trial evaluating the efficacy of repeated (5 weeks apart) single-dose standard vaccine, comparing to single standard vaccine administration in SOT recipients [27]. Two-dose vaccination was associated with a higher seroconversion rate only for A(H1N1) pandemic at 10 weeks, but not other included viral antigens, in the modified intention to treat analysis [27]. However, there was a statistically significant difference with per-protocol analysis, possibly because it was difficult for this population to get vaccinated twice [27]. Also, short-term postvaccination geometric mean titers were not significantly higher in the two-dose group than in the standard group [27]. At this point it appears that if recipients could receive the second dose, it might improve outcomes.

High-Dose Vaccination

GiaQuinta et al. conducted a randomized controlled trial enrolling 63 kidney and 16 liver transplant recipients to compare double-dose and standard-dose influenza vaccination [28]. An immune response was seen in 40% and 26% in double dose and standard dose, respectively ($p = 0.174$) [28]. In the double-dose arm, more patients developed seroprotection against all viral strains after vaccination (88% vs. 69%, $P = 0.048$) [28]. Natori et al. published a randomized controlled trial comparing high dose, which contained fourfold antigens and standard-dose influenza vaccine in SOT recipients [29]. They studied 84 high-dose and 77 standard-dose vaccine group patients [28]. Seroconversion to at least one vaccine containing antigen was statistically significantly higher in the high dose group (78.6% vs. 55.8%) [29]. Seroconversion to A(H1N1), A(H3N2), and B strains was also statistically significantly higher in the high-dose vaccine group (40.5% vs. 20.5%, 57.1% vs. 32.5%, and 58.3% vs. 41.6%, respectively) [29]. Postimmunization geometric mean titers of A(H1N1), A(H3N2), and B strains were also significantly higher in the high-dose group [29]. There was no statistically significant difference in side effects, but the sample size was too small to assess the rate of adverse events with this study [29].

Intradermal Versus Intramuscular

Manuel et al. reported that there was no statistically significant difference in immunogenicity between intradermal versus intramuscular vaccine administration in lung transplant recipients [30]. In this randomized controlled trial, patients received either 6 μg intradermally or 15 μg intramuscularly [30]. Forty-one patients received intradermal vaccine and 44 patients received intramuscular [30]. In the intradermal group, 14.6% of the recipients achieved response and 18.6% achieved in the

intramuscular group ($p = 0.77$) [30]. Seroprotection was statistically significantly higher in the intradermal group for H3N2 and B strains [30]. Morelon et al. reported higher seroconversion and seroprotection rates for influenza A(H1N1) and A(H3N2) but not influenza B in the intradermal group [31]. However, those were not statistically significant differences [31]. Baluch et al. compared high-dose intradermal vaccine against standard-dose intramuscular vaccine in a randomized controlled trial [26]. One hundred five recipients received intramuscular vaccine, and 107 recipient received intradermal [26]. Seroprotection to H1N1, H3N2, and B strains were not statistically significantly different between the groups [25]. Seroconversion to at least one antigen was also similar between groups (46.7% vs. 51.4%, $p = 0.49$) [26]. In summary, to date several randomized controlled trials found similar responses between intradermal and intramuscular influenza vaccination in SOT recipients.

Adjuvanted Vaccine

There are two adjuvanted vaccines available, which are MF59 and AS03. Kumar et al. conducted a randomized controlled trial comparing MF59-adjuvanted versus standard influenza vaccine for kidney transplant recipients [32]. Thirty-one recipients received adjuvanted vaccine, and 29 recipients received standard vaccine [32]. There were no statistically significant differences in seroconversion, seroprotection, and geometric mean titers seen between groups [32].

AS03-adjuvanted vaccine is generally used for pandemic A(H1N1) vaccine. One study enrolling only five recipients (one liver, two kidney, and two lung transplants) found only one recipient achieved seroprotection after vaccination. The number of patients was too small to conclude anything about vaccine performance [33].

Influenza Vaccination Side Effects in SOT Recipients

There have been some concerns with influenza vaccine causing rejection due to developing immunogenicity after vaccination. Some studies assessed HLA antibodies after immunization, and one of them showed that 11.9% of the recipients developed new anti-HLA antibodies.

A recently published systematic review and meta-analysis documented that there was no increased rate of rejection after vaccination when compared to the unvaccinated group [34]. In this systematic review, the incidence of de novo DSA was assessed in 14 studies and it was 1.85%, occurring between 21 and 94 days after vaccination [34]. The incidence of rejection was assessed in 83 studies and was 2.1%, presenting between 0.7 and 6 months after vaccination [34].

Also, there were no increases in HLA alloantibodies in patients who received adjuvanted vaccine [32]. In summary, there is high safety profile for influenza vaccine so far, and no statistically significant difference has been shown in the incidence of rejection in published data.

Vaccination in HSCT Recipients

Similar to the SOT population, there is no study indicating that vaccination will reduce the incidence of influenza infection in HSCT recipients, though one cross-sectional study documented that the rate of hospital admission may be reduced with influenza vaccination [35].

Timing of Vaccination

Recently, the European Conference on Infections in Leukemia (ECIL 7) updated their guideline for vaccination of HSCT recipients [36]. This guideline recommends one dose of seasonal vaccine annually at the beginning of influenza season [36]. Within 1 year after transplant, they also recommend to initiate vaccination 6 months after HSCT [36]. They also recommend an additional vaccine dose administered 3–4 weeks later in high-risk patients such as severe graft-versus-host disease patients or patients with low lymphocyte counts [36]. Even though there is insufficient evidence, they recommend vaccine initiation within 3 months after HSCT if there is a community outbreak.

Vaccine Strategy

Repeated Vaccination

One randomized trial compared immunogenicity between a regular influenza vaccination strategy of single dose versus two doses, 1 month apart [37]. Authors enrolled 65 patients whose transplant occurred more than 2 months previously [37]. The authors could not find any benefit with the two-dose vaccination strategy [37]. There were no documented side effects with repeated vaccination [37]. Again, current guidelines recommend repeated vaccination in the high-risk population.

High-Dose Vaccination

One study enrolled 44 recipients and 15 received standard dose and 29 received high dose. All recipients were vaccinated at least 6 months after transplantation [38]. More injection-site symptoms were noted in the high-dose group [38]. After vaccination, the high-dose group achieved a higher percentage of seroprotection and a higher geometric mean titer against the H3N2 strain [38]. Because of the small study population, it is very difficult to draw conclusions though high-dose vaccine might have some benefit [38].

Adjuvanted

Adjuvanted (MF59) versus standard influenza vaccine was tested by Natori et al. [39] Seroconversion to at least one of three influenza antigens was present in 62.9% versus 53.1% in adjuvanted versus non-adjuvanted vaccine, which was not statistically significant [39]. Factors associated with lower seroconversion rates with multivariate analysis were use of calcineurin inhibitors and shorter duration from transplantation [39]. AS03-adjuvanted vaccine was also studied by Engelhard et al. [40] Authors enrolled 55 allogeneic and 23 autologous HSCT recipients during the 2009 influenza pandemic season (21216315). Authors concluded that two doses of AS03-adjuvanted vaccination should be effective in this population [40]. Mohty et al. also compared 65 HSCT patients with AS03-adjuvanted vaccine group and 138 healthy control group, who received regular vaccine [41]. There was no difference between AS03-adjuvanted HSCT group and healthy controls with regular vaccine in that study although this is not a comparison between regular vaccine and adjuvanted vaccine in the same patient group [41].

Again, even with adjuvanted vaccine, published data could not show statistically significant differences between single-dose regular influenza vaccine and adjuvanted vaccine in HSCT recipients.

Donor Vaccination and Pre-HSCT Vaccination

One study conducted by Ambati et al. documented that pretransplant influenza vaccination could be beneficial even as compared to donor vaccination and no vaccination prior to transplant [42]. Authors concluded pre-HSCT vaccination could improve the seroprotection rate until day 180 after transplantation [42].

Conclusion

Influenza infection has significant morbidity and mortality in SOT and HSCT recipients. It is important to provide proper vaccination to these patients so to prevent infection. Also, when influenza virus infection is suspected in transplant recipients, antiviral medication should be initiated as soon as possible to optimize outcomes.

Key Points

- Influenza infection is commonly seen after transplantation.
- Symptoms of influenza infection may vary. It is important to suspect influenza with atypical presentations in the immunocompromised host.
- Fever may be absent in SOT or HSCT recipients with influenza infection.
- Nucleic acid amplification testing has become the main method of diagnosis.

- Oseltamivir and zanamivir are the main medications used to treat influenza virus infection in this population.
- Lower respiratory infection has been documented in 11.3–35% of transplant recipients with influenza; the incidence varies year to year.
- Lower respiratory tract infection, delayed initiation of antivirals, and infection early post-transplant are factors associated with poor outcomes in SOT and HSCT recipients.
- To prevent influenza infection, vaccination should be provided.
- Influenza vaccination may be administered as early as 1 month after transplant, but the immunologic response may be suboptimal early after transplant.
- In SOT recipients, either high-dose vaccine or repeated regular-dose vaccine should be recommended. In HSCT recipients, vaccination itself must be recommended, but it is still not known which type of inactivated influenza vaccine should be used.
- To achieve better outcomes, as soon as the diagnosis of influenza is suspected in SOT and HSCT recipients, neuraminidase inhibitor therapy should be initiated while waiting for the confirmatory test result.

Introduction

Respiratory syncytial virus (RSV) is a nonsegmented RNA virus belonging to the family *Paramyxoviridae* with two major antigenic subgroups – A and B. It has a worldwide distribution and is a frequent cause of both upper and lower respiratory tract infections. It poses particularly high risk to patients who have undergone allogeneic hematopoeitic stem cell and lung transplantation. This review focuses on the most recent strategies aimed at preventing or treating RSV.

Disease Epidemiology

Although the major morbidity and mortality occurs in children under 2 years of age, it has been increasingly recognized as a significant pathogen in adults with a disease burden similar to nonpandemic influenza A [1]. RSV typically occurs as annual or biennial seasonal epidemic in temperate climates, usually lasting from fall through spring [2, 3]. This is from October to May in the Northern Hemisphere and from May to September in the Southern Hemisphere. Disease in tropical climates can be more variable in onset and duration but often coincides with the rainy season [3, 4]. In the United States, the Centers for Disease Control and Prevention tracks RSV as part of the National Respiratory and Enteric Virus Surveillance System (NREVSS). Data is collected from participating laboratories around the country who submit information on the number of positive tests out of the total number of tests collected per week. Information on the current year can be found at https://www.cdc.gov/surveillance/nrevss/rsv/index.html. As detection methods have shifted to more sensitive molecular techniques such as polymerase chain reaction (PCR) testing, new statistical analysis has resulted in lengthening of the RSV season and changes in peak activity [2]. In addition, the availability of this technology has allowed documentation of nosocomial acquisition of infection and hospital outbreaks [5, 6].

RSV occurs in 3–7% of healthy elderly patients and is found in 1.3–9.2% of adults with a variety of medical conditions presenting to medical attention for acute respiratory tract infections [1, 7]. Within the immunocompromised patient population, the major groups at risk include hematological stem cell transplant recipients and lung transplant recipients. The periodic pattern of risk and onset of the season appears to match that of the general patient population [8]. RSV is estimated to affect 1–12% of hematopoietic stem cell transplant (HSCT) recipients and 2–16% of lung transplant recipients although incidence calculations vary depending on the cohort selected, season, testing method, and follow-up duration (see Table 1 for references and ranges). Some studies limit their patient population to hospitalized patients versus the entire cohort at risk. Studies that follow patients over several years result in the inclusion of patients with recurrent infections in different seasons, while studies confined to short time frames after transplant will usually isolate only the cases in a single season. Changes in testing methods to more sensitive techniques have led to increases in detection rates and higher rates over time [8]. In addition, outbreaks have been reported on high-risk units where vulnerable patients have prolonged stays such as the hematology-oncology ward [5, 6]. These can be challenging to manage, requiring intensified infection control precautions to break the cycle [9].

Incidence rates in other adult transplant groups are less well characterized. Given that children have the highest burden of disease overall, it is not surprising that there are multiple studies in pediatric solid organ transplant (SOT) and stem cell transplant recipients. Rates have varied depending on the group studied and year, but a recent review found that overall the incidence varied between 18 and 72 per 1000 children, with higher incidences in the first 2 years after HSCT or solid organ transplantation [10].

Table 1 RSV incidence in transplant populations

Reference	RSV Test	Location	Year	N	Incidence
HSCT					
Martino et al. [11]	DFA/ culture	Prospective cohort, single center (Spain)	1999–2003	172 allogeneic, 240 autologous	7.5% 2-year cumulative incidence (allo), 2.9% (auto)
Williams et al. [12]	DFA/ culture	Prospective cohort, single center (Spain)	1999–2004	198 allogeneic, 296 autologous	6.6% over 4 years (allo), 2.7% (auto)
Peck et al. [13]	PCR/ DFA/ culture	Prospective cohort, single center (Seattle, WA)	2000–2004	814 allogeneic and autologous transplants	5.8% cumulative incidence at day 100
Schiffer et al. [14]	DFA/ culture	Retrospective cohort, single center (Seattle, WA)	1997–2005	2,013 allogeneic, 751 autologous	1.4–2.1% cumulative incidence at day 100 (allo), 0.7% (auto)
Avetisyan et al. [15]	DFA/ culture	Retrospective cohort, single center (Sweden)	2000–2007	275 allogeneic	11.6% over 7 years
Nichols et al. [16]	Not specified	Retrospective cohort, single center (Seattle, WA)	1989–1999	3,897 total	4.5% overall attack rate, 10% during winter
Lung transplant					
Weinberg et al. [17]	PCR/ viral culture	Prospective cohort, single center (Denver, CO)	2005–2007	60	11.6%
Milstone et al. [18]	PCR/ serology/ viral culture	Prospective cohort, single center (Nashville, TN)	1999–2000	50	16%
Gottlieb et al. [19]	PCR/IF/ culture	Prospective cohort, single center (Germany)	2005–2006	388	1.8%
Pediatric					
Pohl et al. [20]	ELISA/ culture	Retrospective cohort, single center (Pittsburgh, PA)	1984–1991	493 liver recipients	3.7% over study period

(continued)

Table 1 (continued)

Reference	RSV Test	Location	Year	N	Incidence
Feldman et al. [21]	Not specified	Retrospective cohort, multiple centers (United States)	2004–2012	2554 liver recipients	5.3% of hospitalizations over study period
Rowan et al. [22]	PCR/ DFA/ culture	Retrospective cohort, multiple centers (United States)	2010–2014	1522 HSCT, both allogeneic and autologous	3.1% over study period
Hutspardol et al. [23]	Culture/ DFA/ PCR	Retrospective cohort, single center (Toronto, Ontario)	2000–2012	844 HSCT, both allogeneic and autologous	1.8% cumulative incidence at day 100

Clinical Impact in Transplant

The impact of RSV in the general inpatient population rivals that of influenza including the need for care in the intensive care unit (ICU), mechanical ventilation, and mortality [1]. Among the transplant population, there is a significant risk of morbidity and mortality. In both HSCT and SOT recipients, RSV infection can lead to the need for mechanical ventilation and ICU admission. In one study, 15% and 7% of HSCT recipients needed ICU admission and mechanical ventilation, respectively, compared with 18% and 14% of SOT recipients [8]. Overall, 5% and 11% of HSCT and SOT recipients died in that study. In another multicenter study, 67% and 83% of allogeneic HSCT and SOT recipients required hospital admission, respectively, and 17% and 10% required mechanical ventilation [24]. Sixty-day mortality was 8.3% and 13.3%, respectively. Not every paper has been consistent in these findings. A 2010 series from Switzerland reported a low number of complications in their lung transplant cohort despite the fact that patients were not specifically treated [25]. Conversely, higher mortality rates have been found in some HSCT cohorts with lower respiratory tract disease. In one study, 30- and 90-day mortality rates were 39% and 47% following the diagnosis of RSV [26].

Beyond ICU admission and death, RSV can either lead to secondary bacterial pneumonia or present along with bacterial, viral, or fungal coinfection. In the Andersen study, 52% of their transplant patients (both HSCT and SOT) received bacterial or fungal therapy following their RSV diagnosis although only 42% of those patients had microbiologically documented infection [24]. Unique to lung transplant recipients, RSV infection can lead to the development of chronic lung allograft dysfunction (CLAD) which is a leading cause of death in this patient population [27]. Avoidance of all community-associated respiratory viruses is

critical in this patient population, and RSV is particularly feared due to the severe inflammatory reaction induced by the patient's own immune system that is part of its pathogenesis [28]. In the HSCT patient population, early infection posttransplant has a high risk of progressing to lower tract disease and death [29]. As a result, patients with pretransplant RSV infection are in a difficult situation; delay in conditioning poses a risk of relapse, but continuing with therapy may result in RSV lower tract infection and death.

Disease Diagnostics and Clinical Evaluation

Detection of RSV can occur by viral culture, serology, direct fluorescent antibody (DFA) and immunofluorescent antibody assays, rapid antigen testing, and nucleic acid amplification tests (NAAT). Viral culture was once considered the gold standard but has now given way to more rapid, sensitive molecular tests [30]. Similarly, serological diagnosis relies on collection of both acute and convalescent specimens making it more of a historical or research method rather than a tool for diagnosis and management of individual patients [28]. There was a lot of interest in antigen assays, particularly because they did not necessarily require a laboratory and could be used for point-of-care testing with rapid turnaround times. However, antigen assays perform poorly in adults or during periods when the disease incidence is low; they are more reliable in pediatric populations [31]. As a result, molecular methods, particularly single and multiplex PCRs, have now become the new gold standard for respiratory viral detection. In the case of multiplex assays, they have the potential to detect coinfections. Moreover, certain molecular assays have been developed to function as point-of-care tests.

However, all diagnostic testing has limitations. Molecular assays may be commercially available or laboratory-developed with the potential for small variations in test characteristics between assays. In general, most molecular tests have a high sensitivity and negative predictive value. Nevertheless, they are not impervious to false negatives which can occur either from error during collection, transport, or processing of the specimen or from mutations in the virus [32]. In addition, site and collection method may impact whether the virus can be detected. Nasopharyngeal aspirates were the traditional gold standard, but depending on the patient population, this may not be feasible [30]. For example, nasal washes may be used if there is concern about bleeding; however, there can be difficulty in obtaining a good specimen with this technique. Patients with lower tract disease may have negative tests in their upper tract. Bronchoscopy with lavage may be necessary to obtain a specimen for testing. In addition, positive tests can also be difficult to interpret with respect to ongoing active infection and risk of transmission. Immunocompromised patients can have detectable PCR results for many weeks after acute infection, often longer than culture positivity [33]. On average, patients with hematological malignancies or solid organ transplants can have detectable virus for 2–4 weeks after acute infection [33–35]. Although there is interest in using the viral load and its relationship to severity of

illness or risk of transmission, there is no consistent data yet on how to use this clinically [30].

Transplant patients presenting with symptoms of a respiratory tract infection should be evaluated for RSV, particularly during the appropriate epidemiological season. Initial signs can be subtle and may be mistaken for symptoms of mucositis, anemia or deconditioning (dyspnea), or allergy. Asymptomatic carriage is also possible [6]. In cases of outbreaks, routine, periodic surveillance of the entire cohort may be necessary to terminate the outbreak in order to pick up these asymptomatic individuals.

Testing should include some form of sensitive viral assay – preferably a molecular test – as well as evaluation for lower tract disease as this has prognostic implications. Lower respiratory tract infection has a higher risk of complications including mortality [36]. Risk factors for progression to lower tract infection and poor outcome in HSCT patients include smoking, neutropenia, lymphopenia (especially <100 cells/mm^3), age >40, recent transplant, use of a myeloablative conditioning regimen, use of high-dose total body irradiation as conditioning, acute or chronic GVHD, and corticosteroid intake in 30 days before infection [37, 38]. Higher lymphocyte counts appear to be protective. A subset of these factors have been used to stratify patients for treatment (immunodeficiency scoring index) at one center, although validation of this still needs to be performed [37]. Detection of lower tract infection should include lower respiratory tract imaging and/or sampling. Chest X-ray is less sensitive, and patients may need computed tomography to detect disease [34]. Patients should also be evaluated for co-pathogens. Damaged lung tissue is susceptible to secondary bacterial infection although co-pathogens have been reported to be bacterial, viral, or fungal. Careful evaluation for these pathogens should be performed; however, more patients end up on antibacterial or antifungal therapy than have documented coinfections, so judicious use to avoid unnecessary therapy is recommended [24].

Prevention

Infection Control

Given the severity of disease and associated sequelae of RSV infection in HSCT and SOT recipients, and the relative lack of currently available therapeutic options, modalities to prevent disease are an essential component to the management of this infection in vulnerable patient populations. Due to the risk of spread, patients must be isolated ideally as soon as infection is suspected while workup is still pending. At minimum, patients should be placed in contact isolation [39]. National recommendations vary with both droplet and contact isolation precautions recommended by the Public Health Agency of Canada (PHAC). Institutions may want to implement more stringent droplet precautions given it can be transmitted by the respiratory route or even airborne precautions for ventilated patients [6]. Ideally, immunocompromised patients should not be cohorted together, and even patient and visitor activities may

need to be limited during outbreaks to prevent spread [9]. Transplant units should employ several strategies to prevent the acquisition of respiratory viral infections. It is recommended that good hand and respiratory hygiene be strongly encouraged, all visitors and healthcare providers with signs of respiratory illness be restricted from the patient environment, and young children be prevented from visiting transplant wards due to the high risk of respiratory viral transmission [40].

The duration of isolation precautions is unknown given the propensity for prolonged shedding. In immunocompromised hosts, prolonged respiratory viral shedding can occur on average for 2–4 weeks, but it has been reported for as long as 162 days [41]. Prolonged shedding potentially extends the period of infectivity and increases the opportunity for disease transmission. Some centers will require a negative repeat test as there is a potential continued risk of transmission as long as patients have detectable virus. However, it is clear that the sensitivity of the newer molecular tests may result in very long isolation requirements, and this can become very burdensome to manage during outbreaks when bed space is limited. Based on the 1998 guidelines, healthcare workers with febrile acute respiratory infections should be excluded from caring for high-risk patients [42]; an update is forthcoming. However, transmission is more likely to occur from immunocompetent healthcare workers with asymptomatic shedding, which has been found in some outbreak investigations [5]. For this reason, many hospital units caring for this vulnerable patient population have instituted the use of universal surgical masks in all individuals with direct contact with patients. Studies evaluating this intervention have demonstrated a reduction in respiratory viral infections as well as deaths attributable to respiratory viral infections in the post-implementation period [43, 44].

Experience with palivizumab for prevention of RSV in at-risk children has led some centers to utilize palivizumab in high-risk patients in an attempt to prevent transmission during outbreaks of RSV [45]. However, data are lacking to establish the efficacy and moreover the cost-effectiveness of this approach. When analyzed in pediatric populations undergoing HSCT, palivizumab has not been clearly shown to be effective in the prevention of RSV infection; furthermore, restrictive strategies for palivizumab use have not been shown to lead to worse clinical outcomes [46].

Vaccine

Although an area of active research, no vaccines against RSV are currently available. Natural infection does not confer long-lasting immunity to RSV, and repeated infections over a lifetime are common [47]. Therefore, much of vaccine research is focused on finding the appropriate targets which will confer a more durable immune response and protection. Initial RSV vaccine research was hampered by concerns regarding immune enhancement following a trial in the 1960s of a formalin-inactivated candidate vaccine which caused increased disease severity in vaccine recipients with a hospitalization rate of 80% and two deaths [48]. Much of the current vaccine research targeting RSV is focused on vaccination of pregnant women with a hope of conferring immunity via antibody transfer to neonates who are at

greatest risk for the infection [49]. The highest risk period for deleterious outcomes from RSV infection in immunocompromised hosts is during the period immediately post-stem cell transplant [37]. Vaccination strategies during this period are unlikely to provide protective benefit. However, vaccination could be an important adjunct measure in the prevention of RSV infection if it was able to effectively prevent infection in close contacts, healthcare workers, and family members of vulnerable patients. Vaccination of stem cell donors is also a possible consideration to try and enhance immunity prior to graft collection.

Vaccination may be a strategy to prevent infection in lung transplant recipients, who are the other high-risk group among transplant recipients. Likely candidate vaccines being investigated would target the F protein on the virus surface administered with an adjuvant [48]. As with any adjuvant vaccine in the posttransplant setting, studies would be required to ensure that enhanced immune stimulation did not result in an increased risk of allo-sensitization and graft rejection. Additional important end points for vaccine effectiveness in the lung transplant population would be the impact of vaccination on rates and progression of BOS.

Treatment of Respiratory Syncytial Virus Infection

Ribavirin

Ribavirin is a nucleoside analogue with in vitro activity against RSV. It can be administered orally, intravenously, or via aerosol. Practice guidelines recommend the use of ribavirin and/or immunoglobulin in the treatment of RSV infection in immunocompromised individuals [50]. However, there is no consensus as to what constitutes best practice, and surveys of transplant infectious disease clinicians demonstrate a wide range of approaches [40, 51, 52].

Several retrospective studies and case series have suggested that ribavirin therapy may be beneficial in HSCT and lung transplant recipients [36, 41, 53]. Unfortunately, the only randomized controlled study to assess the efficacy of ribavirin therapy for the treatment of RSV in HSCT transplant recipients was terminated due to poor patient accrual and consequently showed no treatment difference between the ribavirin and control arms [54]. In a review of the literature for ribavirin treatment in HSCT recipients with RSV infection, a pooled analysis of study subjects found decreased progression to lower respiratory tract infection (LRTI) and decreased mortality among those treated with any form of ribavirin compared to those not treated [36]. Studies of ribavirin therapy for RSV in lung transplant recipients are generally limited by their lack of comparator group. One single center study which looked at outcomes from a retrospective analysis of paramyxovirus infection in lung transplant recipients demonstrated a reduction in development of bronchiolitis obliterans syndrome in the cohort who received oral ribavirin compared to patients who could not receive antiviral therapy due to contraindications [55].

Aerosolized ribavirin can be either given as a continuous regimen of 6 g over 18 h per day or split into doses of 2 g administered over 2–3 h every 8 h. Both treatment

schedules have been demonstrated to be equally effective at prevention of progression from upper respiratory tract infection (URTI) to LRTI [56]. The largest retrospective study of aerosolized ribavirin for treatment of RSV in HSCT recipients demonstrated that administration of aerosolized ribavirin at the URTI stage was a protective factor in preventing progression to LRTI and mortality [57]. Looking specifically at the effect of aerosolized ribavirin in HSCT patients receiving treatment at the LRTI stage, investigators found that treatment with aerosolized ribavirin was protective against mortality [26]. At least two subsequent retrospective studies in similar patient populations failed to demonstrate a benefit from aerosolized or oral ribavirin although the authors postulate that this may be related to smaller numbers and selection bias [38, 58]. Initial experience in treatment of RSV in transplant recipients utilized aerosolized ribavirin to minimize systemic toxicity. However, this method of administration is costly with recent prohibitively expensive increases in drug costs in recent years. Aerosolized ribavirin also has risks of pulmonary side effects such as bronchospasm and requires special precautions during administration which may interfere with other treatments and patient assessment. This method of administration also raises concerns regarding pregnant healthcare worker exposure and teratogenicity.

Administration of oral ribavirin is an alternative option for treatment of infection with RSV and has been shown to have similar rates of progression to LRTI and similar mortality to treatment with aerosolized ribavirin in HSCT [59]. Similarly, in a small study of lung transplant recipients, treatment with oral ribavirin did not differ from treatment with inhaled ribavirin for the outcomes of mortality or progression of bronchiolitis obliterans syndrome (BOS) although treatment choice was based on clinician preference [60]. It can be dosed in several different ways – as a fixed dose of 600 –800 mg every 8–12 h or as a loading dose of 10 mg/kg and then 20 mg/kg/day divided into three doses [59]. The bioavailability is 64% [61]. The main concern with oral ribavirin is the risk of reversible hemolytic anemia although there are additional concerns of absorption in HSCT patients with GVHD or mucositis. Despite this concern, the risk of hemolytic anemia in recent reports is low, occurring in between 1% and 5% of treated patients [62, 63]. This is rarely a treatment-limiting side effect with the average drop in hemoglobin in one study being 5 g/L. [64]

Intravenous ribavirin is available in Europe but not in North America outside of a limited supply for virologic emergencies such as Lassa fever. There are few studies of this mode of administration. Intravenous delivery overcomes the issue of absorption of the oral formulation and also penetration with the aerosolized formulation when there is significant pulmonary consolidation. A few small case series have shown intravenous ribavirin for the treatment of RSV to be relatively well tolerated with only mild hemolytic anemia reported in one study [65, 66].

Despite multiple studies examining the impact of ribavirin for the treatment of RSV infection, how best to use this treatment in vulnerable patient groups remains unclear. The lack of a prospective, randomized controlled trial definitely demonstrating efficacy and the concerns regarding cost, side effects, and logistics of administration, particularly with the aerosolized formulation, are all important considerations. This has led some authors to propose a risk stratification tool

(immunodeficiency scoring index) to decide which allogeneic HSCT patients may best benefit from ribavirin therapy, with therapy reserved for only those with high-risk scores who are at greatest risk for poor outcome [37]. The immunodeficiency scoring index considers patient characteristics including absolute neutrophil and lymphocyte counts, patient age, conditioning regimen, graft-versus-host disease, and engraftment status to assign a weighted score. Treatment stratification based on risk score demonstrated little treatment effect for those with low or moderate risk scores but a significant reduction in mortality in the high-risk group with a mortality rate of 63% in the untreated group as compared to 8% in the treated group [37]. This scoring system awaits further validation. There is no equivalent scoring system for autologous HSCT recipients and even less data in other hematological malignancies such as acute leukemia that might be at risk of poor outcome. Currently, there is center-to-center variation in practice. Similarly, outside of lung transplant where ribavirin may be used at certain centers, there is almost no data on ribavirin use in other solid organ transplant groups. Duration of therapy is also unknown as there may be differences between clinical resolution of symptoms and negative laboratory studies, particularly as testing becomes more sensitive. Both have been used as end points for therapy. Ideally, as research continues into new treatment options for RSV, these questions about ribavirin therapy may no longer need to be answered.

Immunoglobulins

Palivizumab is a humanized monoclonal antibody to the RSV fusion (F) glycoprotein. It is approved for use as prophylaxis in high-risk children during peak RSV season based on the IMpact-RSV study which demonstrated a 55% relative risk reduction for hospitalization due to RSV in infants who received prophylactic palivizumab compared to infants who did not [67]. Convincing data of the utility of palivizumab for treatment of established RSV infection however is lacking. In the transplant population, data has been limited to two small phase I studies, a few retrospective reviews, and individual case reports [16, 68]. Although it appears safe, the largest review of 40 HSCT patients did not show a difference in outcome [69]. Intravenous immunoglobulin (IVIG) is another therapy that has been proposed for treatment of respiratory viral infection for both direct antiviral activity and immunomodulatory benefits. A dose of 500 mg/kg of IVIG is commonly given by centers with variation in the number of repeats and interval of dosing. At our center, we administer a single dose, with others reporting as many as seven doses administered every other day [57]. A pooled analysis of RSV treatment in HSCT recipient found lower mortality in individuals who received a combination of aerosolized ribavirin and immunoglobulin compared to aerosolized ribavirin alone [36]. Guidelines support the use of IVIG in the management of HSCT recipients with RSV infection and specifically recommend against the use of palivizumab in this patient population [40].

Studies of immunoglobulin therapy for RSV in lung transplant recipients are limited. Similar to the concerns regarding studies of ribavirin therapy, studies of immunoglobulin therapy involve multiple components to the treatment regimen and

lack a control group. For example, 1 study of 23 cases of RSV in single-, double-, or heart-lung transplant recipients treated with aerosolized ribavirin, immunoglobulin, corticosteroids, and palivizumab demonstrated stable forced expiratory volume in 1 s at treatment follow-up. Although this was reported as being an effective therapy, all patients received all four interventions, and there was no control group for comparison [53]. Based on data from HSCT populations, American guideline recommendations are for consideration of ribavirin and IVIG plus/or minus corticosteroids in lung transplant recipients with severe infection due to RSV [50]. Despite the lack of evidence, this recommendation extends to other SOT groups with severe infection.

New Treatments

New treatments for RSV infection are needed. Several candidate therapies are at various stages of investigation. The major targets of drug development include nucleoside analogues and non-nucleoside inhibitors of RNA-dependent RNA-polymerase, inhibition of viral attachment and fusion, and inhibition of messenger RNA (mRNA) signaling (see Fig. 1).

ALN-RSV01 is a small interfering RNA (siRNA) which inhibits mRNA signaling, blocking nucleocapsid production. In a phase 2b study of aerosolized ALN-

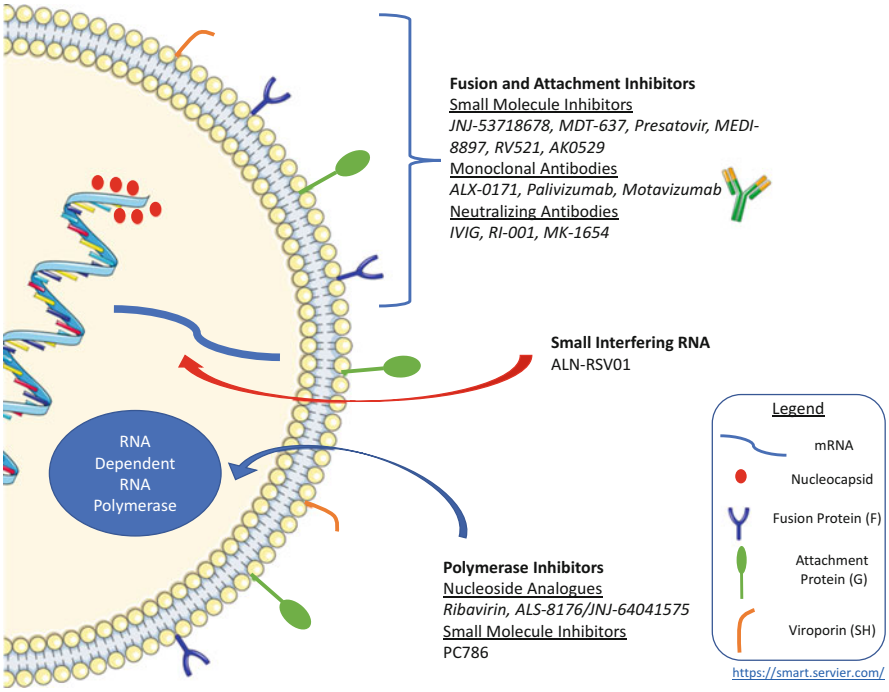

Fig. 1 Current and investigational therapies for RSV

RSV01 compared to placebo in lung transplant recipients, there was a trend toward a decrease in the development of BOS in the treatment arm which was significant in the per protocol analysis [70].

Several candidate fusion inhibitors have been explored including MDT-637, JNJ-53718678, MEDI-8897, ALX-0171, AK0529, RV521, and presatovir (GS-5806). Presatovir showed promising results in viral challenge studies in healthy volunteers. However, two recently completed phase 2b, randomized, double-blind, placebo-controlled trials of presatovir in HSCT recipients with URTI and LRTI, respectively, failed to show a reduction in respiratory failure or mortality [71, 72]. There was a trend in the URTI study for presatovir to decrease progression to LRTI. More data from these trials are coming as reports are currently limited to abstract form. In a healthy volunteer challenge study, JNJ-53718678 demonstrated reduction in RSV viral load and symptom scores compared to placebo [73]. Further clinical trials are required to establish the utility of these treatments.

ALS-8176 and ALS-8112 are nucleoside analogues with activity against RSV in vitro. Data on their treatment efficacy in hospitalized patients with RSV infection is not yet available. PC786 is a small-molecule inhibitor of viral RNA replication which is also pending further study [74].

Monoclonal antibodies against the viral F protein include palivizumab and motavizumab. Both have been studied as prophylaxis to prevent RSV infection in at-risk infants. Neither is routinely recommended for treatment of established RSV infection. Based on the efficacy of targeted monoclonal antibodies for prevention of RSV infection, researchers have investigated the possibility of an inhaled mRNA preparation which would stimulate endogenous production of anti-F antibodies and have shown this to be effective in transfected mouse models [75]. Additional neutralizing antibodies that have been assessed include RI-001 and MK-1654. More data may be coming from these molecules.

Key Points

- RSV is a common respiratory viral infection with significant morbidity and mortality in the HSCT and lung transplant populations.
- Improved diagnostics have led to better understanding of the epidemiology of this infection.
- Antiviral therapy is currently limited to ribavirin and IVIG, with support for their use primarily from observational studies of retrospective cohorts.
- New treatments are needed, and there are several candidates under evaluation.

Conclusion

RSV is an RNA virus infection with significant morbidity and mortality – particularly for HSCT and lung transplant recipients. Despite improvements in detection of this virus in recent years, there is still limited evidence for therapy. Ribavirin remains

an option, particularly for patients with severe infection: however, conclusive evidence of its efficacy is lacking. Immunoglobulin replacement is often used as an adjunctive measure. Ultimately, the best intervention is still prevention, which includes good respiratory hygiene and infection control measures to prevent nosocomial transmission from occurring. Research is still needed to find novel solutions to manage this common pathogen, including vaccination and new targeted therapies of which studies are ongoing.

Introduction

Despite significant advances in surgical and medical therapies, infections remain a significant risk for morbidity and mortality among patients who have undergone both solid organ (SOT) and hematopoietic stem cell transplantation (HSCT). Respiratory viruses, including influenza A and B, respiratory syncytial virus (RSV), parainfluenza viruses (PIV), human metapneumovirus (hMPV), human rhinovirus (hRhV), coronaviruses (CoV), adenoviruses (AdV), and bocavirus (BoV), are among the most common causes of posttransplant infections (Fig. 1) [1].

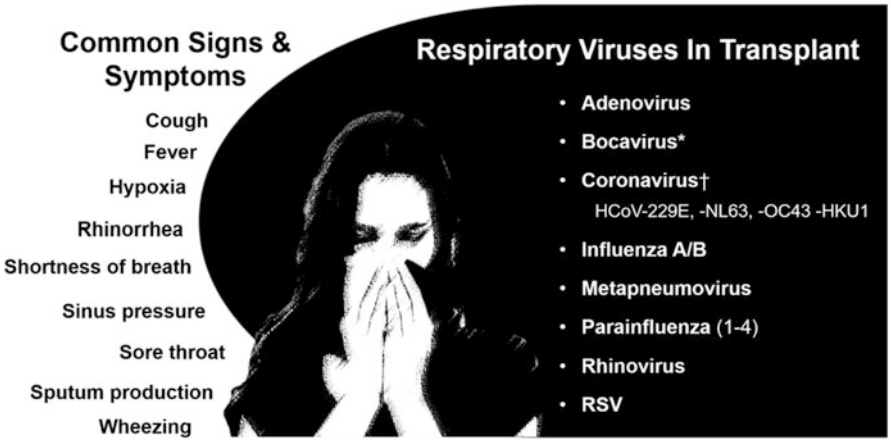

Fig. 1 Common respiratory viruses seen in transplant patients are those seen in normal populations and during seasonal outbreaks. Although most are community acquired pathogens, adenoviruses are often viruses that can reactivate from latent reservoirs in the host or be newly acquired from exposures. *Bocavirus is more often considered a gastrointestinal pathogen, and many multiplex PCR panels may not include this for routine testing. †These four Coronaviruses are human strains see as common community strains, and do not include outbreak strains such as MERS-CoV, SARS-CoV, and 2109-novel CoV. Abbreviations: RSV-respiratory syncytial virus

Clinically, it is challenging to differentiate specific respiratory viruses based on symptoms or presentation. In transplant recipients, a high-index of suspicion is needed as these patients can present with a myriad of infections and inflammatory conditions associated with sinopulmonary symptoms (e.g., idiopathic pneumonia syndrome, cryptogenic organizing pneumonia) [2]. In addition, symptoms may be minimal to absent in many immunosuppressed patients [3]. As a result, it is crucial that the early diagnostic workup include an evaluation for respiratory viruses in order to identify and guide therapy. There are currently approved agents for the prevention and treatment of influenza and RSV. Although emerging experimental therapies [4–6] are becoming more available for other respiratory viruses, alternate antiviral agents which are licensed for other viral infections (e.g., ribavirin) have been used particularly among those with severe disease [7, 8]. In this chapter, we will review the general approach to respiratory viruses and then discuss approaches to the common respiratory viruses with a focus and prevention and treatment.

Respiratory Virus Epidemiology Among Transplant Patients

Multiple contemporary studies of SOT and HSCT patients using molecular diagnostics have helped to define the epidemiology of respiratory viruses in this population. Patients early after their transplant, particularly lung transplant recipients, allogeneic HSCT, and pediatric transplant recipients consistently, have higher rates of clinically significant respiratory viral infections and a higher rate of progression to lower tract

disease. Other risk factors associated with more severe and progressive illness include recent use of lymphocyte depleting agents, lymphopenia <300 cells/μL, use of high-dose glucocorticoids, and severe hypogammaglobulinemia (≤4.5 g/mL) [1]. Seasonal epidemics of respiratory viruses in transplant recipients follow the local seasonal patterns, although disease may be first recognized among immunosuppressed populations [1]. For the northern hemisphere, influenza and RSV are most common November–April; hRhV and CoV are most common in the fall and spring; and there is less seasonal variation with PIV and AdV. HRhV consistently is the most commonly identified pathogen, followed by coronavirus, RSV, PIV viruses, influenza, AdV, human hMPV, and BoV [9]. While cases are more severe among the most immunosuppressed transplant patients, such as those immediately posttransplant or those undergoing treatment of rejection, infections from respiratory viruses can occur at any time after transplant.

Clinical Presentations of Respiratory Viral Pathogens in Transplant Recipients

Transplant patients develop symptoms commonly described with respiratory viral infections, including rhinorrhea, sore throat, cough, and fever; however, presentation is much more varied among these patient populations ranging from asymptomatic shedding to severe lower respiratory tract infections. However, it has been demonstrated that transplant patients are more likely to present with less prominent early signs and symptoms, for example, rhinorrhea, reduced PFTs, or fever may be the sole presenting signs of a respiratory viral infection in lung transplant recipients [1, 9–11]. Similarly, HSCT recipients are more apt to have atypical symptoms, such as fever only, and many patients present with limited symptoms. As a result, clinicians must have a low index of suspicion for testing patients and considering early therapy (Fig. 1, Table 1) [3]. A recent large study of SOT and HSCT recipients with influenza clearly demonstrated the paucity of classic symptoms with only 64% presenting with fever, 35% with a sore throat, and 40% with myalgias [12].

Importantly, immunosuppressed patients are more likely to present with severe life-threatening lower tract infections such as pneumonia [12]. Patients with more severe lower tract disease presentations are more likely to present with shortness of breath, hypoxia, and severe respiratory symptoms that require intubation and ICU level support. Any transplant patient presenting with acute respiratory distress, particularly those with diffuse infiltrates on radiologic assessment, should have common respiratory viral infections included in their early differential diagnosis.

With the development of molecular techniques for detection of respiratory viruses, several studies have also noted that transplant patients can present with asymptomatic infections. These studies which screen patients prospectively demonstrate that patients have documented viral detection (by PCR) but a lack of clinical symptoms [13]; some patients never develop clinical evidence of disease [3]. In part due to atypical symptoms and the potential for asymptomatic shedding, nosocomial transmission in HSCT clinic and hospital settings has been well described. Even well

Table 1 Common respiratory viruses in transplantation

Virus	Isolation recommendations	Prophylactic options	Therapeutic options
Influenza	Contact and droplet	Inactivated influenza vaccine seasonal NAI	NAI
RSV	Contact and droplet	Palivizumab	Ribavirin ± immunoglobulin

organized, careful infection prevention and screening programs targeted to these high-risk patients mitigate but cannot eliminate the risk of respiratory viruses and the development of clinical disease [14, 15].

Disease Progression and Complications

Respiratory viral infections can become life threatening as patients are more likely to progress from upper tract infections to lower tract infections. Rates of progression vary between virus, ranging from 5% to 50% depending on the pathogen and the level of immunosuppression in the host [16]. Among HSCT recipients, a number of factors have been identified to be associated with an increased risk of progression from upper to lower respiratory tract involvement. Commonly identified risk factors include neutropenia ($\leq$500 neutrophils/mL), lymphopenia ($\leq$200 lymphocytes/mL), age $\geq$ 40 years, presence of graft-versus-host disease (GVHD), use of glucocorticoids within 2 weeks of infection, myeloablative chemotherapy within 1 year of infection, cumulative antibiotic exposure, and infection early, especially within 1 year, of HSCT [16, 17]. Other factors include a history of smoking, nosocomial acquisition, hypoxia at diagnosis, use of matched unrelated or mismatched donor,

prior autologous HSCT, and cord blood transplant [5, 18, 19]. Two risk scores have been developed to risk stratify HSCT recipients with respiratory viruses and predict response to therapy [7, 18–20].

In transplant populations with respiratory viruses, bacterial infections are a known but infrequent complications linked to these infections, with *Pseudomonas aeruginosa*, *Streptococcus pneumoniae,* and other common oral and aerodigestive tract bacterial species commonly seen as co-pathogens. Multidrug resistant (MDR) infections such as methicillin-resistant *Staphylococcus aureus* and MDR gram negative infections may also be more likely in these patients due to significant prior hospitalization and antibiotic exposures [21–23].

In addition to disease specific complications, emerging reports have linked respiratory viruses with rejection, particularly among lung transplant recipients. While there remains controversy about the role of respiratory viruses in triggering acute rejection, there is a clear association with an increased risk of developing chronic rejection or chronic lung allograft dysfunction (CLAD) and infectious complications, including aspergillosis, among lung transplant recipients [24–27]. Risk of CLAD appears to be greatest with infection with the pneumoviruses (RSV and HPMV) and with lower respiratory tract involvement (HR 3.0, 95% CI 1.5–5.9) [28, 29]. Although data suggests that this association is linked to symptomatic infections, additional studies on the role of asymptomatic respiratory viral infections on lung transplant patients are needed [24]. Lower respiratory tract involvement with the respiratory viruses is associated with late onset airflow obstruction and infectious complications, including invasive aspergillosis, in HSCT recipients as well [30–32]. Transplant patients may develop encephalitis, myocarditis, or other rare complications that have been reported seen in patients with influenza infection.

Diagnostic Overview

As with most respiratory infections, patients with signs and symptoms of pneumonia should undergo radiologic evaluation. Although patients with upper tract symptoms do not routinely need imaging, patients with lower tract disease symptoms (e.g., cough or shortness of breath) should undergo imaging to evaluate the extent of lower tract involvement [33]. Chest x-rays can be a useful test (Fig. 2a), but among immunosuppressed transplant patients, noncontrast CT scans have increased sensitivity for lower tract disease manifestations and are often the preferred method for radiologic evaluation (Fig. 2b). Transplant patients with lower tract respiratory viral infections most commonly present with diffuse or patchy ground glass infiltrates, tree-in-bud findings, and/or consolidation on CT scans (Fig. 3).

It is nearly impossible to clinically distinguish infection due to one respiratory virus from another. Making a diagnosis among SOT and HSCT recipients is critical not only for infection prevention purposes, but also to enable the treating physician to select the optimal therapy for the patient. While a range of diagnostic methods are available, including serology, culture, and antigen detection, nucleic acid testing

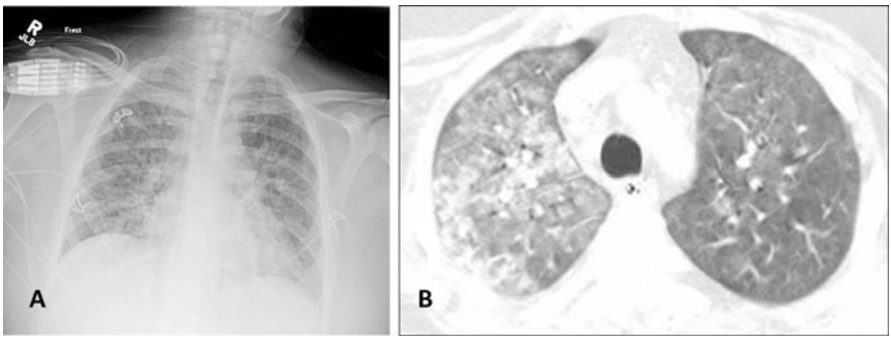

Fig. 2 Allogeneic transplant patient who presented with worsening hypoxia, fever and dry cough, documented to have lower tract human metapneumovirus. Human metapneumovirus documented by multiplex PCR from nasal wash and by bronchoaveolar lavage. A. Posterior anterior chest radiograph demonstrating a diffuse interstitial pattern. B. (PCR) has become the gold standard for the diagnosis of respiratory viruses. There are a range of molecular diagnostics, including a number multiplex panels that allow for concurrent screening of multiple pathogens from a single sample, and most of the currently available assays provide rapid results. In general, immunocompromised patients with any upper respiratory tract symptoms and/or fever should have upper airway samples (nares or nasopharyngeal) sent for multiplex PCR testing for respiratory viruses. False negative testing from the upper respiratory tract samples can occur from inadequate sample collection or among patients who have progressed to lower respiratory tract involvement. In one recent study, upper respiratory tract samples failed to detect a pathogen present in lower airway samples in 14.8% of

patients [34]. Failure to detect a pathogen using upper respiratory samples, particularly in patients with symptoms of lower tract involvement, should prompt collection of lower airway samples, by deep tracheal aspirate or preferably by bronchoalveolar lavage (BAL); BAL samples should be tested using by similar multiplex PCR methods [5, 35]. Sampling lower tract specimens also helps determine if patients with respiratory viral infections have associated co-infections, which may require additional targeted therapy.

Common and Uncommon Respiratory Viral Pathogens

Respiratory viruses present with similar findings, but outcomes, complications, and treatment for various viruses are unique. In the following section, we describe specific epidemiologic details of individual viruses and describe available methods for treatment.

Influenza

Influenza viruses are *Orthomyxoviridae* enveloped and segmented RNA viruses, and Influenza A and B cause the vast majority of infections in transplant patients. Influenza results in seasonal epidemics typically from November to May in the northern and May to October in the southern hemisphere, respectively. Influenza A typically occurs early in the season, followed by Influenza B, however seasonal variation can shift normal patterns. Seasonal epidemics are triggered by viruses that have antigenically drifted, with minor changes in which hemagglutinin or neuraminidase proteins are altered slightly so that preexisting antibodies present in the population no longer neutralize the virus. Far less frequently, an antigenic shift can occur when a novel hemagglutinin or neuraminidase that has not circulated in the human population for a long period of time emerges (e.g., H1N1 Swine influenza) and causes transmission, often associated with significant morbidity and mortality [36].

Among SOT patients, patients present most frequently with cough (85%) and fever (64%) but other cardinal symptoms, such as sore throat (35%) and myalgias (40%), are less common. Twenty-two percent have radiologic evidence of pneumonia on initial evaluation although proven bacterial superinfections are less frequently reported. While most patients in one large study were hospitalized, the length of stay was short (median 6 days), only 11% required ICU-level care, and even fewer required mechanical ventilation (8%) [12]. Among HSCT recipients, symptom presentations are similar, with cough as the most common symptom in most studies, appearing in 70–90% of patients [12, 18, 37]. Reported rates of fever range from 30% to 70% in these same studies, while myalgias are less frequently reported (5–39%). Importantly, rhinorrhea, sore throat, and other URI symptoms can also be among the only presenting symptoms in HSCT patients with influenza [38]. Additionally, patients who develop influenza in the early post-HSCT period may have

less frequent and or prominent symptoms [3]. Hospitalizations and ICU level admission rates appear to be similar to SOT patient populations [12]. Presentations in transplant patients may vary from mild to severe, and this variation is likely related to host immunity, symptom distribution which may also shift between seasons, and unique characteristics of new seasonal strains [18, 39].

Treatment

Currently, there are three classes of antivirals approved for the treatment of influenza: M2 ion channel inhibitors (amantadine and rimantadine), neuraminidase inhibitors (oseltamivir, peramivir, and zanamivir), and the polymerase inhibitor (baloxavir marboxil). Due to widespread resistance in all circulating strains, the M2 ion channel inhibitors are not recommended for the prevention or treatment of influenza. While the polymerase inhibitor baloxavir marboxil is associated with improved activity against influenza B and is associated with much more rapid reduction in viral replication, clinical studies are only available in immunocompetent patients [40–42]. Resistance among these immunocompetent emerged quickly in ~10% of adults and up to 40% of children treated with baloxavir marboxil. Resistance was seen more commonly in those with poor preinfection immunity and in individuals infected with A/H3N2 viruses. The resistant variants are transmissible and associated with longer durations of clinical symptoms and viral shedding in many of the patients [43–50]. As such, routine use of baloxavir is not recommended for transplant patients. If considered for use, it should always only be used in combination with a neuraminidase inhibitor and likely requires repeat dosing; the pharmacokinetics to inform optimal timing for repeat dosing are currently being studied (ClincalTrials.gov: NCT03684044) [36].

Prospective studies have not been performed in the transplant setting to define the optimal dose, route, or duration of antiviral NAI therapy, or the role of combination therapies. NAI therapy is associated with reduced mortality, reduced progression to pneumonia, reduced duration of shedding, and among lung transplant recipients, reduced risk of development of chronic lung allograft dysfunction [51, 52]. Early therapy, defined as initiation in <48 h after symptom onset, is associated with the best outcomes 53]. Nonetheless, therapy appears to be beneficial in this population beyond 48 h and all symptomatic patients should be treated. Unless diagnostic testing results are readily available, antiviral therapy should be initiated as soon as influenza is suspected in a transplant patient presenting with symptoms during influenza season, even if diagnostics are pending; patients without evidence of lower tract disease with negative testing can have therapy discontinued. Viral replication is prolonged with the average duration of shedding being significantly longer than 5 days in HSCT and SOT patients [12, 20]. As such, most experts recommend at least 10 days of therapy with longer therapy in patients that remain symptomatic and have ongoing shedding beyond 10 days. Higher than usual doses (i.e., oseltamivir 150 mg p.o. BID) may be associated with reduced risk of resistance emergence [54] or considered for

treatment of patients with influenza B infections (ClincalTrials.gov: NCT00545532), but recommendations vary about the utility of routine use of high-dose therapy in transplant patients [55–57].

Patients that have persistent symptoms with sustained or worsening viral replication after 5 days should be considered to have virologic resistance, which is more frequently detected among transplant recipients. Not all contemporary multiplex assays provide surrogates for estimating viral loads (i.e., mean florescence or cycle threshold (CT) values or viral loads), but if available, an increasing viral load among patients on therapy is often evidence of virologic failure. Additionally, resistance assays are available at specific centers, the CDC, and some State Health Departments. If your assay does not provide these surrogate endpoints, it is recommended that repeat testing with assays that provide such data can help discern whether the patient is experiencing virologic failure. At medical centers without such tools, patients with prolonged viral detection and progression of symptoms while on therapy should also be considered to potentially have antiviral resistant infection.

If resistance is considered or documented by molecular techniques, most recommend a switch to an alternative therapy (ideally a combination of two active drugs). Resistance testing of clinical samples is recommended, if not already sent. Since most centers use oseltamivir as primary therapy, a switch to zanamivir is often recommended if possible as some resistant strains maintain susceptibility to zanamavir [58]; however, resistance to oseltamivir is more likely to be associated with cross resistance to peramivir [59]. Caution should be used with zanamivir in patients with reactive airways and among those intubated and receiving respirator support, as the drug is inhaled. Transplant patients with mutations conferring multidrug resistance have been described, so consideration for dual therapy (NA inhibitor and another agent) is often recommended in those failing therapy [60]. The most effective combination therapies have not been studied except in small case series [61]. Most commercially available assays only detect the most common H275Y mutation that is relevant for oseltamivir resistance in influenza A/H1N1 viruses; if other agents or other viruses require testing, samples can be sent to CDC through state or local health departments in the USA or through local public health agencies.

Prevention

Although screening and contact precautions can help prevent healthcare associated transmission, prevention is best accomplished through use of the inactivated influenza vaccine. Current guidelines recommend annual influenza vaccination in all transplant patients, their close contacts, and healthcare workers caring for them. Ideally, vaccination should happen 3–6 months posttransplant, but earlier vaccination should be considered if there is an ongoing local epidemic [5, 35]. A number of different formulations of influenza vaccine are available. Although studies have generally been small, all formulations of inactivated vaccine have been demonstrated to be effective in preventing influenza [62]. In general, live-attenuated influenza

vaccine (Flumist®) should be avoided in transplant patients because of the theoretical risk of developing clinical disease from the vaccine, unless the live attenuated vaccine is the only option for vaccinating the patient during a period where the potential risk outweighs the benefit of vaccination (e.g., center level outbreak). The CDC and others also recommend that family members should not receive the live virus vaccine, but if live vaccine receipt occurs, close contacts should be separated from the transplant recipient for at least one week [63, 64].

In general, transplant patients have less robust responses to influenza vaccine than normal hosts even when considering seasonal variance in vaccine responses [65]. Poor responses have been demonstrated with vaccine within 6 months of HSCT, in patients with active GVHD, in patients who are on ≥2 g of daily mycophenolate mofetil (MMF) and who are ≥65 years [66–69]. All standard dose inactivated vaccines are quadrivalent (currently containing the influenza A/H1N1, A/H3N2, B/Victoria and B/Yamagata strains), including the egg-based, cell culture based, and recombinant HA vaccines. The high dose and MF59 adjuvanted influenza vaccine currently are only approved in trivalent forms (both lack the B/Yamagata strain); a quadrivalent high dose vaccine was recently approved and will become commercially available during the 2020–2021 season. Adjuvanted vaccine did not appear to result in improved responses compared to unadjuvanted vaccine in HSCT and SOT recipients [70–72]. Among HSCT patients, lower seroconversion was associated with use of calcineurin inhibitors ($P < 0.001$) and shorter duration from transplantation, as well as GVHD [68, 72].

Two commonly studied approaches to improve vaccine responses include giving a booster vaccine 4–8 weeks after initial vaccine or the use of high-dose influenza vaccine. Booster dosing has been most commonly utilized in individuals needing vaccination shortly after transplant. This approach is associated with a consistent but modest improvement in seroconversion and seroprotective humoral responses (10–12% increased seroprotection with the second vaccine) [73]. The European Conference of Infections in Leukemia (ECIL) recommend a second dose of inactivated vaccine administered 3–4 weeks after the first dose should be considered in patients with severe GVHD or low lymphocyte counts. Additionally, they recommend early vaccination at 3 months post-HSCT during outbreaks, followed by an additional dose 3–4 weeks later [74]. Current US guidelines recommend single dose inactivated influenza vaccine at 6 months post-HSCT, or a dose at 3 months followed by a second dose 3–4 weeks later [64].

Inactivated high-dose influenza is a trivalent vaccine that contains 4 times the hemagglutinin protein and has also been studied in various transplant populations. In the largest study to date, high-dose vaccine was associated with an improved seroconversion rate in SOT recipients (A/H1N1: 40.7% vs. 20.5%; A/H3N2: 57.1% vs. 32.5%; B: 58.3% vs. 41.6%) although there were no significant difference in seroprotection, likely due to high prevaccine titers [75]. A pilot study in adult HSCT patients demonstrated that high dose vaccine was found to be safe and associated with a higher percentage of individuals with titers ≥1:40 and a higher geometric mean titer (GMT) against the H3N2 strain compared with that of the standard dose group [76]; a randomized clinical trial comparing standard dose or

high-dose followed by boosting at 4 weeks post-HSCT has currently completed enrollment but final study results are pending at the time of this update. Without Advisory Committee of Immunization Practices, support for routine use in immunosuppressed patients access may be limited due to costs and insurance restrictions, so high-dose vaccine is generally only given to patients ≥65 years of age for which it is specifically indicated [77]. None-the-less, current guidelines in SOT recommend the routine use of high-dose vaccine in all SOT recipients; available HSCT guidelines have not supported routine use, other than to those ≥65 years of age, due to the limited data available in this population [35, 78].

For patients who would be predicted to have a poor influenza vaccine response, seasonal antiviral prophylaxis can be considered, particularly during large outbreaks and is supported by a randomized clinical trial. In this trial, patients were given oseltamivir 75 mg once daily or placebo for 12 weeks when influenza was first recognized in the community. Such an approach was associated with reduced incidence of PCR positive (1.7% vs. 8.4%) and culture-confirmed (<1% vs. 3.8%) viral breakthrough infections, yet without evidence of NAI resistance mutations in viruses that failed prophylaxis [79]. While generally well tolerated, clinical experience demonstrates challenges in drug approvals from health insurance carriers and a high incidence of discontinuation because of intolerance.

Postexposure prophylaxis using the lower prophylactic dose (daily vs. twice daily) is not recommended for those with documented household or nosocomial exposures since transmission may have already occurred and the risk of clinical and virologic influenza breakthrough should be clearly avoided, especially in immunocompromised patients where resistance is a major concern [36]. Instead, empiric treatment using the therapeutic dosing (i.e., 10 days of twice daily oseltamivir) should be restricted to high risk transplant recipients (HSCT within 6 months of transplant or unvaccinated lung transplant recipients). Low-risk patients should be monitored closely and started on early full dose treatment if they develop any symptoms. If used, therapy be should be started as soon as the diagnosis is confirmed in the contact but should not be started if there has been >48 h of exposure to a symptomatic contact; in such situations active symptom monitoring with proactive treatment is recommended.

Respiratory Syncytial Virus

RSV was reclassified in 2016 into the family *Pneumoviridae,* genus *Orthopneumoviridae* [80, 81]. RSV is an enveloped, nonsegmented, negative sense, single-stranded RNA virus which encodes 11 proteins: 2 nonstructural and 9 structural [82]. RSV isolates are divided into two major antigenic groups A and B, each of which are further divided into 13 RSV A genotypes and 20 RSV B genotypes [80, 81].

Studies involving SOT recipients have demonstrated significant mortality in lung transplant patients where LRTIs with RSV can be a risk factor for CLAD and for death (mortality rate up to 20%) [83, 84]. Local inflammation and enhanced exposure of the immune system to pulmonary antigens lead to injury in the airway

epithelial cells and sub-epithelial structures, leading to obliteration of the small airways, and subsequently CLAD [85].

Among adult HSCT recipients with RSV infection, progression from URTI to LRTI occurs in 40–60% of cases and LRTI is associated with mortality rates up to 80% [86–89]. Two available risk scores (see Table 2) are helpful in predicting outcomes for RSV.

In the first scoring system, patients with more than 2 SID (Severe Immunodeficiency) factors (VSID, Very Severe Immunodeficiency) were found with RSV-attributed mortality rates of 18% [7]. The immunodeficiency scoring index RSV (ISI-RSV) score demonstrates an increasing risk of progression from upper to lower tract disease (7%, 15% and 48%, respectively) and mortality (0%, 3%, and 29%, respectively) across the 3 risk levels [19]. These scores have been proposed as tools for determining need for hospital admission and antiviral therapy.

Treatment

The standard of care for the management of RSV infection in adults is mainly limited to supportive care with bronchodilators, supplemental oxygen, intravenous fluid, and antipyretics [90]. Ribavirin and immunoglobulin preparations are the therapies most

Table 2 Risk score for HSCT recipients with RVI to predict risk of progression to lower tract disease and death

(a) Severe immunodeficiency score		
Moderate immunodeficiency (MID)	Severe immunodeficiency (SID)	Very severe immunodeficiency (VSID)
≥1 factor present	Only 1 factor present	≥ 2 factors present
	Neutropenia <0.5 10^9/L	Neutropenia <0.5 10^9/L
	Lymphopenia <0.1 10^9/L	Lymphopenia <0.1 10^9/L
	Allo-HSCT <6 months ago	Allo-HSCT <6 months ago
GVHD<2 or limited GVHD	GVHD ≥2 or requiring treatment	GVHD ≥2 or requiring treatment
T-cell depletion >3 months	T-cell depletion <3 months	T-cell depletion <3 months
B-cell depletion >3 months	B-cell depletion <3 months	B-cell depletion <3 months
	Hypo-γ-globulinemia <4.5 g/L	Hypo-γ-globulinemia <4.5 g/L

(b) Immunodeficiency Score Index (ISI)	
Factor	Score
Neutropenia <0.5 10^9/L	3
Lymphopenia <0.2 10^9/L	3
Pre-engraftment or Allo-HSCT <1 months	1
GVHD (acute/chronic)	1
Corticosteroids	1
Myeloablative conditioning	1
Age > 40 years	2
Interpretation: 0–2: Low risk; 3–6: Moderate risk; 7–12: High risk	

commonly utilized and are generally limited to HSCT and lung transplant recipients [82]. Ribavirin is a guanosine analogue that is FDA approved, in its aerosolized formulation, for the treatment of RSV in infants and young children only. Intravenous ribavirin is not commercially available in most parts of the world. Due to challenges in drug delivery and the high cost of aerosolized ribavirin, many centers utilize oral ribavirin off-label for the treatment of immunocompromised patients despite a lack of prospective efficacy data [91–93].

Available studies suggest that if therapy is to be used, it is of greatest benefit when started early to prevent progression to lower tract disease [94–96]. When used for lower tract disease, ribavirin has been shown to be less effective [97]. Furthermore, a comprehensive review of the available literature shows that patients treated with aerosolized ribavirin and an antibody preparation, including standard intravenous immune globulin (IVIG), RSV immunoglobulin, or palivizumab had the lowest risk of progression to lower tract disease and death [16, 89]. If aerosolized ribavirin is used, continuous dosing (6 g over 18 h daily) has been shown to be equally effective in preventing progression to LRTI compared to intermittent dosing (2 g over 3 h every 8 h) [98].

Oral ribavirin is increasingly used among transplant centers globally due to ease and cost considerations [92]. A range of doses have been utilized across centers, although aggressive dosing is likely needed to approach the drug concentration needed in alveolar lung fluid to treat RSV; dosing approaches must be balanced with adverse effects such as hemolytic anemia [93, 99–119]. Most studies in HSCT recipients that have compared oral to inhaled ribavirin have demonstrated similar efficacy, although none have been randomized and none included a placebo arm. Among lung transplant recipients, IV ribavirin has been associated with 100% survival rate with only 5% developing post-RSV BOS, a rate lower than historical data [120]. Several retrospective observational studies of oral ribavirin have consistently shown similar outcomes compared with IV or inhaled ribavirin in lung transplant patients. The majority of studies have not been placebo controlled. However, two recent studies of novel RSV drugs found that when ribavirin was utilized in transplant patients, it was not shown to convincingly improve outcomes compared to patients that did not receive ribavirin [6, 121]. These data, the lack of availability of intravenous ribavirin, the cost of inhaled ribavirin, and the lack of placebo-controlled studies in transplant patients highlight the challenges and ongoing need for safety and efficacy studies of ribavirin in the transplant population.

The current approach used in most centers is the use of aerosolized or oral ribavirin for treatment of RSV in HSCT and lung transplant recipients; antibody preparations are often added to ribavirin in HSCT recipients with more severe disease [5, 35, 82, 122]. Most centers will utilize standard intravenous immunoglobulin (IVIG) for the antibody preparation. Recently, a high titer RSV immunoglobulin (RI-002) was approved by the FDA without a specific RSV indication but in a compassionate use study was associated with a high survival rate in HSCT recipients (73%) [123]. Limited data on treatment in adults suggests reduced progression to lower tract disease with early combination therapy using IV palivizumab and ribavirin [16, 124, 125]. However, use of palivizumab in combination therapy was

not found to decrease mortality in a large retrospective study of patients with RSV pneumonia and is not recommended by most centers [126]. The largest single-center study utilizing palivizumab in younger adults (median age 16 years old) with HSCT also failed to show significant impact on outcome as assessed by progression to LRTI, early mortality rate, and 1-year overall survival rate [124].

Two investigational agents provide further insight into antiviral therapy in this population but did not meet prespecified study endpoints. The first, ALN-RSV01, is a small interfering RNA (siRNA) that was studied to assess its impact on prevention of BOS in lung transplant patients. Two completed studies in lung transplant patients demonstrated a statistically nonsignificant decrease in new or progressive BOS at day 180 (13.6% vs. 30.3%, $p = 0.058$) but no impact on viral parameters or symptom scores. Early therapy was associated with greatest impact [127]. Although this agent is no longer under clinical development, it demonstrated the ability to use CLAD as a potential endpoint in studies in lung transplant recipients. The second, presatovir (oral GS-5806), is an oral small molecule fusion inhibitor that has been studied in lung and HSCT recipients. Unfortunately, despite excellent data in human challenge models and a clear safety profile in clinical studies, presatovir did not achieve the clinical or virologic endpoints in the transplant studies [6, 121, 128]. A small effect was noted in patients with significant lymphopenia with upper respiratory tract illness [121]. Several other experimental therapies (JNJ-53718678: ClinicalTrials.gov Identifier NCT03379675, NCT03656510; RV521: ClinicalTrials.gov Identifier NCT03782662; and MDT-637) are undergoing clinical development, including some studies in the transplant setting [82].

Prevention

Prevention of RSV is limited by the lack of an approved vaccine to protect against the virus. Palivizumab is an RSV-specific monoclonal F antibody that is currently approved by the FDA and European Medicines Agency for the prevention of RSV only in pediatric patients at high risk of RSV disease. In high risk infants, palivizumab is 55% effective at reducing rates of pediatric hospitalization and has been shown to reduce morbidity although not mortality [129]. Given cost constraints, there are limited data on the use of palivizumab as preventative therapy in immunosuppressed patients and the elderly (cost per adult dose of >$10,000 in the United States) [130]. Palivizumab has been successfully utilized to prevent an outbreak of nosocomial RSV transmission in a single adult HSCT unit [131]. Palivizumab is used by some but not all pediatric lung transplant programs based on a recent survey [132].

Human Metapneumovirus

Human metapneumovirus (hMPV) is a negative-sense, single-stranded RNA virus in the Paramyxoviridae family. There are two subtypes with two subgroups of each (A1, A2, B1, and B2). Much like other members of the Paramyxoviruses, hMPV

has a propensity to cause LRTI and has been associated with high mortality. There are limited data in SOT, with the preponderance of data in lung transplant recipients. hMPV is symptomatic in about half of patients and two-thirds go on to develop LRTI [11]. hMPV has also been associated with development of CLAD and additional infectious complications including CMV reactivation in these patients [133–135].

There have been few HSCT patient studies focused on hMPV but those suggest that approximately 25% of patients develop LRTI progression at a median of 7 days after initial symptom onset (range 2–63 days). Progression to LRTI is associated with steroid use $\geq$1 mg/kg prior to URI diagnosis (HR, 5.10; P = 0.004), low lymphocyte count (HR, 3.43; $P = 0.011$), and early onset of HMPV infection after HSCT (before day 30 after HSCT; HR, 3.54; $P = 0.013$) [136]. Interestingly, baseline viral load was not associated with risk of LRTI progression. Mortality rates at 100 days in some studies have been high (reported as high as 43%), and mortality has been associated with steroid therapy, oxygen requirement >2 L, or mechanical ventilation, and bone marrow as stem cell source [137]. Reports also suggest higher attack rates in pediatric and adolescent HSCT populations [138].

Treatment and Prevention

Based on in vitro activity, some centers use inhaled, intravenous, or oral ribavirin with and without immunoglobulin for the treatment of hMPV [139–145]. Since there are no comparative studies, the clinical benefit of this approach cannot be assessed particularly since the majority of patients who receive treatment are those with severe LRTI disease; due to lack of other treatment options, these remain in clinical use [145, 146]. There are few novel drugs in the market that target hMPV, but a novel sialidase inhibitor, DAS-181, has shown some promise in animal models of hMPV infection [147]. There are no currently available vaccines to prevent hMPV and no prophylactic treatments approved that target hMPV.

Parainfluenza Viruses

PIVs are negative sense single stranded RNA viruses in the Paramyxoviridae family. There are four different serotypes (PIV-1, -2, -3, -4) [148]. The envelope is studded with two different glycoproteins; one contains hemagglutinin-neuraminidase (HN protein) activity while the other is involved in the fusion mechanism (F protein) [149]. The HN is responsible for attachment to sialic acid-containing receptors on respiratory epithelial cell surfaces. The four different serotypes of PIV also show remarkably different seasonal patterns, but together lead to a nearly yearly presence of PIV infections. PIV-1 follows a biennial pattern, marked by a dramatic increase in cases in the months of September to December of odd-numbered years [150]. Outbreaks of PIV-3 infections occur yearly, primarily in the months of April to

June. During the absence of endemic PIV-1, PIV-3 shows increased activity, either as a longer spring season or as a second but milder season in the months of November to December [151]. Similar to PIV-3, outbreaks of infection with PIV-2, which are smaller in magnitude, occur on an annual basis [151]. Data on PIV-4 is less clear, as it is less frequently tested for and isolated, making it difficult to draw conclusions on the seasonality of this serotype [150, 151].

Together PIV infections pose a large infectious burden on HSCT and lung transplant recipients [152, 153]. In multiple studies investigating the incidence of PIV infection in adult and pediatric HSCT patients, an overall incidence of 4% (0.2–30%) was identified, with an estimated 3–7% of patients becoming infected with PIV within the first 100 days of transplantation [154]. PIV-associated mortality is highest in patients with LRTI disease, who often progress to multiorgan failure, and in those who develop pulmonary co-pathogens, with an average mortality rate of 27% (0–62%) [152].

Treatment and Prevention

There are currently no approved vaccines for the prevention of PIV [155]. Likewise, there are currently no FDA approved treatments for PIV infection. Ribavirin is active against paramyxoviruses through the depletion of intracellular GTP pools secondary to the inhibition of IMP dehydrogenase [156]. However, ribavirin and IVIG have been studied in transplant patients without convincing efficacy in most retrospective nonrandomized studies. Oral, aerosolized, and intravenous ribavirin have been administered in the management of PIV but studies have not demonstrated significant improvement in viral shedding or mortality (77.3% aerosolized ribavirin vs. 86.3% no treatment) among patients with PIV-associated pneumonia when compared to no treatment [155]. Despite the negative data, ribavirin ± IVIG therapy are recommended for the treatment of severe PIV infection in transplant patients in current guidelines, due to the lack of other available therapies [35, 122].

DAS181 is a novel inhaled host-active antiviral composed of the *Actinomyces viscosus* sialidase catalytic domain linked to the human AR glycosaminoglycan-binding sequence [157]. DAS181 selectively cleaves host cell sialic acids, which are required by influenza and PIV for binding of the virus to the host cell [158]. DAS181 showed promise when used as treatment for patients who received the drug through compassionate use access to the drug, where DAS181 resulted in improved pulmonary function and reduced viral loads in most, but not all of the patients [159–165]. Nonresponders frequently had co-infections and typically died of the infection [165]. A randomized, placebo-controlled study of DAS181 in HSCT recipients with PIV was recently conducted (Clinicaltrials.gov identifier: NCT01644877). DAS181 was well tolerated but the study failed to demonstrate superiority in terms of the primary endpoint (clinical stability survival, defined as being alive with normalization of vital signs and resolution of supplemental oxygen requirements, at day 45 after randomization; 39.2% DAS181 vs. 31.4% placebo, $p = 0.29$). Post hoc analysis demonstrated a trend to higher rates of return to room air

in patients with lower tract PIV infection who did not require mechanical ventilation [166]. Based on this post hoc analysis and being granted Breakthrough Therapy Designation by the US FDA, a phase 3 trial is currently enrolling nationally (Clinicaltrials.gov identifier: NCT03808922).

Rhinovirus

Human rhinoviruses (hRhV) are *Picornaviridae* in the genus *Enterovirus*. They are small enveloped single-stranded positive sense RNA viruses [167]. While there are a large number of recognized hRV types (over 160), they can all be classified into three species (A–C). hRVs are the most commonly isolated viruses among both SOT and HSCT recipients and are associated with prolonged shedding, which can occur for months posttransplant [11, 168–171]. A high baseline viral load has been associated with more prolonged shedding for all 3 species [169]. Among lung transplant recipients, hRV is not convincingly associated with acute or chronic rejection but may be associated with an increased risk of bacterial co-infections [10, 172]. Despite a sense by many treating transplant patients that hRV infections are a nuisance, fatal cases of LRTI hRV infections have been described and reports suggest that mortality rates associated with LRTI are similar to other respiratory viruses [173, 174]. More recently, a risk score that incorporates the risk of low lymphocyte count, low albumin, positive cytomegalovirus serostatus, recipient statin use, and steroid use $\geq$2 mg/kg/day has been developed that predicts progression to LRTI among HSCT patients [175].

Treatment and Prevention

Unfortunately there are no active vaccines for hRhV, and while several drugs have been studied against hRhV, none have been licensed to date; there are no current trials of investigational agents in transplant patients [176].

Coronavirus

CoVs are a broad group of respiratory pathogens that span animal and human strains. The most common circulating human CoVs, HCoV-229E, and -NL63, and HCoV-OC43 and -HKU1, are large, enveloped single-stranded RNA viruses that are common causes of respiratory infection in transplant recipients [171]. Clinically, most patients have mild upper respiratory tract infections often with a prolonged period of asymptomatic shedding [171, 177–180]. Clinical symptoms of LRTI appear to be less frequent than other respiratory viruses among SOT and HSCT patients, but often when present co-infection is noted in patients with severe lower tract signs or symptoms. Data among HSCT recipients with clinical signs and symptoms of LRTI and detection of CoV in the lower tract demonstrate increased

oxygen requirements (60%) at presentation and mortality rates within 90 days (54%) of diagnosis were high [179].

Animal CoV of clinical significance to humans, MERS-CoV, SARS-CoV, and the recently emergent SARS-CoV-2, have resulted in high rates of mortality in regional epidemics and global pandemics [181, 182]. Data on outcomes in transplant patients are uncertain with these pandemic CoVs as few patients have been affected by MERS-CoV or SARS-CoV. When infection has been described with these emerging CoV, patients may have atypical infection or a prolonged period of asymptomatic shedding [183–185]. Data on transplant patients affected by the emergent COVID-19 are still undergoing study at this time but slightly worse outcomes have been described clinically [186–188].

Treatment and Prevention

There are no known vaccine candidates for human or emergent animal CoVs, and there are no currently available therapies which are approved for treatment. Respiratory etiquette and infection prevention strategies remain the foundation of CoV prevention. Importantly, for MERS-CoV, SARS-CoV, and COVID-19, airborne, droplet, contact, and standard precautions are recommended; eye protection is recommended for aerosol-generating procedures [189].

Adenovirus

Human adenoviruses (AdV) are divided into seven species (A–G) with over 80 serotypes [190]. They are double-stranded, nonenveloped DNA viruses. AdV can cause a range of clinical manifestations including infections of the central nervous system, the eye, the gastrointestinal tract, the genitourinary tract, and the respiratory tract; disseminated disease, defined as $\geq$2 sites of infection typically with viremia, is more common among HSCT patients and associated with the highest risk of mortality (Fig. 4). Asymptomatic AdV viremia is common in SOT recipients [191, 192]. Adenoviral hepatitis, typically caused by AdV 1, 2, or 5, is most common among liver transplant recipients and can be diagnosed by detection of viremia, elevated liver function tests, or visualization of viral intranuclear inclusions on liver biopsy [1]. AdV enterocolitis occurs in small bowel transplant recipients and may mimic rejection [193]. Adenoviral pneumonia is associated with graft loss, death, or progression to obliterative bronchiolitis in lung transplant recipients. AdV causes hemorrhagic cystitis with or without interstitial nephritis in kidney transplant recipients. Such patients typically present with fever, hematuria, and new-onset renal dysfunction [194]. AdV DNA in biopsy specimens is associated with worse outcomes among pediatric heart transplant patients [195, 196]. AdV in SOT patients is most common in pediatric transplantation, small bowel recipients, and those who receive lymphocyte depletion [1].

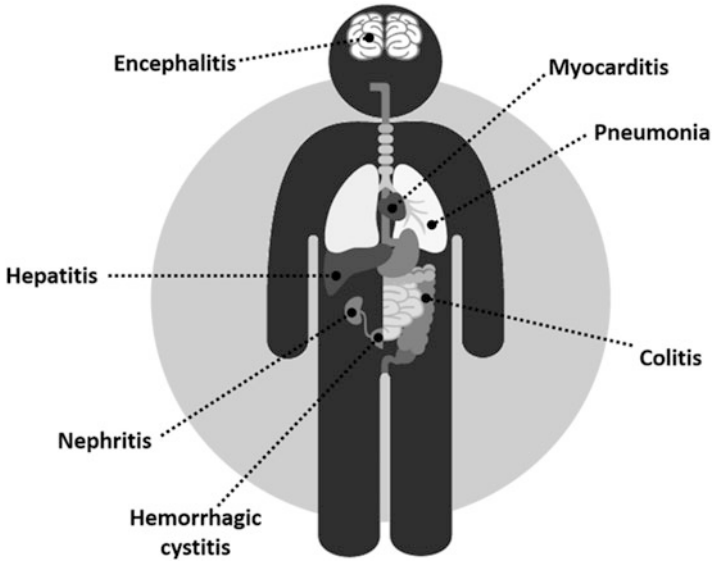

Fig. 4 Locations of adenovirus disease among transplant patients. (Most common locations for AdV disease among transplant patients include the gastro-intestinal tract, genitourinary tract and respiratory tract. This figure does not represent isolated viremia or disseminated disease (with multiple organ sites and associated viremia). Image courtesy of Kyoko Kurosawa)

Among HSCT recipients, AdV is most common among those with an allogeneic transplant, cord blood transplant, cell-depleted graft, receipt of alemtuzumab, and patients with acute graft-versus-host disease. Severe lymphopenia (<300 cells/μL) has been associated with disseminated disease. Although disseminated disease only effects 1–7% of HSCT recipients, it is associated with a significant risk of mortality (8–26%) [1]. Similar to SOT recipients, AdV can present as a number of manifestations, including pneumonia/pneumonitis, CNS disease, colitis, hepatitis, cystitis, and nephritis, and can be seen as isolated viremia in some patients (Fig. 4) [197, 198]. While the majority of AdV cases are associated with reactivation from latent infection in the recipient, patients can also develop community-acquired upper and lower respiratory tract infections, and there are reports of outbreaks of AdV on HSCT units [199]. Since early detection of AdV in stool and blood predicts disease, especially in pediatric HSCT patients, screening is often utilized to identify patients in whom interventions may reduce risk of disease progression [200–204]. A threshold of 5 $\log^{10}$ copies/g feces has been shown to be predictive of developing adenoviremia in one study [200].

Treatment and Prevention

No antiviral agents are currently FDA approved for the treatment of AdV. Ribavirin has not shown clear clinical benefit, despite having activity in vitro

[190, 205]. Cidofovir has demonstrated clinical utility using either 5 mg/kg weekly or 1 mg/kg three times a week in combination with probenecid and hydration, but significant nephrotoxicity and bone marrow toxicity limit its long term treatment of severe infections; toxicity also makes routine use of preemptive Cidofovir challenging for pediatric hematopoietic stem cell transplantation patients with persistent or rising AdV viral loads [1, 190, 205, 206]. Brincidofovir, a lipid conjugate of cidofovir available in tablet and liquid form, appears more potent against AdV than cidofovir with less bone marrow and renal toxicity [207]. The one significant toxicity that is associated with Brincidofovir is GI toxicity which often presents as diarrhea and can mimic GVHD [208, 209]. In clinical studies and case series, brincidofovir appears to be associated with antiviral and clinical benefit among HSCT and SOT patients who have been treated [207, 210–212]. Unfortunately, clinical development of the drug for AdV has been suspended although the drug remains available for compassionate use until current supplies of the drug are expended (ClinicalTrial.gov Identified: NCT02596997).

A newer approach using AdV- and multivirus-specific T cells is also being studied in prospective trials (ClinicalTrial.gov Identified: NCT03425526, NCT03378102, NCT03266627, NCT02532452, NCT02510417, NCT02007356, NCT01945814) [203, 213]. While these agents remain experimental, early studies suggest significant clinical benefit.

Bocavirus and Other Uncommon Respiratory Viruses

Bocaviruses (BoV) are single stranded nonenveloped DNA viruses of the Parvovirinae in the virus family Parvoviridae that are associated with both respiratory and GI infections. Data on prevalence and outcomes in transplant patients are limited, but among those with a documented respiratory pathogen BoV may make approximately 8% of all detected viruses. These same data suggest that BoV patients with active symptoms are more likely to have a co-pathogen when detected [214]. Increased detection among HSCT recipients in stool may be evidence that the GI tract is the more common location for this pathogen [215]. Novel enterovirus (EV), such as EV-D68, are infrequent but are known to lead to clinical illness among transplant patients that varies between mild URI to severe respiratory disease [216].

Infection Control Practices to Protect Transplant Patients from Respiratory Viruses

Transplant centers should develop standard respiratory virus protocols which can be implemented throughout floors, units and clinics where high risk immunosuppressed patients receive care. In order to track such efforts and plan for interventions, Infection Prevention teams should set up surveillance systems among transplant patients, as outbreaks of multiple respiratory virus pathogens have been seen in these

populations [14, 217, 218]. Policies should target high level compliance with hand hygiene, and protocols aimed at early identification of patients with active respiratory symptoms. Enhanced Infection Control strategies, for respiratory virus prevention including recommended contact and droplet precautions for many of these pathogens; most centers isolate patients with active respiratory symptoms (Table 1) [189]. Eye protection should be routinely used (face shield or goggles) and consideration for use of N95-level protection is recommended for aerosol-generating procedures (Fig. 5) [189]. Airborne isolation, droplet, and contact isolation (including placement in negative pressure rooms) are required for patients who are diagnosed with MERS-CoV, SARS-CoV, or 2019-nCoV due to high risk for transmission.

Placing patients with active respiratory symptoms into single rooms, masking symptomatic patients on units while outside of their rooms, shifting efforts to rapid molecular testing and implementing early treatment protocols, particularly for influenza, are targeted efforts that can help limit the spread of respiratory viruses. In addition, actively screening those who enter the unit or clinic for respiratory symptoms on arrival can assure early detection and isolation of patients and prevent transmission from caregivers or hospital staff with symptoms [15]. Some centers also restrict access to high-risk units to young children, to help limit possible exposures.

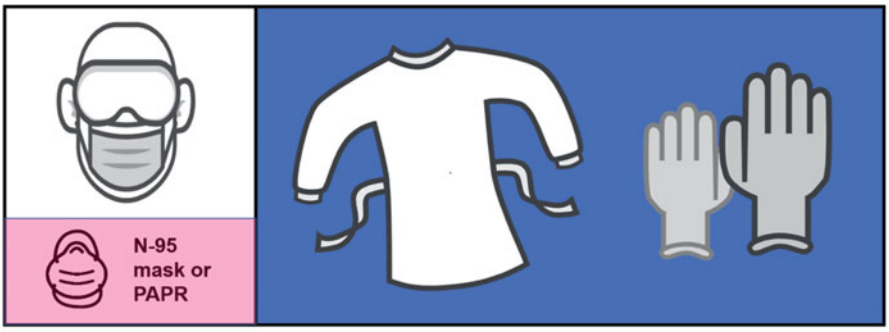

Fig. 5 Personal protective equipment for patients with respiratory viruses. Respiratory virus prevention should include personal protective equipment for contact and droplet precautions with a surgical mask (with goggles or face shield to protect eyes), a gown and gloves. Red: For some high-risk invasive procedures, such as bronchoalveolar lavage, interventionalists may want to consider wearing a fit-tested N-95 mask for infections such as Influenza. It is critical to remember that N-95 or Powered Air Purifying Respirator (PAPR) is required for emerging coronaviruses, such as MERS-CoV, SARS-CoV and 2019-nCoV. (Image courtesy of Kyoko Kurosawa)

Standardized CDC guidelines recommend contact and droplet precautions (masks with face shields or goggles) for staff caring for patients during the duration of clinical illness [189]. Masking of symptomatic patients can help limit production of secretions and help limit spread of respiratory viruses; however, routine use among patients and staff remains controversial. Many centers consider routine masking during high risk respiratory virus season (November–April), while others target all inpatients regardless of season. Older studies gave conflicting data on the utility of wearing gowns and masks to decrease nosocomial transmission, but two recent studies demonstrate a potential correlation with universal mask use, particularly for providers who come in contact with HSCT patients; albeit nonrandomized longitudinal single center comparison studies may be biased by seasonal variations [219–223]. Routine masking can help address those who are contagious prior to development of symptoms (e.g., influenza) or patients with asymptomatic shedding.

It is also critical for centers to assure staff, caregivers, and visitors avoid entering units or clinics while symptomatic. Efforts to avoid presentism can be critical as health care workers can both be affected by and possibly be linked to outbreaks in such units [15, 224]. Since outpatient care for transplant patients is often through transplant clinics, organized outpatient prevention programs are needed in clinic spaces where patients cohort together [15]. As discussed above, efforts to assure high-level influenza vaccine compliance and dedicated vaccination campaigns among healthcare workers and families/caregivers can also provide additional protection for high risk patients [225, 226]. Furthermore, dedicated educational efforts targeted towards patients and their caregivers to promote active hand hygiene, appropriate respiratory hygiene, and awareness of the risks of respiratory viruses are important.

Unique Donor and Recipient Issues

Respiratory viruses raise unique concerns of donor-derived infectious disease transmission to the recipient. In general, viremia is not a significant concern for most respiratory viruses, so risk of disease transmission is generally limited to lung donors. As such, lung donors with proven influenza, RSV, hMPV, PIV, or AdV infections are generally excluded from infection. Although current guidelines do not recommend the use of influenza-infected donors and infection has been demonstrated to be transmitted to recipients, some centers will consider the use of these organs with the concurrent use of oseltamivir in the recipient, especially if the donor has received therapy as well [35, 227–229]. Viremia and disseminated infection can occur with novel influenza viruses, including avian viruses, as well as AdV. As such, donors with these viruses generally should not be used. Donors with other respiratory viruses can generally be considered for nonlung donation without significant risk of disease transmission.

In the setting of HSCT, one controversial issue is how to proceed with transplant in recipients who have symptomatic infections at the time of induction. Symptomatic patients with viruses detected pre-HSCT had increased mortality (unadjusted HR

3.5, 95% CI 1.0–12.1, $p = 0.05$); asymptomatic patients with detected virus had no increased mortality risk [37]. As such, most experts recommend testing patients with symptoms of a URI prior to induction and delaying transplant if virus, even hRhV, is detected if feasible [5].

Conclusions

Respiratory viral pathogens remain common complications among SOT and HSCT recipients. Despite progress in improved diagnostics, transplant immunosuppression, and prevention strategies, respiratory viral pathogens are a still major cause of morbidity and mortality among transplant patients, particularly among the most immunosuppressed. Respiratory viruses often present with fever, cough, and upper respiratory symptoms, but classic symptoms seen in normal hosts may be missing in these patients, and they are more likely to progress to life-threatening pneumonia. Only influenza viruses have approved therapies, but emerging trials may provide future options for treatment for other respiratory viruses. Influenza vaccination for patients and their close contacts and infection prevention practices to prevent person-to-person transmission remain critically important to limit outbreaks and clusters in transplant centers.

Key Points

- Respiratory viruses are common causes of morbidity and mortality among transplant patients.
- Patients with respiratory viruses may present with atypical or less prominent clinical symptoms, despite being at high risk for progression to lower tract disease.
- Awareness and early diagnosis are key to managing and isolating patients with active respiratory viral symptoms.
- All patients with influenza should be treated with antiviral agents, but treating teams should be aware of increased risk for the development of resistance.
- Influenza vaccine should be promoted to all patients, caregivers/family, and staff at transplant centers.
- Aggressive infection prevention policies aimed at early detection, isolation, and treatment of patients is key to prevent outbreaks in transplant populations.

Introduction

Human adenoviruses (HAdV) can cause self-limiting infections, involving the respiratory tract, intestines, and conjunctiva in immunocompetent hosts. In solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients, HAdV can present as asymptomatic viremia, localized infection, or disseminated disease with significant impact on morbidity and mortality [1, 2]. In addition, HAdV infection can

negatively impact the graft survival of SOT recipients [3]. Management of HAdV can be challenging since therapies have limited efficacy and significant toxicities. As with CMV, a preventative strategy using screening for viremia by polymerase chain reaction (PCR) and preemptive antiviral therapy is advocated by experts in at-risk HSCT recipients. This chapter will discuss the virology, epidemiology, clinical presentation, diagnostics, and treatment strategies for HAdV in HSCT and SOT recipients.

Virology

HAdVs are non-enveloped double-stranded DNA viruses of the family *Adenoviridae*. At present, more than 67 HAdV types have been characterized. These are grouped using distinct but intersecting classification schemes which include serotypes, genotypes, and species subgroups. Historically, serotyping of SN and H1 HAdV epitopes leads to the identification of 51 HAdV serotypes, whereas subsequent types, also known as genotypes, were identified using analysis of genomic sequences. HAdVs are further categorized into seven species subgroups (A to G) based on hemagglutination properties, genetic homology, oncogenicity, and cellular tropism (Table 1) [4]. Subgroups B, C, and E typically target respiratory tract and, together with subgroup D, the eye, whereas subgroups A and F preferentially infect the gastrointestinal tract. The ability of certain HAdV subgroups and types to infect specific host cells is reflective of a propensity toward certain disease manifestations, although there can be clinical overlap, especially in severe cases where disseminated disease occurs. For example, HAdV F (types 40 and 41) causes gastroenteritis in children, whereas HAdV B (type 11) is associated with hemorrhagic cystitis post-hematopoietic stem cell transplantation (HSCT). Given their ability to target a wide variety of host cells, HAdV has been utilized as vectors for gene delivery in gene-based therapy [5]. Certain HAdV types, especially within subgroup A, have demonstrated oncogenic potential in animal models, but whether they cause neoplastic alterations in human cells remains unclear [6]. After acute infection, the virus can establish lifelong latent infection in lymphoepithelial tissue including intestinal T cells, lung epithelium, and renal epithelium and can reactivate if HAdV-specific T-cell immunity is impaired as in the posttransplant setting [7–9].

Epidemiology

Mode of Transmission

Most HAdV infections occur in young children, below 4 years of age. Other susceptible populations include persons living in close quarters such as college students and military recruits and immunocompromised patients, particularly those with impaired T-cell immunity [10]. Viral transmission occurs most commonly via droplet inhalation and direct inoculation into the oral mucosa or conjunctiva often from fecal contamination; virions are highly resistant to gastric acid and shed in high quantities in the stool [11]. Acquisition via infected blood and other body fluids and

Table 1 Human adenovirus disease manifestations per subgroup and type

Disease	Frequently associated HAdV subgroups and types	Predilection for immunocompromised hosts
Ocular manifestations		
Conjunctivitis	B: 3, 7 C: 1, 2 E: 4	No
Epidemic keratoconjunctivitis	D: 8, 9, 37	No
Hemorrhagic conjunctivitis	B: 11	No
Pharyngoconjunctival fever	B: 3, 7 E: 4	No
Respiratory manifestations		
Upper respiratory infection	B: 3, 7 C: 1, 2, 5	No
Pneumonia	B: 3, 7, 21 E: 4	Yes
Pertussis-like syndrome	C: 5	No
Acute respiratory distress syndrome	B: 7 E: 4	No (military recruits)
Gastrointestinal manifestations		
Gastroenteritis	F: 40, 41	No
Hepatitis	B: 3, 7 C: 1, 2, 5	Yes
Other manifestations		
Disseminated infection	B: 11, 34, 35 C: 1, 2, 5	Yes
Encephalitis	B: 7	Yes
Hemorrhagic cystitis	B: 11	Yes
Myocarditis	B: 7, 21	No
Reactivation disease	A: 12, 31 B: 3, 11, 16, 34, 35 C: 1, 2, 5 (Predominant)	Yes
Sexually transmitted infection	C: 2 D: 37	No

donor-derived transmission during organ donation have also been reported [12]. The incubation period ranges from 2 to 14 days after acquisition, depending on the mode of transmission and the viral inoculum. After initial infection, HAdV can establish persistent asymptomatic infection in lymphoid tissue of infected hosts and lead to prolonged shedding over months or longer. In one study of immunocompetent adults with respiratory infections, a regression model determined that shedding of HAdV type 55 occurred for 55 days [13]. HAdV infections occur perennially though outbreaks are more common in the winter and spring months. While there is some geographic variation in HAdV strains, global strain circulation occurs [4]. In the environment, HAdVs remain stable for weeks, and their lack of a glycoprotein and lipoprotein-rich envelop makes them much less susceptible to disinfectants than

enveloped viruses. Application of 85–95% alcohol solutions for 2 min or sodium hypochlorite for 10 min is effective at neutralizing the virus from environmental surfaces [14]. In immunocompetent hosts, HAdV infection mostly causes self-limited upper respiratory, conjunctival, or gastrointestinal disease.

Epidemiology in Transplant Populations

Primary infection with HAdV during childhood leads to lifelong latency in lymphoepithelial tissue and development of anti-HAdV immunity, including cellular and humoral responses. By targeting conserved antigenic elements within the HAdV hexon protein, a T-cell-dominant anti-HAdV response offers broad protection across all HAdV types. Immunity develops after exposure to HAdV, preventing reinfection with the same type and partial but not complete protection against other types. A humoral antibody response consisting of neutralizing antibodies against HAdV also forms. Loss of HAdV-specific T cells, as in the post-SOT and HSCT settings, is associated with an increased risk for viral reactivation from a latent state. HAdV infections in adult transplant patients arise chiefly from reactivation of latent viruses (most commonly subgroup C), whereas most infections in pediatric patients represent de novo infection, except for subgroup C serotype infections [15]. In allogeneic HSCT patients, HAdV strains isolated from clinical specimens prior to transplantation are usually identical to those detected after transplantation, and high titers of anti-HAdV dneutralizing antibody titers predict type-specific reactivation in the post-transplant period [16].

Epidemiology in Hematopoietic Stem Cell Transplant

Reactivation disease in transplant patients generally occurs within 100 days of HSCT and usually presents as asymptomatic viremia [17]. In adult HSCT patients, the incidence of HAdV viremia is 3 to 15% post-allogeneic HSCT. In comparison, the incidence of HAdV viremia in pediatric patients is significantly higher up to 47% for allogeneic HSCT, likely as a result of a higher incidence of primary HAdV infection [2]. In adult allogeneic HSCT patients, the progression from viremia to invasive disease occurs in 10–20% of cases but is uncommon in autologous HSCT [18, 19]. Invasive disease is more common in specific transplant populations with profound losses of HAdV-specific cellular immunity either via T-cell-depleted grafts or a requirement for increased immunosuppression. The highest-risk categories for the invasive adenoviral disease are allogeneic HSCT with T-cell depletion, unrelated HSCT, cord blood transplantation, GVHD grades III and IV, and receipt of alemtuzumab (CD52 antibody targeting both cellular and humoral immune branches) or antithymocyte globulin. In adult allogeneic HSCT patients, mortality for overall HAdV infection is low (<1%) but is much higher in symptomatic or disseminated disease (26%) [20], in those with risk factors such as unrelated grafts or receipt of alemtuzumab (32–49%) [21, 22], and in the presence of high-level HAdV viremia (60–80%) [23, 24].

Epidemiology in Solid Organ Transplant Recipients

In SOT, HAdV viremia usually develops within 6 months of transplantation. The incidence of HAdV viremia is less than 10% in adult kidney, heart, and liver SOT [25, 26] except for lung SOT where the incidence is higher (22%) [27], correlating with higher requirements for immunosuppression in the latter group and likely direct symptomatic infection of the graft. As with HSCT, the incidence of HAdV viremia is higher in pediatric patients (up to 38% liver SOT, up to 50% lung and heart SOT, and up to 57% with multi-visceral SOT) [2]. The rate of progression from asymptomatic viremia to invasive disease is not well characterized but is likely lower than HSCT populations except for lung and multi-visceral SOT. Risk factors associated with invasive disease in SOT also include receipt of thymoglobulin or alemtuzumab, prolonged lymphopenia, and donor-positive, recipient-negative HAdV transplants and allograft types with greater lymphoid tissue contents (such as multi-visceral or intestinal transplantation) [26]. Mortality is low overall except for lung transplantation, where courses are often rapidly progressive and early mortality can be seen [26]. In lung SOT, HAdV infection is also implicated in late mortality and graft failure through bronchiolitis obliterans and chronic rejection [28].

Clinical Presentation

HAdV infections in transplant recipients can range from asymptomatic to severe disseminated disease. Establishing the diagnosis of adenoviral disease versus asymptomatic infection can be a challenge as a transplant recipient can shed virus for months in the absence of symptoms. Clinical presentation may vary widely between transplant recipients. There is no consensus on definitions of adenovirus infections and disease; however, for discussion, the definitions proposed by the American Society of Transplantation Infectious Disease Community of Practice guidelines are used for this chapter [29] (Table 2). Several papers cited in this chapter have further defined adenoviral disease into (i) **proven disease**, which requires histopathological confirmation at the appropriate site of infection, and (ii) **probable disease**, which is adenoviral disease without histologic evidence [4, 30, 31].

Hematopoietic Stem Cell Transplant

HAdV infection is most commonly asymptomatic in HSCT recipients. Frequently reported early symptoms and laboratory evidence of adenoviral disease include fever, diarrhea, elevated liver enzymes, and cytopenias [32]. As noted previously, there is variation between HAdV subgroups. The spectrum of adenoviral disease can range from mild gastrointestinal or respiratory symptoms to severe pneumonitis, enteritis, hepatitis, tubulointerstitial nephritis, hemorrhagic cystitis, and meningoencephalitis [2, 23]. Unusual presentations of HAdV include cutaneous involvement

Table 2 Definitions of adenoviral infection[a]

	Definition
Asymptomatic infection	1. No clinical signs and/or symptoms of illness 2. Presence of adenovirus in any biologic sample (i.e., stool, blood, urine, respiratory tract) detected by viral culture, antigen tests, or PCR
Adenoviral disease	1. Signs and /or symptoms of illness 2. Detection adenovirus in one of the following: (a) Biopsy specimen by immunohistochemical stain[b] (b) Cerebrospinal fluid or bronchoalveolar lavage detected by culture, antigen detection, or PCR 3. Absence of other diagnosis
Disseminated adenoviral disease	1. Meets definition of adenoviral disease with 2. Involvement of two or more organs, excluding viremia

[a]Based on Ref. [29]
[b]Detection of adenovirus by PCR from tissue or fluid and negative immunohistochemical stain is **not consistent** with invasive disease

[33] and hemophagocytic lymphohistiocytosis [34, 35]. Disseminated disease occurs in up to 10–20% of cases [18, 36–38]. Retrospective studies have reported the onset of adenoviral disease predominantly within the first 100 days of HSCT, both because this is likely associated with the greatest degree of functional lymphopenia and also the most intensive monitoring [23, 39, 40]. With the implementation of HAdV screening, viral detection in blood, stool, or urine was shown to occur very early in the course of HSCT with a median time of 17–21 days from time of HSCT, almost always preceding clinical manifestation of the disease [2].

Detection of HAdV at multiple sites has been correlated with increased risk for invasive disease in pediatric HSCT [18, 39, 41]. Also, a rapidly rising or a sustained elevated HAdV viral load in blood or plasma has been associated with severe disease in both adult and pediatric HSCT [22, 41, 42]. The mortality of disseminated disease is up to 50% in this population [24, 40, 42].

Solid Organ Transplant

The clinical presentation of HAdV infection in solid organ transplant depends on the site of infection and the type of transplanted organ. Often, infection involves the allograft, representing either a primary infection or reactivation of latent infection in the recipient (recipient-derived) or donor organ (donor-derived). The infection may manifest differently depending on the transplant; bronchiolitis or pneumonitis is common in the lung allograft, hepatitis in the liver allograft, hemorrhagic cystitis in the renal allograft, or enteritis in the intestinal allograft.

Liver Transplant

In liver transplant recipients, HAdV can affect the liver, lungs, kidneys, and gastrointestinal tract. Clinical symptoms may include any of the following: fever, upper respiratory tract symptoms (reactive airway, rhinorrhea), diarrhea, hematuria, or

elevated liver enzymes [43, 44]. Frank hepatitis is a common presentation in pediatric liver transplant recipients. In a retrospective study of 49 pediatric liver transplant recipients who developed HAdV infection, 20 developed invasive disease that manifested as hepatitis ($n = 12$), hepatitis with pneumonia ($n = 2$), and pneumonia ($n = 5$) [43]. The most common serotypes recovered were 1, 2, and 5; type 5 was associated with hepatitis. There was an attributable mortality of 18% due to invasive disease. Eight of the 14 hepatitis cases survived, but among them, 4 patients developed graft loss requiring re-transplantation. In this cohort, the median time from transplant to isolation of the HAdV was 26 days. The timing of infection suggested either reactivation, donor-derived transmission, or hospital nosocomial acquisition. In a separate study at a single center, adenoviral hepatitis was proven by biopsy in seven pediatric liver transplant recipients with an associated mortality of 57% [45]. Focal hepatic lesions with or without associated tissue necrosis, a rare manifestation of adenoviral infections, were reported in two pediatric liver transplant recipients [46, 47].

In a cohort of adult liver transplant recipients, HAdV was isolated in 11 of 191 cases [30]. Of the 11 cases, 4 had an asymptomatic infection, and 7 had tissue-invasive disease (2 definite, 1 probable, and 4 possible). Clinical presentation included urinary tract infection, pneumonia, fulminant hepatitis, and disseminated multi-visceral disease. The mean time from transplant to HAdV isolation by culture was 66 days, while the mean time from transplant to symptomatic disease was 55 days (range 3–180 days). In a prospective cohort study by Humar et al., 263 CMV D+/R- adult SOT recipients were assessed for adenovirus infection using molecular surveillance technique [26]. Eight percent (10/121) of liver transplant recipients had detectable HAdV viremia during the first 12 months of transplantation. Of the 19 SOT recipients with detectable HAdV by PCR, 11 were asymptomatic (58%), and only a few presented with gastrointestinal (2/19, 10.5%) or respiratory (2/19, 10.5%) symptoms. A recent study of Majorant et al. evaluated adult and pediatric SOT recipients with HAdV-positive testing [48]. Four of 17 liver (31%) and 16 of 58 (27%) combined liver/intestine/pancreas recipients with detectable HAdV developed adenoviral disease. In this cohort, there was an increased rejection rate and higher mortality among those with the disease compared to those with asymptomatic infection, although only mortality was found to be significantly different.

Renal Transplant

In the study of Humar et al. that was previously mentioned, HAdV viremia was detected in 6.5% of 92 adult renal transplant recipients prospectively monitored by PCR, and most were asymptomatic [26]. A 2-year prospective cohort study of 75 pediatric renal transplant patients found that 14.5% ($n = 11$) developed HAdV viremia at a median onset of 173 days (interquartile range 109–310 days) and 6 (8%) were asymptomatic [49]. Renal transplant recipients frequently present with hemorrhagic cystitis due to HAdV characterized by fever, dysuria, urgency, frequency, and hematuria [12, 25, 34, 50–54]. In a 3-year, single-center experience [25], 16 of 17 adult kidney transplant recipients developed HAdV hemorrhagic

cystitis, and most (75%) presented during the first 3 months of transplant. Hemorrhagic cystitis in pediatric renal transplant recipients is infrequently reported compared to adult populations. In the study of Engen et al., only 3% had HAdV hemorrhagic cystitis. HAdV infection may occasionally involve the renal parenchyma causing necrotizing granulomatous nephritis that can occur with or without hemorrhagic cystitis [55–60]. The findings of necrosis, granulomas, and hemorrhage on renal biopsy specimens favor HAdV over polyomavirus nephritis, although immunohistochemistry can usually differentiate the two also [61]. Adenoviral nephritis can be confused with acute rejection. Graft dysfunction can often be seen with hemorrhagic cystitis; however, it is once again more frequently reported in adults than in their pediatric counterpart [25, 50, 62, 63]. Hofland et al. [50] and Watcharananan et al. [25] observed graft dysfunction among those with HAdV hemorrhagic cystitis in 35 of 37 patients (95%) and 11 of 17 patients (65%), respectively. The graft dysfunction resolved in the majority of patients after the resolution of adenoviral disease [25].

In addition to hemorrhagic cystitis, adenoviral HAdV disease in renal transplant recipients may present outside the graft, with enteritis, pneumonitis, hepatitis, and orchitis [25, 64, 65]. However, few cases of interstitial pneumonitis [64–66], colitis [67], and hepatitis [68] have progressed to disseminated disease and subsequent death, perhaps consistent with lower degrees of immunosuppression in this solid organ transplant population.

Lung Transplant

Detectable HAdV in plasma was observed in 22.5% of adult lung transplant with a median time of detection from transplant of 134 days (range 1–370 days) [69]. HAdV involving the allograft in lung transplant recipients can have deleterious consequences, including graft dysfunction, acute graft rejection, bronchiolitis obliterans, and death [28, 70, 71].

Mortality due to adenoviral pneumonia is significant in this population. In a study conducted by Ohori et al., all lung transplant recipients (4/4) with adenoviral pneumonia died within 45 days posttransplant despite no evidence of disseminated disease [70]. In a prospective study of 16 pediatric lung and lung-heart transplant recipients for viral pneumonia, HAdV was the most commonly detected virus, accounting for 50% of recipients with a median time from transplant to HAdV detection of 46 days (range 1–458 days) [28]. Of the eight patients, only two survived. Two deaths occurred early in the posttransplant course due to fulminant respiratory failure, one of which was secondary to donor-derived infection. More importantly, this study demonstrated the association of adenoviral infection with bronchiolitis obliterans and graft loss as a late phenomenon sometimes many months after initial infection.

Heart Transplant

As with other SOT recipients, heart transplant recipients are most commonly diagnosed with HAdV infection within the first year of transplant, often by performing HAdV PCR on endomyocardial biopsy specimens [72, 73]. Detection of HAdV by

PCR does not necessarily equate to disease. However, Shirali et al. found that it was predictive of adverse cardiac events, including coronary vasculopathy, acute rejection, or chronic graft failure within 3 months post-biopsy result [72]. Both Shirali et al. [72] and Moulik et al. [73] demonstrated an association between detectable HAdV genome in the myocardium of pediatric transplant patients and reduced graft survival. Pediatric heart transplant recipients with detectable HAdV nucleic acid in allograft specimens diagnosed during rejection surveillance by endomyocardial biopsy were found to have histologic evidence of multifocal moderate to severe rejection [74]. This finding alluded to the possible role of HAdV in rejection, akin to late onset bronchiectasis in lung transplants, but a causal relationship remains to be proven. In addition to cardiac complications from HAdV, extra-cardiac adenoviral disease in heart transplant recipients has been reported, similar to other organs, including conjunctivitis with disseminated disease [75], hepatitis [76], and pneumonia [77, 78].

Intestinal Transplant

Most studies on HAdV infections in intestinal transplant involve pediatric patients [79–81]. Cases may be diagnosed incidentally on routine graft biopsies, not necessarily prompted by symptoms. Ziring et al. performed a retrospective review of 33 patients (30 children, 3 adults) who underwent intestinal transplantation between 1991 and 2003 [80]. Four of the 20 identified cases of enteritis were due to HAdV. One of the four HAdV cases suffered from graft loss, but all survived. Pinchoff et al. [79] reported 14 intestinal transplant recipients (6 intestinal transplant only, 8 liver/intestinal transplant) with routine graft biopsies that were positive for HAdV viral cultures. Of these, only eight were confirmed as adenoviral enteritis by histopathology. The most common symptom in this study was increased ostomy output. Three of the eight patients died; two deaths were attributed to HAdV. In another study, 23.5% of 98 pediatric intestinal transplant recipients developed adenoviral disease, and 15% were asymptomatic shedders that did not progress to invasive disease [81]. Nineteen of 23 cases (82.6%) involved the allograft and occurred within the first year of transplant. The remaining four cases had HAdV pneumonia, three of which developed disseminated disease and died. In both studies, younger age at the time of transplantation was a risk factor for infection [80, 81].

Diagnosis

Several methods are available for the diagnosis of HAdV infections. These include historical methods now rarely used in clinical practice, such as viral culture, shell vial centrifugation, serology, and antigen detection, as well as newer techniques including histopathology with immunohistochemical staining, electron microscopy, PCR, and metagenomic sequencing. Some of the tests, particularly culture immunohistochemical staining, electron microscopy, and metagenomics, which require significant laboratory expertise and hands-on skill are more likely available in resource-replete settings and may not be readily available in smaller medical centers

or rural areas. The specimen types submitted for testing should be guided by the clinical syndrome and include blood, plasma, stool, urine, ocular fluid, cerebrospinal fluid, bronchoalveolar lavage fluid, and nasopharyngeal swabs, among others.

HAdV can be identified using conventional cell culture techniques by detecting a characteristic cytopathic effect (CPE) in a monolayer of host cells. Classic HAdV CPE consists of grape-like aggregates of refractile cells with a lacy configuration [82]. Serotypes 40 and 41 do not produce distinctive CPE and so cannot readily be identified using viral culture. Using this technique, most HAdV can be identified within 2–5 days, but CPE may take up to 4 weeks to develop with specific serotypes or a low viral burden. The sensitivity of culture for HAdV is low, limiting its utility as a routine diagnostic method. Moreover, HAdV can be asymptomatically shed, so positive results must be taken into consideration of the clinical context, with a few exceptions such as ocular fluid in which HAdV detection is considered diagnostic. At the present time, cell culture is limited to public health and epidemiological investigations, given the time and resource consuming nature of the work.

Detection of HAdV can be achieved using rapid culture methods in a shorter time frame. Shell vial cell centrifugation culture techniques employ immunofluorescence to detect early viral antigens prior to the development of detectable CPE. Such methods are particularly useful for viruses that require prolonged incubation periods. After the addition of clinical specimen, shell vial culture tubes are centrifuged to inoculate a cell monolayer. After incubation for up to 4 days, monolayers are stained with virus-specific immunofluorescent antibodies and examined for the presence of intracellular viral antigens. Though more rapid, shell vial centrifugation is less sensitive than culture and may fail to detect low concentrations of virus or certain HAdV types [83].

In the setting of infection, HAdV CPE can be detected in clinical tissue specimens submitted for histopathological evaluation. Histopathologic evidence of HAdV is still considered by many to be the gold standard for the diagnosis of invasive adenoviral disease [29]. Cells infected with HAdV develop large nuclei with prominent basophilic nuclear inclusions and a narrow cytoplasm, giving the appearance of "smudge cells." Formation of granulomas has been described in some case of renal allograft infection. Cytopathic changes are often subtle and easily overlooked in hematoxylin and eosin-stained specimens. Moreover, in SOT, the pathologic findings associated with HAdV graft infection, especially nephritis, can be challenging to discern from acute organ rejection [84]. Therefore, the use of immunohistochemical or immunoperoxidase stains is advisable when HAdV infection is suspected (Fig. 1) [85]. If HAdV is suspected, discussion with pathology colleagues can ensure adequate staining is performed. Electron microscopy, if available, can demonstrate adenoviral particles within infected cells, but this method is mostly reserved for research purposes.

Several commercially available rapid antigen detection assays for HAdV based on enzyme immunoassay, immunochromatography, or latex agglutination are applicable to ocular and stool specimens. In comparison with PCR, the sensitivity of these assays is poor in older and immunocompromised patients [86], but the performance on ocular fluid appears to be better [87]. Direct and indirect

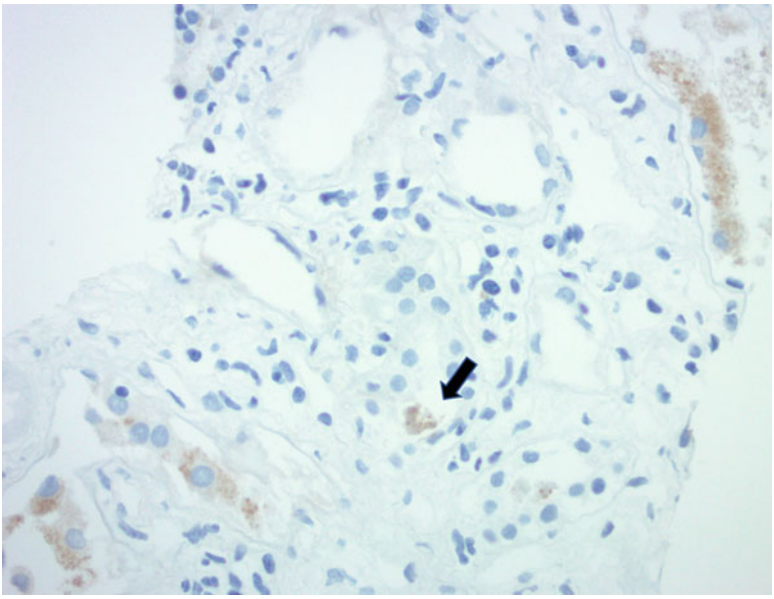

Fig. 1 Immunohistochemical staining of kidney tissue demonstrating presence of adenovirus antigen (see arrow)

immunofluorescence assays are usually performed on respiratory specimens (Fig. 2). The advantage of this method is the ability to evaluate specimen quality by assessing for the presence of exfoliated ciliated columnar epithelial cells from the posterior nasopharynx or mid-turbinate, which is indicative of a well-collected specimen and squamous epithelial cells, indicative of an unsatisfactory specimen. Whereas the use of chromophore-bound monoclonal antibodies allows for high specificity, immunofluorescence techniques are, in fact, less sensitive even than viral culture, which is not the case for other respiratory viruses [88]. Serology for HAdV is not useful diagnostically, especially in immunocompromised patients such as transplant recipients who may be unable to mount a humoral response. However, assessment of neutralizing antibodies to specific serotypes is useful for immunoepidemiologic studies of HAdV infection [16].

By virtue of significantly greater sensitivity and specificity and much shorter processing times, amplification of adenoviral DNA followed by detection using PCR has superseded all other methods to become the test of choice for the diagnosis of HAdV infections, at least in North America [89]. PCR assays capture the vast majority of HAdV types by targeting well-conserved regions including the transactivating region of E1A gene and N-terminal region of hexon gene, though other targets are sometimes included to identify rare HAdV types or to capture emerging types [90]. Both single-target PCR assays and multiplex panels targeting multiple pathogens at once are available. Many academic centers rely on laboratory-developed tests for HAdV detection, especially on blood or plasma.

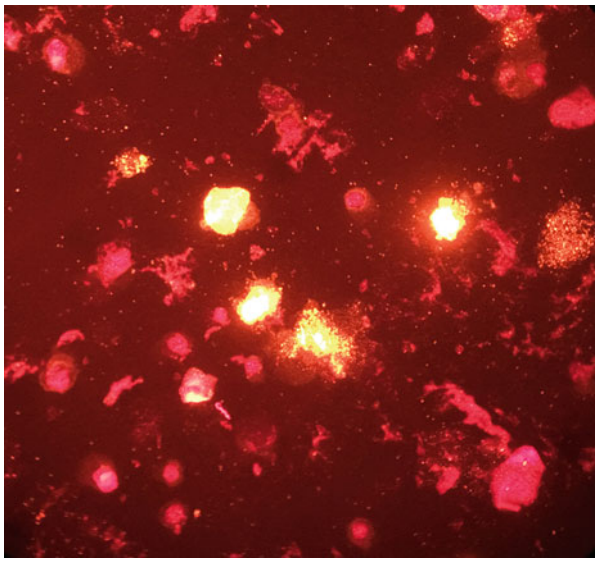

Fig. 2 Direct immunofluorescence assay of a nasopharyngeal swab specimen demonstrating yellow-gold fluorescence of nasopharyngeal cells, indicating the presence of adenovirus antigen

These often employ a real-time PCR approach, which is more rapid, provides quantitative information, and is less prone to contamination [91]. Quantitative PCR assays on blood are especially useful for screening and diagnosis in severely immunocompromised patients, for whom HAdV viremia is predictive of disseminated disease [41]. Analytical sensitivity of 10^2 virus copies/mL is required to ensure early detection of the virus in peripheral blood and to prevent false-negative results. However, due to significant assay heterogeneity and a wide variety of patient populations tested, results of PCR assays cannot readily be interpreted across assays and laboratories. Efforts at developing a universal calibration standard for HAdV are currently underway [92], but there is presently no accepted threshold value of HAdV viremia beyond which antiviral treatment is recommended. Though a well-defined cut-off value to distinguish reactivation from disease is not yet available, a rapid rise in viral load may be associated with the development of invasive or disseminated infection [41]. They can also be helpful to sequentially follow HAdv in the blood, so as to assess virologic improvement. The high sensitivity of PCR assays may result in detection of low-level HAdV from various sites. In asymptomatic subjects, low-level viremia with stable or decreasing kinetics often represents viral shedding rather than disease.

Several commercial FDA-approved multiplex PCR assays that include HAdV targets have become available in recent years. Among these, there are assays applicable to respiratory specimens and stool (Table 3). Respiratory panels generally perform well in comparison to monoplexed real-time PCR methods. However, initial versions of the BioFire RP (v1.6) assay were significantly less sensitive (67%) than comparator PCR assays for the detection of HAdV. An

Table 3 Commercial monoplex and multiplex PCR assays, available in the United States, for HAdV detection

Commercial PCR assays and manufacturer	Monoplex or multiplex	Validated specimen	HAdV subgroups covered	Turnaround time
FilmArray Respiratory Panel (RP) and RP 2 plus, BioFire Diagnostics	Multiplex	Respiratory (NPS)	A, B, C, D, E, F, G	RP: 65 min RP 2 plus: 45 min
FilmArray Respiratory Panel EZ, BioFire Diagnostics	Multiplex	Respiratory (NPS)	A, B, C, D, E, F, G	60 min
FilmArray Respiratory Pneumonia Panel, BioFire Diagnostics	Multiplex	Respiratory (BAL or mini-BAL)	A, B, C, D, E, F, G	60 min
eSensor RVP, GenMark Diagnostics	Multiplex	Respiratory (NPS)	B, C, E	6 h

Abbreviation: *NPS*, nasopharyngeal swab; *NS*, nasal swab; *NW*, nasal wash

updated version (v1.7) reported significantly improved sensitivities (91%) mainly due to improved coverage of HAdV types [93], but a subsequent study among a large pediatric cohort found that the BioFire RP v1.7 had lower sensitivity for species A, D, and F [94]. In this study, approximately 5% of specimens that were negative by BioFire RP v1.7 were positive using a laboratory-developed PCR. Several of these cases occurred among immunocompromised patients prompting the authors to caution against the use of the RP v1.7 as the stand-alone test to rule out HAdV in this population.

Unlike respiratory PCR panels that target the majority of HAdV types, most gastrointestinal panels only cover serotypes F40 and F41. Whereas these serotypes are the most common causes of gastroenteritis in immunocompetent children, HAdV species C are more common in the setting of transplantation because they are associated with reactivation. Therefore, these panels should not be used to rule out HAdV infection in high-risk transplant populations [95]. High viral loads of 10^6 virus copies/ml in the stool are associated with a greater risk for future viremia in HSCT patients [17].

Metagenomic next-generation sequencing (mNGS) is an emerging technique that allows for rapid and comprehensive pathogen identification by sequencing the entire nucleic acid present in a clinical specimen. Though less sensitive than directed PCR assays for known targets, mNGS may identify novel, emerging, or genomic mutated HAdV strains not captured by PCR. Several cases of HAdV infections determined by mNGS assays and missed by PCR have been recently reported [96, 97]. As such, mNGS may have a role in the diagnosis of transplant patients with clinical syndromes consistent with HAdV but with negative PCR testing. Testing using mNGS assays may be performed using (1) assays developed within academic medical centers (laboratory-developed assays) and as such may be performed in-house with shorter turnaround times or (2) commercially available assays which require specimen transport/shipping with processing times of up to 10 days. Commercial testing is often very costly, limiting use to difficult or illusive clinical scenarios.

Treatment

Antivirals currently used for the treatment of HAdV infection are not supported by randomized clinical trial data nor FDA-approved for the treatment of HAdV infections. Cidofovir, ganciclovir, and ribavirin have in vitro efficacy against different HAdV serotypes [98, 99] and have been reported in case reports and case series as therapeutic interventions for HAdV infection.

Ganciclovir is a nucleoside analogue of guanosine that has in vitro activity against HAdV. Only one study to date has demonstrated a protective effect against the development of HAdV infection in HSCT [20]. Published reports of its use for the treatment of adenoviral disease in HSCT and SOT are limited to case reports [100–102].

Ribavirin is a guanosine analogue that has in vitro activity against most HAdV isolates within subgroups A, B, and D and all isolates from subgroup C [98]. Its mechanism of action against HAdV is not well established. The limited therapeutic benefit was observed in treated immunocompromised patients, attributed mainly to the failure to decrease viral titers [103, 104]. Ribavirin was not recommended as a treatment of choice for adenoviral disease by the European Conference on Infections in Leukemia [32].

Cidofovir is a cytosine analogue of cytosine that is converted by cellular kinase to an active intracellular metabolite, cidofovir diphosphonate; this form acts as a

competitive inhibitor and alternative substrate for 2-deoxycytidine 5′ triphosphate of the DNA polymerase and subsequently inhibits viral replication [105]. Cidofovir has in vitro activity against different HAdV serotypes [98], and evidence for efficacy against HAdV is the most robust [106–108]. It is currently available in an intravenous formulation which is limited by dose-dependent nephrotoxicity [109] and ocular toxicity [110–112]. To reduce nephrotoxicity, hydration and co-administration with probenecid are recommended [113]. Two regimens can be used for the treatment of adenoviral disease: (1) 1 mg/kg three times a week or (2) 5 mg/kg /week for 2 weeks followed by 5 mg/kg every 2 weeks dosing until clinical resolution of HAdV infection [29, 32]. These two strategies have not been compared with regard to efficacy; however, the 1 mg/kg three times a week is associated with less nephrotoxicity [114, 115]. Virologic response to cidofovir, monitored by plasma HAdV viral PCR, correlates with clinical response [116, 117]. Failure to achieve ≥ 1 $\log_{10}$ reduction in viral load in the first 2 weeks of cidofovir therapy is associated with disease progression and death secondary to symptomatic disease [116].

Brincidofovir (CMX001, Chimerix Inc.), a lipid conjugate of cidofovir, is currently in development. Brincidofovir has good oral availability and achieves better intracellular levels of the active drug compared to cidofovir [118]. Compared to cidofovir, brincidofovir is 5- to $\geq$2500-fold more potent against HAdV [119]. Importantly, brincidofovir is not nephrotoxic; however, dose-limiting gastrointestinal toxicities (such as nausea, vomiting, diarrhea) have been reported more commonly in HSCT recipients [120]. A study involving 13 immunocompromised patients (11 HSCT, 1 intestinal transplant, 1 severe combined immunodeficiency) with life-threatening adenoviral disease refractory or intolerant to cidofovir were treated with brincidofovir [121]. Eight patients (61.5%) had a >1 $\log_{10}$ drop in viral load after the first week of therapy, and 9 patients (69.2%) achieved virologic response by 8 weeks of therapy. Patients with virologic response had more prolonged survival in contrast to those without virologic response (median 196 days vs. 54.5 days, $p = 0.04$). A phase II study evaluated two different doses of brincidofovir in preemptive therapy of HSCT recipients with asymptomatic viremia [122]. Patients were randomized to brincidofovir 100 mg twice weekly, brincidofovir 200 mg weekly, or placebo for 6 to 12 weeks. After 1 week of therapy, 8 of 12 (67%) patients with twice weekly dose had undetectable HAdV viral load compared to 4 of 14 patients (28%) in once weekly dose and 5 of 15 (33%) of placebo. A phase III, open-labeled study on the safety and efficacy of brincidofovir for HAdV infection has been completed; results are not yet published (ClinicalTrials.gov Identifier: NCT02087306). Ongoing availability of brincidofovir is limited, with compassionate access also restricted.

Reduction in immunosuppression remains the cornerstone of treatment. Immune reconstitution is essential in the resolution of HAdV infection. In a study of Feuchtinger et al., individuals who cleared HAdV infection had more HAdV-specific T cells compared to those who failed to control infection [123]. The decline in viremia and survival of HSCT recipients with HAdV infection is associated with increases in lymphocyte count, presence of HAdV-specific CD4+ T-cell responses, and increases in neutralizing antibody titers [40, 124, 125]. Currently, there is no

particular consensus on how to approach to immunosuppression reduction and when to restart immunosuppression after HAdV infection [29]. Due to the role of lymphocyte reconstitution in the clearance of infection, several small studies and phase I/II clinical trials have explored the utility of donor-derived HAdV specific T cells in the treatment of HAdV infection in HSCT [126–131]. Results were encouraging without an increased risk for GVHD associated with the reduction of immunosuppression. To date, there are no available data in SOT recipients. Use of intravenous immunoglobulin has been reported in case reports and case series of severe HAdV disease in combination with antiviral therapy [78, 132–134]. No specific conclusion can be made based on these limited data. However, patients with severe hypogammaglobulinemia (IgG $<$ 400 mg/dl), who are generally at risk for opportunistic infections, may benefit from intravenous immunoglobulin infusions [29, 135].

Prevention

Preemptive treatment strategies have been advocated for certain HSCT with increased risk for HAdV (see the section on "Epidemiology"). Because progression from viremia to disease is uncommon in SOT patients, screening strategies are not recommended in this group. The process involves HAdV monitoring in stool or peripheral blood by PCR and reduction in immunosuppression if HAdV is detected [17, 32, 136]. The rationale of this approach is to initiate therapy before clinical symptoms occur. It was previously observed that a period of asymptomatic viremia precedes disseminated adenoviral disease [41]. In addition to the reduction of immunosuppression, the administration of HAdV-specific T cells as part of the preemptive strategy has been described [17, 136]. Preemptive treatment strategy with cidofovir has been reported [114, 136, 137]; however, nephrotoxicity limits its use. More studies are needed to evaluate the role of brincidofovir in preemptive treatment [122].

Conclusion

HAdV infection most commonly presents as asymptomatic viremia in transplant patients, but progression to tissue-invasive or disseminated disease can occur. The incidence of severe disease is highest in HSCT and lung transplant patients and is associated with very high mortality. Diagnostic testing of clinical specimens should be guided by the presenting clinical syndrome as HAdV types preferentially infect specific host tissues. PCR-based assays are now the tests of choice, but results must be carefully interpreted to distinguish asymptomatic shedding from disease and to rule out the possibility of false-negative results due to serotype noncoverage or novel mutations. Reduction of immunosuppression remains the cornerstone of HAdV treatment as antivirals are often toxic and suboptimally effective. The advent of brincidofovir and HAdV-specific T cells represents new and potentially valuable tools that may revolutionize the treatment of HAdV infections.

Key Points

- Human adenoviruses (HAdV) are non-enveloped double-stranded DNA viruses of the family *Adenoviridae*.
- After acute infection, the virus can establish lifelong latent infection in lymphoepithelial tissue and can reactivate if HAdV-specific T-cell immunity is impaired as in the posttransplant setting.
- Reactivation disease in transplant patients generally occurs within 100 days of HSCT and usually presents as asymptomatic viremia.
- The incidence of HAdV viremia is 3–15% post-allogeneic HSCT in adults, and progression from viremia to invasive disease occurs in 10–20% of cases.
- The incidence of HAdV viremia is less than 10% in adult kidney, heart, and liver SOT except for lung SOT, where the incidence is higher (22%).
- The clinical presentation of HAdV infection can range from asymptomatic infection to end-organ disease, including pneumonitis, enteritis, hepatitis, tubulointerstitial nephritis, hemorrhagic cystitis, and meningoencephalitis in SOT and HSCT.
- In SOT, HAdV infection may involve the allograft, either as a primary infection or a reactivation of latent infection in the recipient or donor organ.
- Graft dysfunction in adenoviral infection has been observed in SOT recipient occasionally resulting to graft loss; however, no causal relationship has been established between HAdV and graft rejection.
- Methods for the diagnosis of HAdV infection include viral culture, shell vial centrifugation, histopathology, immunohistochemical staining, electron microscopy, immunofluorescence assays, antigen detection, serology, polymerase chain reaction (PCR), and metagenomic sequencing.
- By virtue of greater sensitivity and specific and shorter processing times, the test of choice for diagnosis of HAdV infection is PCR.
- Though a well-defined cutoff value to distinguish reactivation from disease is not yet available, a rapid rise in viral load may be associated with the development of invasive or disseminated infection.
- Reduction of immunosuppression is the cornerstone of management of HAdV infection.
- There is no current FDA-approved drug for the treatment of HAdV infection; however, among current antivirals, cidofovir has the most evidence for efficacy against HAdV.
- Immunotherapy may have a role in the treatment of HAdV in cases which poorly responded to reduced immunosuppression and antiviral therapy.
- A preemptive treatment strategy may have a role in the prevention of adenoviral disease progression in at-risk patients with asymptomatic viremia.

Introduction

A frequent complication in kidney transplantation (KT) and allogeneic hematopoietic stem cell transplantation (HSCT) results from uncontrolled replication of BK polyomavirus (BKPyV). BKPyV is the causative agent of polyomavirus-associated nephropathy (PyVAN) seen in 1–15% of KT patients and polyomavirus-associated hemorrhagic cystitis (PyVHC) occurring in 5–20% of HSCT recipients. In addition, PyV-associated urothelial cancer (PyVUC) has been recognized as an emerging entity [52, 71]. Immunocompetent individuals are not affected by these diseases despite three striking facts: First, more than 90% of the general human population has been exposed to BKPyV according seroprevalence studies around the world [20, 51]. Second, the virus is not cleared from the human host, but persists in the kidneys despite the presence of potent neutralizing antibodies and virus-specific T cells [75, 84]. Third, at least 10% of BKPyV-IgG-seropositive immunocompetent healthy blood donors shed the virus asymptomatically in the urine indicating viral immune escape [20]. These virologic characteristics contribute to rendering BKPyV one of the most successful human-specific viruses, whereby the absence of known health impact argues for a long-standing coevolutionary adaptation with the human host. Conversely, this carefully established virus-host balance is likely to be significantly perturbed in patients' developing disease. Moreover, the differences in pathology and between the two key populations at risk for disease argue that specific aspects of relevance to the pathogenesis must differ. If so, research on the relevant viral and host factors and the specific perturbing factors should allow understanding of specific risk profiles as well as targeted prevention and therapy approaches. Indeed, PyVHC is rarely observed after KT, while PyVAN is rarely diagnosed after allogeneic HSCT, and both are very infrequent in non-kidney solid organ transplants (SOT) [29, 85]. Here, we review the key manifestations of BKPyV pathology, the diagnostic tools, and the epidemiological markers of risk and treatment response (Fig. 1).

Polyomavirus-Associated Nephropathy: PyVAN

Pathology and Clinical Impact

Proven PyVAN is defined by the detection of BKPyV proteins in cytopathically altered renal tubular epithelial cells. The most commonly used marker of BKPyVAN is the immunohistochemical detection of the large T antigen (LTag) using the cross-reacting monoclonal antibody raised against the homologous protein of the monkey SV40 polyomavirus [6, 16, 76]. An estimated 8% (95% CI 1–15%) of kidney transplant (KT) recipients are at risk of proven PyVAN [38]. In the first case series from the USA and Europe, increased immunosuppression involving steroid pulses in response to acute rejection episodes and switching to high-dose tacrolimus-containing "rescue" immunosuppression have been consistent hallmarks [34], a combination that also emerged from prospective studies [38, 42].

The clinical impact of uncontrolled BKPyV replication in KT can be projected when considering that, following induction with depleting antilymphocyte or non-depleting interleukin-2 antibodies, the combination of tacrolimus, mycophenolate, and steroids is the current standard maintenance immunosuppression for approximately 90% of KT recipients around the world. According to a large international multicenter open-label study having BKPyV-DNAemia post-transplant up to month 6 post-transplant as secondary endpoint, BKPyV-DNAemia was detected in 16.3% of the patients in the tacrolimus arm (probable PyVAN), of which 9.4% had plasma BKPyV loads of more than 10,000 copies/mL (presumptive PyVAN) [42]. At the follow-up visit at month 12, BKPyV-DNAemia was still seen in 12% and significantly associated with a reduced estimated glomerular filtration rate (eGFR) of 60.4 mL/min compared to 65.7 mL/min in non-BKPyV-DNAemic patients [42]. In a simplified estimate, approximately 200,000 patients with terminal renal failure are listed for KT in North America and Europe, 50,000 are transplanted each year, and 10,000 patients decease while wait-listed. Taking BKPyV-DNAemia rates of 15% and 10% at month 6 and 12 post-transplant, 7500 and 5000 KT patients annually must be considered at risk for BKPyV-associated premature renal allograft failure in North America and Europe, hence not reaching the average kidney graft survival time of 13–15 years. Given the complex interactions of too high and too low immunosuppression and acute and chronic rejection pathologies, the direct attribution of premature allograft failure to persisting BKPyV replication and PyVAN is difficult. This is not because the ability and interest in modern diagnostic work-up is fading, but because so far, inflammatory changes in the renal allograft biopsy cannot be readily attributed to either viral damage or antiviral or anti-donor immunity. Importantly, these entities should not be regarded as mutually exclusive as long as validated markers are lacking to assess their potential coexistence, contribution, and dynamics. This applies also to subsequent unspecific histological changes including interstitial fibrosis/tubular atrophy ("chronic allograft failure"), which may be partly caused by difficult overlapping management issues for acute cellular rejection and/or antibody-mediated rejection. Importantly, the perspective of returning to waiting lists and retransplantation may be dire because of the higher immunological risk, the prolonged waiting times, and death while waiting as well as the increased risk of recurrent PyVAN. The impact on patient and relatives as well as the associated health-care costs of this condition should not be underestimated.

The first large systematic description of histological features of renal biopsies of PyVAN proposed five histological stages that were increasingly associated with graft loss as the most severe outcome. Cytopathic effects of viral replication, the extent of inflammation, as well as tubular atrophy and fibrosis were considered (Fig. 2). Immunohistochemical detection of LTag using SV40 antibodies showed BKPyV-replicating cells typically confined to nephrons next to unaffected tissue emphasizing the focal nature of the disease (Fig. 2). This (multi)focal distribution increases the likelihood of a PyVAN-negative biopsy especially early in the disease. Indeed, biopsies from the same patients obtained simultaneously had discordant negative and positive biopsies in 10–30% of cases, mostly without inflammatory infiltrates [17].

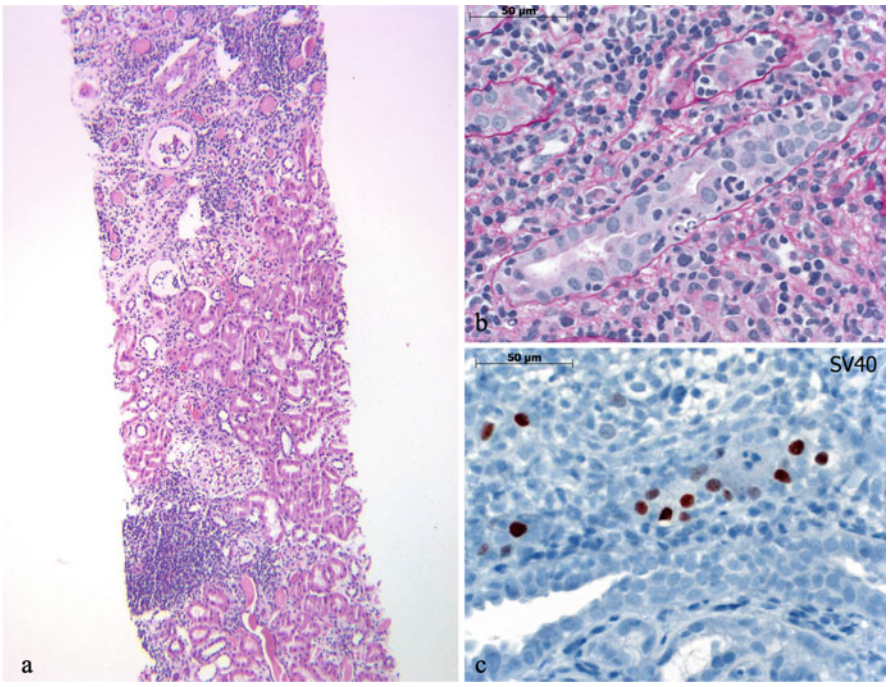

Fig. 2 (**a**) Renal biopsy showing viral cytopathic changes and interstitial inflammation. NB, not all areas are affected. (**b**) Tubulus with viral inclusions (enlarged nuclei) in renal proximal tubular epithelial cells. Viral replication leads to denudation and tubular atrophy. (**c**) Immunohistochemistry with SV40 LTag cross-reacting antibodies (dark spots) demonstrates viral presence. Histology images courtesy of Professor Helmut Hopfer (Pathology, University Hospital Basel).

Based on this initial study, PyVAN is classified into three categories: PyVAN-A (mild viral cytopathic changes), PyVAN-B (cytopathic changes and significant interstitial inflammatory infiltrates of increasing intensity), and PyVAN-C (less cytopathic changes, less interstitial inflammation but extensive tubular atrophy and interstitial fibrosis). PyVAN-B is further subdivided in three subgroups according to the extent of interstitial inflammation in the biopsy core (B1 of 11–25%, B2 26–50%, or B3 >50%, respectively) [17, 40]. All PyVAN patients showed significant viruria (mean of 2.5×10^8 c/mL), decoy cells (cells with enlarged nuclei and viral particle inclusions) in urine, and BKPyV-DNAemia (mean of 2.32×10^7 c/mL) [17, 24] (Table 1).

Recently, the Banff Working Group of Pathologists have proposed scores from 1 to 3 according to the intrarenal PyV load (PyVL) and the interstitial fibrosis ci score from 0 to 3 (Table 1). Analyzing 192 patients with proven PyVAN, PyVL and ci score were significantly correlated with renal function at time of index biopsy, renal function at 2 years post-transplant, and eventual graft failure. Since inflammation may have an independent role in affecting the renal allograft function, proven PyVAN is currently recommended to be scored by either classification until independent prospective re-evaluation is possible in the future [44].

Table 1 Clinical and laboratory observations in patients with BKPyV-associated disease

PyVAN	PyVHC
Clinical diagnosis: • Possible: high-level BKPyV-viruria >7 $\log_{10}$ c/mL and/or decoy cells • Probable: BKPyV-DNAemia >3 $\log_{10}$ c/mL sustained for >2 weeks • Presumptive (laboratory-confirmed): increasing BKPyV-DNAemia of >4 $\log_{10}$ c/mL • Proven: renal biopsy showing cytopathic changes plus viral protein expression demonstrated by immunohistochemistry *Evaluation of biopsy*: PyVAN-A: mild viral cytopathic changes, little or no inflammation, little or no fibrosis or tubular atrophy PyVAN-B: cytopathic changes and significant inflammation (extent of inflammation: B1 = 11–25%, B2 = 26–50%, B3 = >50%). PyVAN-C: little viral cytopathic changes, little interstitial inflammation, extensive (>50%) tubular atrophy and interstitial fibrosis *Classification of PyVAN (Banff working group)* PyVAN class-1: PyVL=1 Banff Ci score = 0-1 PyVAN class-2: 1 2-3 2 0-3 3 0-1 PyVAN class-3:3 2-3 (PyVL 1 ≤ 1%, PyVL 2 > 1% – ≤10%, PyVL 3 >10% of all tubules/ducts SV40+LTag; Ci score: extent of interstitial fibrosis of the cortical area of 0 ≤ 5%, 1 = 6–25%, 2 = 26–50%, 3 >50%)	*Clinical and laboratory triad*: 1. Clinical symptoms of cystitis: dysuria, urge, frequency, lower abdominal pain 2. Grade 2 or higher hematuria 3. BKPyV-viruria of >7 $\log_{10}$ c/mL *and* Exclusion of other relevant causes of HC: other infectious agents, bleeding disorders, metastatic neoplasia, trauma including stents or catheters *Grading of hematuria*: Grade 1: microscopic Grade 2: macroscopic Grade 3: macroscopic with clots Grade 4: macroscopic with clots and post-renal failure *Adjunct diagnostic considerations*: BKPyV-DNAemia >4 $\log_{10}$ c/mL (seen in approximately 70% of cases with triad)

Clearance of PyVAN was recently evaluated by Menter and colleagues in patients treated with reducing immunosuppression [63]. They observed a significant increase in interstitial inflammation and in intraepithelial lymphocytes, often with disappearance of the SV40-LTag signal, but a rise in serum creatinine levels with resolving PyVAN. While these observations support the independent role of inflammation affecting renal allograft function, the self-limiting nature without explicit anti-inflammatory or antirejection treatment in that series argues that regaining BKPyV-specific immunity may transiently affect renal allograft function akin to immune reconstitution inflammatory syndrome (IRIS) prominently described in HIV/AIDS [39] and to multiple sclerosis patients discontinuing natalizumab for progressive multifocal leukoencephalopathy, another PyV pathology caused by JC polyomavirus in the brain [41]. However, acute interstitial cellular rejection remains an important differential diagnosis in this setting, which currently cannot be distinguished molecularly or morphologically.

Nevertheless, plasma BKPyV-DNAemia dynamics can be correlated with the histopathology, whereby inflammation and early decline in BKPyV loads in SV40-cleared renal biopsies favor the diagnosis of antiviral immune reconstitution over acute cellular rejection [63].

The low sensitivity of allograft biopsy compared to plasma BKPyV-DNAemia is supported by another study of proven PyVAN, reporting faster clearance of SV40-LTag in the biopsy than BKPyV-DNAemia [48]. A 50% clearance rate of SV40-LTag detection by immunohistochemistry was seen after approximately 4 months (total 18/22 (81.8%) patients at 6.2 +/− 7.5 months) compared to approximately 8 months for BKPyV-DNAemia (total 17/22; 77.3%) following tacrolimus to cyclosporine A conversion or administration of intravenous immunoglobulin (IVIG) preparations [48]. Finally, allograft nephrectomy in KT patients with terminal PyVAN was followed by a drop to undetectable levels of BKPyV-DNAemia [23]. Since immediate clearance of BKPyV-DNAemia was also observed without reducing immunosuppression as in kidney-pancreas transplantation, it can be concluded that plasma BKPyV loads reflect BKPyV replication in the renal allograft.

The role of inflammation also emerged from two recent studies having similar major findings [19, 70]. SV40-LTag was not detected in approximately 23% of biopsies having minor interstitial inflammation which predated a subsequent diagnosis of proven PyVAN. However, tubular injury attributed to viral replication was associated with inflammation in about three quarters of cases, and interstitial inflammation was stable over repeated biopsies. Viral clearance (resolving PyVAN) concurred with increasing inflammation as reported [63]. Currently, it is not possible to distinguish if inflammation is caused by innate responses to viral cytopathic damage, adaptive immunity to BKPyV antigens or to allo-antigens defining rejection, or their relative contributions in case of coexistence. More than half of the PyVAN cases were diagnosed with acute rejection after reducing immunosuppression rather than IRIS, and hence >40% of graft loss was attributed to rejection [70]. The impressive discordance to the recent Basel report of approximately 10% acute rejection indicates differences in management of BKPyV in KT rather than diagnosis and suggests that treatment by reducing immunosuppression should not be delayed or await a diagnosis of proven PyVAN, but rather be based on probable and presumptive PyVAN defined by plasma BKPyV-DNAemia [37, 44].

Since false-negative histology on biopsies occurs especially with the early PyVAN-A, plasma BKPyV-DNAemia quantification should always be performed concurrently with any allograft biopsy (protocol or for cause), to guide histopathology. The relationship of renal function, BKPyV-DNAemia, PyVAN stage, false-negative biopsies, and predicted graft outcome is illustrated in Fig. 3.

Clinical Evaluation and Diagnostics

Clinical evaluation of KT patients is based on serial renal function using the eGFR, plasma BKPyV-DNAemia, and protocol biopsies and/or anti-donor immunity such

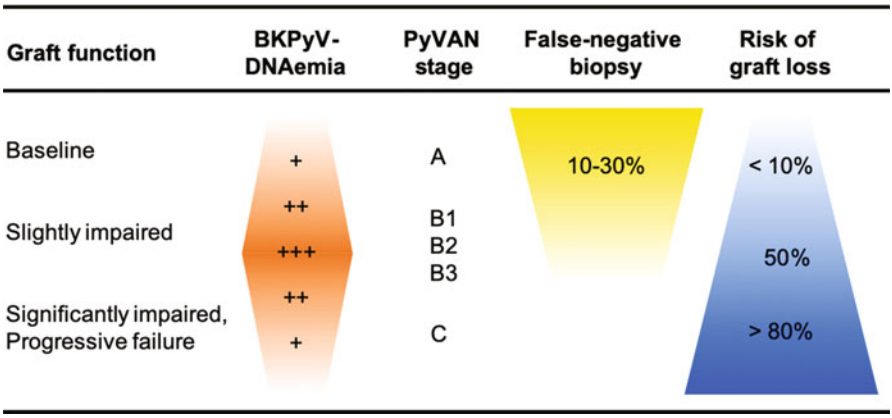

Fig. 3 Kidney graft function gradually declines with progression of PyVAN to later stages. BKPyV-DNAemia reflects viral replication dynamics, and high loads initially correlate with decreasing graft function and a higher risk of graft loss. The rate of false-negative biopsies is up to 30% in early-stage PyVAN with focal involvement (probable and presumptive PyVAN defined by plasma BKPyV loads), for which response to reducing immunosuppression is highest.

as antibody assays. Screening describes testing KT patients without any specific findings and at baseline renal function. The current AST-IDCOP guidelines recommend monthly screening for plasma BKPyV-DNAemia, and to better reflect the continuum of BKPyV replication in the renal allograft, detection of plasma BKPyV loads >3 $\log_{10}$ c/mL sustained for >2 weeks is denoted probable PyVAN and increasing BKPyV-DNAemia to >4 $\log_{10}$ c/mL as presumptive PyVAN (Table 1) [44]. In KT patients with baseline renal function lacking an increased immunological risk, renal allograft biopsy is not required before reducing immunosuppression, which streamlines the timeliness of this intervention. However, any renal allograft biopsy should be accompanied by the less invasive, more sensitive testing for plasma BKPyV-DNAemia to guide histopathology and prime early intervention. In case of SV40-LTag-positive immunohistochemistry and undetectable plasma BKPyV-DNAemia, a rare case of JCPyV-associated nephropathy should be considered and a molecular evaluation of plasma, urine, and biopsy be performed for both viruses [18, 45, 56, 64].

Monthly screening for the first 9 months and thereafter once every 3 months until 2 years post-transplant is strongly recommended, recognizing that detection of PyVAN in early stages generally leads to a much better outcome. The incidence of BKPyV-DNAemia is highest in the first 6 months post-transplant, but in 20–30% of cases, this occurs later, most within the following 3 months [8, 46, 57, 82] as discussed recently [37]. In about 18% of adult KT patients, PyVAN manifests after the first year post-transplant [47].

Longer screening periods may be considered for children because the clinical course may differ from adults, e.g., BKPyV-seronegative status or hyperfiltration caused by donor-recipient size mismatch; the latter may hide a progression to

PyVAN with tissue damage due to a delayed observed increase in serum creatinine. Roughly 10% of new-onset BKPyV-DNAemia in pediatric patients occurred after 2 years post-transplant [46]. BKPyV-DNA QNAT should always be performed if an allograft biopsy is taken to support diagnosis, establish causality, and guide treatment [44].

For the reasons outlined above, the predictive value of BKPyV-DNAemia is 10–50% for proven PyVAN, but increases with duration and decreasing eGFR [18, 44]. High-level viruria (decoy cells or >7 $\log_{10}$ c/mL) has a low positive predictive value but a high negative predictive value (>95%) allowing to rule out BKPyV-DNAemia and proven PyVAN within the next 4 to 8 weeks.

Disease Epidemiology and Risk Factors

Several genetic, immunological, and other factors have been associated with a higher risk of developing BKPyV-DNAemia and PyVAN in KT recipients. Donor factors include deceased donor, HLA mismatch, female gender, donor BKPyV viruria, and high BKPyV-IgG levels, the latter two indicating a risk of higher BKPyV transmission via the renal allograft. Recipient factors include low or undetectable BKPyV-IgG, low or absent BKPyV-specific T cells, higher number of HLA mismatches, AB0 incompatibility, male gender, and older age in the fifth decade of life except for pediatric KT, where younger children presumably due to no previous exposure are considered to be at increased risk [94]. Post-transplant, ureteric stents, acute rejection and antirejection treatment, higher cumulative steroid exposure, maintenance immunosuppression (tacrolimus > cyclosporine A > mTor inhibitors), and retransplantation (especially if BKPyV-DNAemia has not been cleared and allograft still in place) have an increased risk of BKPyV-DNAemia and PyVAN. Most of these factors have been independently observed in several studies, yet translation into clinical decisions is pending, i.e., screening of donor or recipient, living and deceased donor organ allocation, or potential antiviral prophylaxis is not supported by sufficient clinical data evaluating risk/benefit; hence the best approach has not yet been established [49].

Management

Since no specific antiviral treatment is available for BKPyV replication, treatment for probable, presumptive, or proven PyVAN is to promptly reduce immunosuppression. Clearance of BKPyV-DNAemia is then successful in 80–100% of cases [9, 32, 83]. Lower response rates have been observed in patients with prolonged BKPyV-DNAemia and proven PyVAN [48, 83, 87], stressing the benefit of immediate preemptive treatment in patients that are not at risk of acute rejection. Relapse of BKPyV-DNAemia is seen in about 10% of patients who initially cleared [8]. This suggests that plasma BKPyV loads below the lower level of quantification (LLOQ) or even the limit of detection (LOD) still reflect the

negotiated net balance between immunosuppression and immune control. In KT patients with probable or presumptive PyVAN and normal renal function who are not at high risk of acute allograft rejection, lowering immunosuppression can be done without a kidney biopsy. Conversely, in KT recipients with a high risk of rejection and/or significant decline in renal function (e.g., eGFR decrease of >20%), a biopsy may be helpful to rule out acute rejection.

Immunosuppression is typically reduced stepwise, depending on the response, starting with the calcineurin by 25–50% followed by lowering the dose of the antiproliferative drug by 50%. Alternatively, and with no data to support superiority of either approach, this is applied in reverse: first a reduction of the antiproliferative drug, followed by the reduction of the calcineurin inhibitor, and subsequent discontinuation of the antiproliferative drug. Orally co-administered prednisone is tapered to ≤10 mg per day. As a first target, immunosuppressive drug levels should be for tacrolimus <6 ng/mL, cyclosporine <150 ng/mL, mycophenolate mofetil/mycophenolic acid ≤50% of the daily maintenance dose, and sirolimus <6 ng/mL (Table 2). Tacrolimus trough levels of <3 ng/mL and cyclosporine <100 ng/mL may be required in patients not responding by BKPyV-DNAemia decline and sustained clearance or with disease progression. Importantly, immunosuppression reduction is monitored by serum creatinine concentrations and BKPyV-DNAemia, respectively, in at least 2-weekly intervals until BKPyV-DNAemia is cleared. Time to clearance correlates with advanced disease stage and higher plasma viral load, but may occur within 8–12 weeks in early and uncomplicated cases. After successful and stable clearance of plasma BKPyV-DNAemia, standard maintenance immunosuppression may be reinstated to counteract rejection [44]. Although no explicit data are available in this regard, this is usually considered after 6–8 weeks of sustained BKPyV-DNAemia clearance.

Switching from tacrolimus to low-dose cyclosporine A or to mTOR inhibitors (sirolimus, everolimus), from mycophenolic acid to low-dose mTOR inhibitor or leflunomide, has been discussed as an alternative treatment option [43, 59, 60]. Despite these virologically sound and promising outcomes, dedicated randomized control trials are lacking to recommend one treatment strategy over another.

Retransplantation has been performed successfully in over a hundred cases where the renal allograft loss was caused by PyVAN. It is presently unclear, whether or not removal of the first damaged transplant is beneficial to decrease the likelihood of recurrent PyVAN in the new graft. However, sustained clearance of BKPyV-DNAemia for 3 months is tentatively recommended as a marker of sufficient BKPyV-specific immune effectors. Moreover, the source of BKPyV-DNAemia can be attributed to the new allograft if the damaged transplant had been removed [36]. Preemptive retransplantation in patients failing their kidney transplant due to PyVAN should be evaluated with caution. An at least >2 $\log_{10}$ decline of BKPyV-DNAemia and removal of the first allograft should be considered [15, 26, 36]. Finally, a theoretical concern is the risk of superinfecting the new graft, which may be increased due to ureteric stenting and backwash of BKPyV viruria from the old graft following bladder contraction [24, 68, 95].

Antiviral or immune therapy is not established since data on efficacy, risk, and benefit has not been evaluated in proper randomized control trials. However, several alternative or adjunctive treatment options have been reported in mostly small case series. In most cases, the intervention was confounded by simultaneous application of different interventions such as reducing or switching immunosuppression or administration of IVIG [48]. The nucleotide analog cidofovir approved to treat ganciclovir-resistant cytomegalovirus retinitis has been shown to have in vitro activity against BKPyV replication in primary human tubular epithelial cells [5]. No clear benefit could be shown, and the in vitro inhibitory concentration of cidofovir (IC_{90} of 40 μg/mL) may not be reached making its application highly questionable. Moreover, nephrotoxicity and uveitis are feared side effects that were observed in about a fifth of patients receiving intravenous cidofovir. High-dose intravenous cidofovir may not be more efficient due to the need for probenecid preventing uptake in the renal tubule cells, which is supported by mostly failures of treating rare cases of PyVAN in non-kidney SOT [3]. Brincidofovir (CMX001), the lipid-ester prodrug of cidofovir, is thought to increase bioavailability and intracellular drug concentrations and may potentially be the safer drug. Brincidofovir shows higher activity against BKPyV replication in vitro both in renal tubular and urothelial cell culture models [5, 77, 79, 91]. Clinical studies are lacking, and a balanced representation of failures is not available to draw conclusions [78].

Fluoroquinolone antibiotics were shown to have some efficacy against BKPyV replication, likely by inhibition of the helicase domain of the viral large T antigen. Initial studies proposed some protective activity when used prophylactically, but a randomized control trial with levofloxacin could not demonstrate a reduction of BKPyV-DNAemia when compared to the placebo control. Importantly, fluoroquinolone-resistant bacteria increasingly emerged [53, 86].

IVIG preparations contain neutralizing antibodies, and several reports showed clearance of BKPyV-DNAemia. Even though the results look promising, the strength of the effect of IVIG is difficult to assess because administration was combined with lowering of immunosuppression and antivirals [48, 93]. Administration of IVIG or monoclonal antibody therapy for prophylaxis has not been tested yet. Thus, caution is required when administering compounds with presumed antiviral activity, leaving possibly only IVIG as an adjunctive, rather expensive therapy with acceptable risk-benefit profile and potentially anti-inflammatory, steroid-saving properties, if administered in high-dose (Table 2).

Polyomavirus-Associated Hemorrhagic Cystitis: PyVHC

Pathology and Clinical Impact

The pathology of PyVHC is not well established due to reluctance of cystoscopy in early and mild cases and, conversely, reluctance for taking biopsies in advanced cases needing urological intervention in order to avoid further injury to the already widely denuded, profusely bleeding bladder surfaces. Otherwise, few histopathology

Table 2 Current management strategies of PyVAN and PyVHC

PyVAN	PyVHC
Strategy 1: Reduction of calcineurin inhibitor: 25–50% in 1–2 steps Reduction of antiproliferative drug: 50% in first step, discontinued in next step *Strategy 2*: Reduction of antiproliferative drug: 50% Reduction of calcineurin inhibitor: 25–50% in 1–2 steps Discontinue antiproliferative drug Prednisone (corticosteroids) adjusted to ≤ 10 mg/day *Recommended trough levels*: Tacrolimus <6 ng/mL (<3 ng/mL in non-response) Cyclosporine <150 ng/mL (<100 ng/mL in non-response) Mycophenolate mofetil/mycophenolic acid ≤50% of the daily maintenance dose or stop Sirolimus <6 ng/mL *Not recommended*: Fluoroquinolones, cidofovir *Prophylaxis*: Not established *Experimental*: Switching from tacrolimus/mycophenolate to low-dose cyclosporine A/mTOR inhibitors (sirolimus, everolimus) Leflunomide Brincidofovir Intravenous immunoglobulins	*Supportive therapy*: Analgesics, (hyper-)hydration, forced diuresis, platelet transfusion *Weakly recommended*: Fibrine glue Hyperbaric oxygen therapy Intravenous cidofovir (No agreement on dose, most experience with: 3–5 mg/kg/ every 1 or 2 weeks with probenecid or 0.5–1.5 mg/kg 1–3 times per week without probenecid) *Not recommended*: Fluoroquinolones, cidofovir (intravesicular); reducing immunosuppression *Prophylaxis*: Hyperhydration and bladder irrigation during conditioning regimen to prevent extensive urotoxicity of drugs and/or irradiation *Experimental*: Brincidofovir Virus-specific T-cells (mesenchymal stoma cells)

studies are available from cystectomy as the ultimate intervention to control anemic bleeding, leaving little hence not representative histology information. Thus, more emphasis needs to be placed on a stringent case definition of PyVHC. The clinical definition of PyVHC requires the triad of (i) symptoms of cystitis such as dysuria, lower abdominal pain, urge, and/or frequency; (ii) macroscopic hematuria (grade ≥2); and (iii) high-level BKPyV viruria defined as >7 $\log_{10}$ c/mL. Each of the markers may occur alone and is not sufficient. Hematuria is graded according to the severity and is classified into four stages that guide diagnosis of PyVHC: grade 1 microscopic or test-derived; grade 2 macroscopic; grade 3 macroscopic with clots; and grade 4 macroscopic with clots and post-renal failure [4].

Notably, high-level BKPyV viruria is very frequent after allogeneic HSCT, without macrohematuria or cystitis [2], and, hence, is by itself not sufficient for a diagnosis of PyVHC. Similarly, painless macrohematuria can be due to a number of etiologies after allogeneic HSCT and is also not sufficient for the diagnosis of PyVHC. Importantly, other potentially coexisting etiologies of cystitis should be

ruled out, the most difficult one being graft-versus-host disease (GVHD) as detailed below.

The pathogenesis of PyVHC is not fully elucidated, but a sequence of events has been elaborated by Hirsch in the year 2000, after reviewing all available data at that time [7]: First, the conditioning regimen, especially with cyclophosphamide, busulfan, or ifosfamide, or full-body irradiation induces cytopathic damage to the urothelial tissue. Hyperhydration with forced diuresis and mesna (given in combination with cyclophosphamide or ifosfamide) is able to reduce toxicity with virtual disappearance of early-onset HC while still causing subclinical urothelial damage and rarefication of the urothelial layers. Second, high-level BKPyV replication is favored due to the ablation of innate and adaptive immune effectors and systemic stress responses, transcriptional activation stimulated by inflammatory responses leading to NFκB signaling of early viral genes [35], and immunosuppression administered as GVHD prophylaxis. Third, as urothelial cell regeneration is impaired following the conditioning, high-level cytopathic BKPyV replication leads to denudation of the rarefied bladder epithelium resulting in urine leakage, chemical inflammation, and hemorrhage. Following engraftment of neutrophils and other immune effectors, inflammation is exacerbated [35]. In this situation, BKPyV-stimulated as well as independent progression to mucosal GVHD can be envisaged, which has been described as a risk factor or confounder of PyVHC. This scenario is complex and difficult to investigate unless significant factors including high-level BKPyV replication can be reliably removed, preferably early and before onset. Conversely, definitions of clinical response may not allow to capture successful antiviral inventions suggesting that viral endpoints need to be part en route to a multitargeted clinical therapy approach.

PyVHC causes significant morbidity in the approximately 10–15% of allogeneic HSCT patients affected and leads to higher health-care costs due to longer hospitalization and the extensive care needed and, in rare cases, renal failure or other complications can be life-threatening and require urological interventions. BKPyV is highly associated with late-onset HC which manifests 2–8 weeks post-HSCT (range 1 week to 6 months), and it needs to be discriminated from early-onset HC that is directly caused by toxicity of the drugs used in the conditioning regimen that usually occurs within 2 days after transplantation [11, 35]. The natural course of PyVHC usually resolves within 3–5 weeks. However, declining kidney function and coexisting PyVAN have been diagnosed in allogeneic HSCT patients suggesting that more extensive renourinary involvement may complicate this disease in an already compromised patient population [1, 61].

To estimate the clinical impact, some simplified estimates should be discussed. In North America, approximately 10,000 allogeneic HSCTs are currently performed each year [12]. The activity survey of the European Society for Blood and Marrow Transplantation reports >17,000 allogeneic HSCTs in the same year [74]. Taken together, at least 27,000 allogeneic HSCTs are currently performed annually in North America and Europe combined, and the indications and actual numbers are increasing. Assuming a PyVHC complication rate of 10–15%, an estimate of 2700–4050 patients are affected each year. Taking the average of 3–5 weeks of significant

manifestations translates into 56,700–141,750 days of annual excess morbidity, a clinical impact not to be neglected. Assuming that only 5% have a very severe clinical course facing prolonged hospitalization and death, still 135–202 persons are at risk annually. Clearly, more data and research is needed to tackle this neglected, unmet clinical need.

Clinical Evaluation and Diagnostics

Diagnosis of PyVHC must fulfill the following three criteria: (1) clinical symptoms of cystitis (dysuria, abdominal pain), (2) macroscopic grade 2 or higher hematuria, and (3) viruria of >7 $\log_{10}$ c/mL determined by QNAT. In addition, other potentially coexisting etiologies must be ruled out, such as viruses including herpes simplex virus, cytomegalovirus, or adenovirus [2, 58], bacterial infection, or mechanical reasons (ureteric stenting and vesical catheters), graft-versus-host disease, metastatic neoplasia, or thrombocytopenia or clotting disorders [11] (see Table 1).

Imaging-based technologies as well as cystoscopy for histology are not usually necessary for the diagnosis, but may be informative when noninvasively evaluating extent and clinical course including urinary retention, intravesical clots, and ureteric involvement, which may even present as pyelonephritis. Of note, BKPyV-DNAemia >3–4 $\log_{10}$ c/mL are seen in approximately 70% of the more severe BKPyV-HC cases [11]. With clinical recovery of cystitis BKPyV-DNAemia and viruria decline. Asymptomatic HSCT recipients are currently not routinely screened for BKPyV because of a lack of effective preemptive treatment options. Thus, while high-level BKPyV viruria is required for the diagnosis PyVHC with the presumed pathophysiologic role in denudation, extensive inflammation and denudation of the bladder wall may also account for the predictive role of BKPyV-DNAemia for the more severe PyVHC cases [21].

Disease Epidemiology and Risk Factors

The PyVHC incidence after allogeneic HSCT in adults is 16% (range, 7–54%) and 18% (range, 8–25%) in children [11]. Children aged <7 have a lower risk than older children [55]. High-level BKPyV viruria is observed in >50% of allogeneic HSCT, indicating that other factors must play a role in progression to PyVHC. The incidence is highest in haplo-HSCT patients that received cyclophosphamide post-transplant. Autologous HSCTs have a much better outcome, and PyVHC is very unlikely to develop, indicating that immunosuppression and GVHD are major contributing factors in disease pathophysiology. Consistently, a lower risk is generally reported if the donor is related (matched or mismatched) than unrelated donors and a higher risk with severity of acute GVHD [28, 67]. High level of viruria of >7 $\log_{10}$ c/mL and BKPyV-DNAemia >3 $\log_{10}$ c/mL are predictive for PyVHC and have a reported sensitivity of 100% and 86%, respectively. As discussed above for this patient population of allogeneic HSCT, the specificity of viruria is lower at 60%, while 86% for BKPyV-DNAemia [10].

The type and intensity of the conditioning regimen has an impact. Conditioning with cyclophosphamide, busulfan, anti-thymocyte globulins, total body irradiation, and myeloablative, compared to reduced intensity conditioning, concurs with a higher risk for PyVHC [25, 28, 62, 81]. However, recently increasing use of haploidentical donor transplants with post-transplant cyclophosphamide application is also reflected in later PyVHC rates. The stem cell source is also a risk factor with bone marrow grafts having a lower risk than cord blood or peripheral blood [27, 81]. Further coinfection with other viruses, such as adenovirus, CMV, or HHV6, has been reported as an independent risk factor although only in a single study each [31, 55].

Management

PyVHC treatment is mainly based on supportive therapy including analgesia, hyperhydration, forced diuresis, erythrocyte and platelet substitution, and bladder irrigation to prevent clots and obstructions in the urinary tract (Table 2). In contrast to PyVAN, reducing immunosuppression is not considered a standard treatment option. The risk/benefit ratio is too high, increasing severe and generalized damage from GVHD from alloreactive donor cells.

Antiviral drugs have been used, but evidence is often weak, and most data come from small uncontrolled studies. In many reports of high clinical and virologic response rates, however, the response kinetics appear rather slow, making discrimination from the spontaneous resolution of PyVHC difficult.

Cidofovir use has been reported in more than 10 studies, mostly retrospective, for PyVHC. Dosing and application differed using intravenous application of 3–5 mg/kg/week with the addition of probenecid, to reduce nephrotoxicity by inhibiting cidofovir uptake into renal tubular epithelial cells, or lower doses of 0.5–1.5 mg/kg/week without probenecid. Other studies dosed 5 mg/kg/week for intravesical administration. Overall, a clinical response rate was reported in approximately 50%, whereby the virologic response, defined as a reduction of at least 1 $\log_{10}$ c/mL, was for viruria between 38% and 62% and for BKPyV-DNAemia between 45% and 84% [11]. Following intravenous application roughly a fifth of patients had increased serum creatinine levels. Despite a lack of evidence from randomized control trials, intravenous administration of cidofovir may be considered as a treatment option [11]. Overall, our experience with intravenous or intravesical cidofovir administration has been rather disappointing and was abandoned.

A case report describes the use of brincidofovir in a HSCT patient that developed PyVAN. Treatment (100 mg, twice weekly), without reduction of immunosuppression, resulted in a decline of BKPyV-DNAemia of almost 4 $\log_{10}$ c/mL, and the renal function remained sufficient until the patient died of unrelated bacterial sepsis [73]. Although only reported in few cases with issues regarding oral bioavailability and gastrointestinal adverse events, brincidofovir may be a safer and more potent drug than intravenous cidofovir. At this time, clinical development of brincidofovir has been halted.

The fluoroquinolone ciprofloxacin was assessed for prophylaxis of PyVHC in three studies (two retrospective, one cohort-prospective). There was a weak effect on BKPyV replication but none on clinically significant PyVHC. A single case study reports complete clinical responses using levofloxacin to treat severe refractory cases of PyVHC in three HSCT patients [90]. But again, it is not clear whether levofloxacin treatment or spontaneous resolution was responsible for the successful outcome. Some treatment success was also reported in several older cases with the adenine analog vidarabine, intravesical sodium hyaluronate, FXIII concentrate, or estrogens. In a more recent study, 6 out of 14 pediatric patients received choreito, a traditional formula from Japanese traditional medicine. The study reported a significantly shorter duration until resolution of hematuria and cystitis, and BKPyV viruria decreased significantly after choreito administration [50]. Similarly, leflunomide used in two studies reported higher clearance and a decline in BKPyV-DNAemia and viruria; however, randomized control trials have not been conducted.

Since no highly effective antivirals are available and given the central role of the immune system in pathology immune cell therapy is another approach that has been investigated. Allogeneic mesenchymal stoma cells were administered by infusion in seven patients with severe PyVHC, with the idea of using their anti-inflammatory, immunomodulatory, as well as tissue-repairing properties to heal the tissue damage. In five patients HC cleared after infusion with mesenchymal stoma cells, and hematuria disappeared after 3 (median, range, 1–14) days [80]. Another study reported a prothrombotic effect of mesenchymal stroma cells potentially jeopardizing its therapeutic use [65].

Promising results have been obtained with adoptively transferred virus-specific T cells (VSTs). VSTs were generated from third-party donors and were exposed to peptide libraries from 12 immunogenic proteins from BKPyV as well as CMV, EBV, ADV, and HHV6 for in vitro stimulation [72, 92]. The major drawbacks are the costs, complexity, and time to produce VSTs. Tzannou and colleagues conducted a phase II trial with cryopreserved, HLA-matched, third-party ("off-the-shelf") VSTs in allogeneic HSCT patients with viral infections. The results were very encouraging reporting cumulative complete or partial response rate of >90% and 100% for BKPyV in all 16 patients after a single-dose infusion. A complete resolution of gross hematuria was reported in 13 (out of 14) patients with PyVHC by week 6 [92]. The readily available banked VSTs could instantly be used for treatment. Moreover, VSTs may protect against five other double-stranded DNA viruses that all are notoriously problematic, occur simultaneously, and have been associated with a higher mortality in HSCT [33].

There is no documented benefit of IVIG for treating PyVHC, although we speculate that high-dose IVIG administered might be more effective than the usual low-dose IVIG applied every 3–4 weeks in many allogeneic HSCT patients to non-specifically protect against infections. Different interventions aimed at regeneration and damage repair of the urothelial mucosa are hyperbaric oxygen therapy [97] and cystoscopic application of fibrin glue [89] to the damaged tissue. Both had complete clinical response rates of 86% and 83%, respectively. BKPyV loads in urine decreased in about two thirds of patients receiving hyperbaric O_2 therapy. Both

offer treatment alternatives in severe or refractory cases of PyVHC; several disadvantages exist though: Hyperbaric O_2 therapy requires special facilities that are often not available, and there is a risk of ear barotrauma, pressure intolerance, and claustrophobia during treatment. Fibrin glue application is invasive requiring cystoscopy.

Preventive measures include aggressive hyperhydration and possibly prophylactic bladder irrigation during the conditioning regimen to reduce or prevent urotoxicity. Mesna is often used prophylactically in patients that receive cyclophosphamide or ifosfamide to reduce drug toxicity. These interventions are also effective for early-onset HC, since its application, the incidence could be lowered to <3%. Hyperhydration bears the risk of fluid overload, and bladder irrigation is invasive, administered through a three-way Foley catheter, and discomforting for patient [11]. Thus, treatment of PyVHC (Table 2) is still largely unsatisfactory with mainly supportive therapy leaving PyVHC a significant and unmet clinical need.

PyV-Associated Urothelial Cancer: PyVUC

PyVs have been linked to different tumors, ever since the first isolated PyV from mouse was found to induce multiple tumors in newborn mice [30], hence the name *poly-* and *-oma* meaning "many tumors" in Greek. Later studies with the monkey SV40 confirmed these findings in newborn or immunodeficient rodents and demonstrated their ability to transform cell lines in vitro. In fact, SV40 research has been instrumental in defining the concept of tumor suppressor inactivation of DNA tumor viruses as opposed to oncogene activation in retroviral tumorigenesis [66]. BKPyV was therefore seen as potentially oncogenic, and initial infection of the nonspecific (non-human) rodent cells, resulted in oncogenic transformation of those cells. Subsequently, oncogenic transformation was linked to the early viral gene region (EVGR) encoding the large and small tumor antigen (LTag and sTag, respectively). LTag and sTag drive the infected host cell into the S-phase before arresting in G2/M to provide an environment with abundant building blocks for viral replication. LTag inhibits the tumor suppressor protein p53 and pRB and recruits the host cell DNA polymerase to the origin of viral replication located in the noncoding control region (NCCR). LTag then promotes expression of the late viral gene region (LVGR)-encoded capsid proteins Vp1, Vp2, and Vp3, as well as the regulatory agnoprotein. This then leads to virus assembly, cell lysis, and release of the viral progeny. Thus, host cell lysis required for efficient release of the non-enveloped BKPyV virions from the nucleus works as an oncolytic safety barrier against cell transformation and cancer. In the absence of LVGR expression and virally induced cell lysis, the transforming properties of LTag increase the risk of further genetic alterations toward malignancy [13, 14]. Merkel cell PyV is the first human PyV clearly linked cancer, namely, Merkel cell carcinoma [22]. In most cases investigated, the MCPyV genome was chromosomally integrated and so that the gene for LTag was truncated, and no late proteins no late proteins were expressed [88].

Urothelial cancers of the bladder have been found to frequently carry alterations in tyrosine receptor kinase-Ras pathway in the case of low-grade papillary tumors, whereas high-grade metastasizing cancers have alterations in p53 and pRB pathways [96]. Recent evidence points to a role of BKPyV in high-grade urothelial cancers occurring in KT patients without pRB or p53 alterations [52, 71]. Several cases of PyVUC in KT patients with a history of PyVAN identified chromosomal integration of BKPyV genomes [52]. Thereby, viral genome replication and LVGR expression was disrupted preventing viral assembly and viral cell lysis, as predicted [13]. In another case, BKPyV-LTag expression was seen in a high-grade PyVUC derived from a 4-year-old deceased donor [69]. The cancer cells carried a chromosomal integration of a truncated BKPyV genome in addition to a full-length episomal BKPyV genome. Both the integrated and episomal BKPyV genome carried an identical 17bp deletion in the viral NCCR, which activated LTag expression, but interfered with LVGR expression. The integration site was not associated with altered oncogenesis-driving genes, and no other known chromosomal mutation was present [69]. Of note, despite surgical removal, the patient suffered two recurrences leading to life-threatening metastasizing disease, which only resolved into complete remission after discontinuing immunosuppression and abandoning the kidney transplant [69]. In summary, the reported cases suggest that long-lasting high-level BKPyV replication in immunosuppressed patients may lead to genetic accidents of non-lytic transformation and PyVUC, which is seen mostly after KT, but may also affect other transplant patients [54]. Thus, besides surgical removal, reducing or discontinuing immunosuppression may be key to permit antimalignancy immunity to BKPyV-encoded tumor antigens, especially in cases of metastasizing PyVUC. However, this option is limited in non-kidney SOT.

Conclusion

PyVAN, PyVHC, and PyVUC are three distinct pathologies caused by BKPyV, which jeopardize otherwise successful transplantation outcomes in KT and HSCT patients. Despite a variety of treatment options, effective validated therapies are not available, and the current management is far from ideal. Reduction of immunosuppression has significant success rates in KT patients, if applied early for probable and presumptive PyVAN, but approximately 10–20% of patients have a prolonged course or do not respond to treatment. Irreversible damage to the allograft feeds on its lifespan even after PyVAN resolution. Reliable discrimination between acute rejection and PyVAN is still unresolved. Reducing immunosuppression is hardly feasible for non-kidney SOT or allogeneic HSCT as the risk and consequences of immune damage due to rejection or GVHD are dire. The current knowledge about risk factors has yet to be translated into the clinics to improve diagnostics and management. Novel therapeutic approaches have reported promising results in "proof-of-concept" studies but await further validation and controlled clinical trial including switching immunosuppression to low-dose cyclosporine/mTOR inhibitor combinations or immune therapies using IVIG, monoclonal antibodies, and/or

VSTs. Research in vaccine development is pending, and peptide-derived viral proteins and a DNA-vaccine targeting CMV and BKPyV are currently in phase 1 trials.

Significant impact would be expected to come from new safe and effective treatments in the form of a small molecule drug to inhibit BKPyV replication. However, drug development for BKPyV is challenging, facing three major issues: (i) there is no simple high-throughput in vitro system for screening compound libraries for selective anti-BKPyV activity; (ii) preclinical animal models do not exist or require advanced humanization efforts, limiting generalizations; and (iii) the "druggable space" of this small DNA virus is very limited relying heavily on host factors for replication. LTag is a multifunctional protein which includes a helicase domain, a known drug target in bacteria. However, LTag is also a potential oncogene which may unfold once LVGR expression and viral host cell lysis are slowed down or abrogated. The emergence of PyVUC indicates that genetic accidents, leading to only partial LTag functions often lacking the helicase following chromosomal integration, may be oncogenic, particularly in immunocompromised transplant patients. Targeting host proteins and functions that are essential for BKPyV may be considered, but sparing renal function may be a huge obstacle in preclinical and clinical evaluation. Thus, the remarkable coevolutionary adaptation of PyVs and BKPyV in particular to the human host underlies the significant challenges of PyVAN, PyVHC, and PyVUC in transplantation, rendering these widely underestimated diseases an unmet clinical need.

Key Points

- BKPyV-associated diseases PyVAN, PyVHC, and PyVUC have emerged as persistent threats to otherwise successful transplantation outcomes in KT and HSCT patients.
- At least 5000 KT patients annually must be considered at risk for premature renal allograft failure due to BKPyV in North America and Europe, not reaching the average graft survival of 15 years.
- At least 3000 allogeneic HSCT patients in North America and Europe suffer from excess morbidity due to PyVHC causing additional 60,000 days of patient care, often as in-patients.
- The impact of PyVUC cannot be estimated at the present time, but assuming rates of 1%, approximately 500 cases may be attributed to BKPyV in KT patients.
- Antiviral drugs for prevention or treatment are lacking and vaccination to booster BKPyV-specific immunity is unavailable.
- Reducing immunosuppression early for KT patients with sustained BKPyV-DNAemia is currently the only option outlined in current recommendations, but approaches are empiric and dependent on center experience.
- Reducing immunosuppression is not a viable option in PyVHC after allogeneic HSCT due to precipitating GVHD leaving prevention with hyperhydration,

symptomatic analgesic treatment, and poorly efficacious intravenous cidofovir for desperate cases.

- PyVUC diagnosis is dependent on clinical signs and a high index of suspicion, and in the case of LTag expression from chromosomal integration, reduced immunosuppression may be tried in addition to conventional oncologic approaches.

Introduction

Human papillomaviruses (HPV) are small, non-enveloped DNA viruses that infect epithelial cells [1]. Cutaneous HPV (cHPV) types are found ubiquitously on the skin and are associated with cutaneous warts [2]. Anogenital HPV types specifically infect the anogenital and upper digestive tract and are sexually transmitted [1]. There is a 75–80% lifetime risk of anogenital HPV infection among all sexually active men and women [3], rendering HPV the most common sexually transmitted agent [4].

Of about 40 anogenital HPV types, almost half are considered oncogenic or "high-risk" (hr-HPV) [5]. Infection with these hr-HPV strains is a common precursor to squamous intraepithelial lesions (SIL), and persistent hr-HPV infection may, in some cases, lead to the cancer precursor high-grade SIL (HSIL). A small proportion of HSIL in turn progresses to invasive squamous cell carcinoma (SCC) giving rise to 99.9% of cervical cancers, 90% of anal cancers, 70% of oropharyngeal cancers, and a high percent of penile, vaginal, and vulvar cancers [6]. The hr-HPV type 16 carries the strongest association with invasive cancer: it is detected in over 50% of cervical cancers, 85% of anal cancers, and almost 90% of HPV-positive oropharyngeal cancers [7]. HPV type 18 is the second most common type associated with cervical cancer (detected in approximately 20% of specimens) but is less prevalent at other cancer sites [7].

Infection with low-risk HPV (lr-HPV) anogenital types is associated primarily with low-grade squamous intraepithelial lesions (LSIL), which include genital warts or condyloma acuminata. Lr-HPV types 6 and 11 cause 90% of genital warts [8]; these are of low oncogenic potential but can be difficult to eradicate and often lead to discomfort and psychological distress.

Solid organ transplant (SOT) recipients have a higher prevalence of HPV infection [9–14] and are at greater risk for complications from HPV compared with the general population [15]. While data are more limited in hematopoietic stem cell transplant (HSCT) recipients, they are likely also at higher risk for complications. Thus, it is important to identify transplant recipients at risk for HPV infection and to develop methods of prevention and/or early detection of malignancy in these patients. In this chapter, we review the pathogenesis and epidemiology of HPV infection in SOT and HSCT with particular focus on anogenital HPV. We also discuss the prevention of complications from HPV infection, including cervical and anal cancer, the two most common HPV-related malignancies.

Pathogenesis of HPV Infection

Initial Infection

Anogenital HPV types preferentially infect areas of metaplasia in both the cervix and the anus referred to as transformation zones where columnar glandular epithelium is actively being replaced by stratified squamous epithelium [5, 16]. To initiate

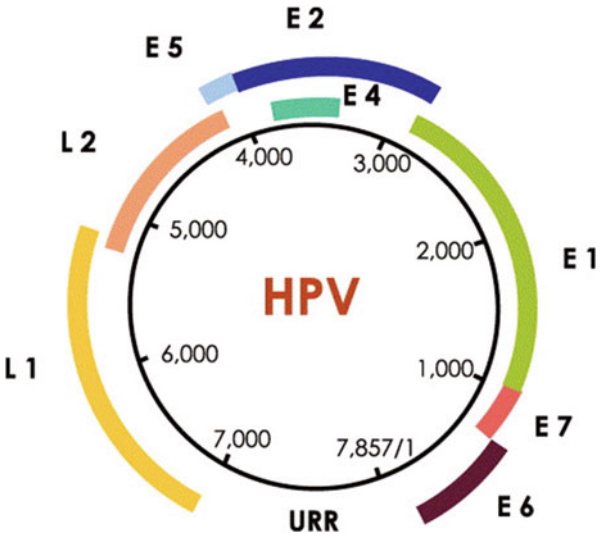

Fig. 1 Schematic presentation of the HPV genome showing the arrangement of the early E or nonstructural genes, the late L capsid structural genes (L1 and L2), and the upstream regulatory region (URR). (Adapted from Ref. [115])

infection, the virus first infects the basal cells of the epithelium, often at sites of microtrauma [17].

The HPV genome is comprised of approximately 8 kb of double-stranded circular DNA, which can be divided into an *early* region, coding for the E1, E2, E4, E5, E6, and E7 proteins, and a *late* region, which encodes two structural capsid proteins termed L1 and L2 [18]. The upstream regulatory region (URR) or long control region (LCR) lays between these two regions and is a non-coding portion that contains numerous binding sites for E2 and multiple transcription factors (Fig. 1).

Once inside the basal layer, the HPV genome is sustained as a quiescent episome. HPV replication and protein expression surge as the infected cells migrate into the suprabasal cell layers and then undergo epithelial differentiation. This may result in changes that are recognized as SIL both clinically and histopathologically. Latently infected cells in the basal cell epithelium likely also persist [19, 20] with the potential to reactivate and lead to SIL.

Terminology

Prior nomenclature reflected a morphologic continuum ranging from low-grade lesions to increasingly higher-grade disease, ending in invasive cancer [21]. Low-grade lesions on cytology were termed LSIL, and on histology they were called intraepithelial neoplasia (IN) grade 1. High-grade lesions were designated HSIL (cytology) and IN grades 2 and 3 (histology). The nomenclature for IN

was further modified depending on site of infection. Thus, IN from the cervix was named cervical intraepithelial neoplasia (CIN) grades 1–3, IN from the anal canal was named anal intraepithelial neoplasia (AIN) grades 1–3, and so forth.

However, it is now known that the majority of low-grade lesions are transient and (even with hr-HPV infection) do not progress to high-grade dysplasia [5, 22]. It is increasingly thought that HPV infection progresses via two distinct pathways, resulting in either high-grade (precancerous) or low-grade (benign) lesions. The College of American Pathologists and the American Society for Colposcopy and Cervical Pathology now recommend the use of LSIL/HSIL terminology for both cytology and histopathologic grading of disease and across all anogenital sites where HPV infection occurs [23]. The use of p16 immunohistochemistry, a biomarker for cellular proliferation, is recommended to clarify the diagnosis of IN 2 by classifying all p16-negative IN 2 lesions as "LSIL" and all p16-positive IN2 and all IN3 lesions as "HSIL" [23]. As such, LSIL reflects active HPV replication and virion formation (i.e., infection), while HSIL reflects HPV-induced transformation (Fig. 2) [24]. The therapeutic implications of this classification are significant: LSIL is not considered pre-cancerous and does not need to be treated, while HSIL is treated in order to reduce the risk of progression to cancer.

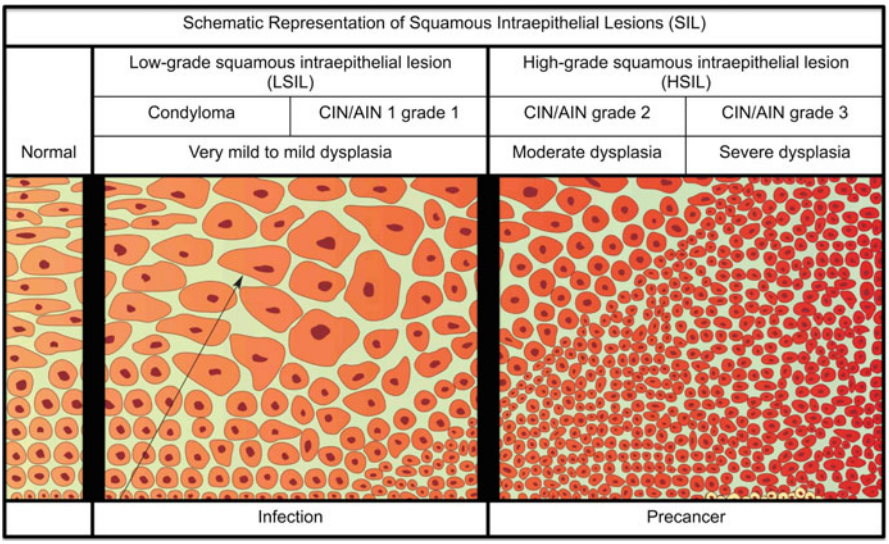

Fig. 2 Schematic representation of the two-tiered system to classify cytology and histology of squamous intraepithelial lesions. Low-grade squamous intraepithelial lesions (LSIL) include cervical intraepithelial neoplasia (CIN) grade 1, anal intraepithelial neoplasia (AIN) grade 1, and condyloma (genital warts). High-grade squamous intraepithelial lesions (HSIL) include CIN/AIN grades 2 and 3. The distinct biology underlying LSIL and HSIL is reflected in this classification. (Adapted from Ref. [116])

Development of HSIL

There are two key HPV oncogenes, E7 and E6, that result in persistent HPV infection and development of HSIL [17]. The proto-oncogene *retinoblastoma* (Rb) is bound by E7, which results in release of the host E2F transcription factor from Rb and cellular entry into the cell cycle S-phase. The oncogene E6 binds and inactivates p53, the tumor suppressor protein, which induces DNA repair enzymes and cellular apoptosis when DNA damage cannot be repaired. Thus, E7 increases the rate of mutations by enhancing replication and E6 allows these mutations to accumulate (Fig. 3). Such progressive genomic instability eventually leads to invasive cancer.

Additionally, E5 protein contributes to malignant transformation by reducing turnover of epidermal growth factor receptors on the cell surface, thus rendering cells more susceptible to the mitogenic effects of epidermal growth factor. Integration of HPV DNA into the cellular genome is another transformative mechanism. The E2 gene codes for a trans-activating protein that binds the URR of the HPV genome and downregulates E6 and E7 expression (Fig. 3). HPV integration disrupts the E2 gene, and the loss of E2 binding to the URR in turn increases E6 and E7 expression [25].

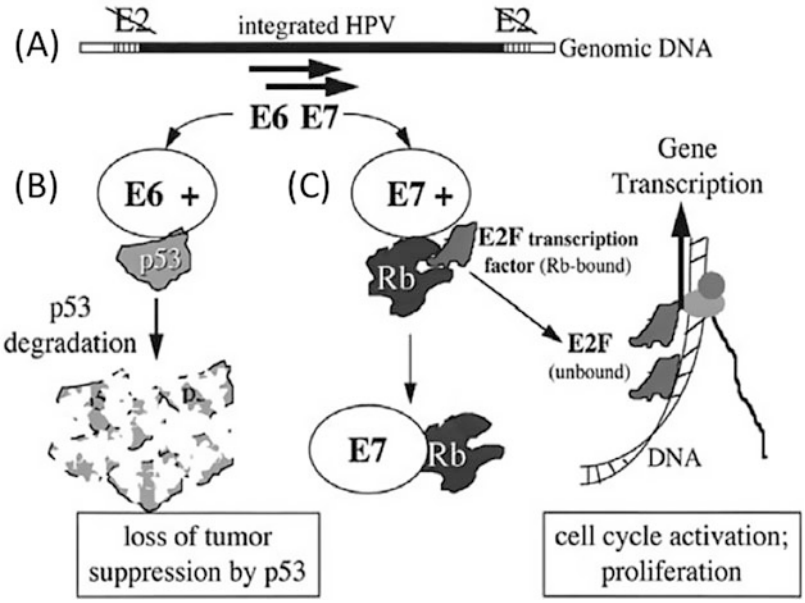

Fig. 3 (**a**) HPV DNA integration disrupts the E2 gene resulting in upregulation of E6 and E7 expression. (**b**) E6 binds and inactivates the tumor suppressor protein p53 resulting in loss of DNA repair and cellular apoptosis when DNA damage cannot be repaired. (**c**) E7 binds to the proto-oncogene *retinoblastoma* (Rb), resulting in release of the host E2F transcription factor from Rb and cellular entry into the cell cycle S-phase. (Adapted from Ref. [117])

The mechanisms determining whether HPV is transforming, resulting in HSIL and cancer, or primarily replicative, leading to LSIL, are not fully understood. HPV type seems to be a major determinant; differences in cellular affinity and function of the E6 and E7 proteins of hr-HPV types compared with lr-HPV types predispose infected cells toward the transformative pathway [26].

Immune Mechanisms of HPV Infection

HPV establishes infection by evading the host innate immune system [27]. Mechanisms of evasion include an exclusively intracellular productive life cycle without viremia or viral-induced cell death as well as viral downregulation of host innate immune signaling pathways resulting in the absence of pro-inflammatory cytokines or recruitment of dendritic cells or macrophages [27].

Despite this, most anogenital HPV infections are eventually cleared [28]. This process is thought to be regulated by adaptive cellular immunity. Longitudinal animal studies of canine oral papillomavirus note the emergence of anti-E2 specific T-cells prior to genital wart regression [29]. In humans, immunohistochemistry studies show that regression of genital warts is preceded by infiltration with CD4 T-cells and Th1 cytokines [30]. E2- and E6-specific T-helper cells are frequently detected in healthy individuals as evidence of previous exposure [31, 32], and the presence of E2-specific T-cells is associated with clearance of cervical SIL in women [33]. Conversely, people with human immunodeficiency virus (HIV) and the associated acquired defects in cellular immunity associated are at increased risk of HPV infection, SIL, and HPV-related malignancies [34]. In transplant recipients, defects in cellular immunity from immunosuppressant drugs and/or myeloablative therapy are similarly associated with increased susceptibility to HPV. The epidemiology of HPV infection specific to SOT and HSCT recipients is discussed in the next section.

Epidemiology of HPV in SOT and HSCT Recipients

HPV Infection

Infection with anogenital HPV in the general population is common and typically occurs soon after sexual debut [35, 36]. Risk factors for cervical HPV infection include early onset of sexual activity, a history of multiple sexual partners, and history of other sexually transmitted infections [5]. In addition to determinants mentioned above, risk factors for anal HPV infection include a history of anal receptive intercourse [34] and, for women, a history of cervical HPV infection or of cervical, vaginal, or vulvar SIL or cancer [37–40].

From cross-sectional studies, the prevalence of cervical hr-HPV infection ranges from 17% to 35% in renal transplant recipients (RTR) [9, 14, 41] and is 10% in liver transplant recipients (LTR) [11]. The largest cross-sectional study involved 218 RTR from the Netherlands where the prevalence of cervical HPV and cervical hr-HPV infection was 27.1% and 17.4%, respectively [41]. The authors compared this to cervical HPV infection prevalence of 9–10% in the general, age-matched Western-European population [42]. Testing for cervical hr-HPV before and after transplantation in a subgroup of 59 women further identified a significant increase in the prevalence of cervical HPV infection post-transplant despite the absence of changes in sexual risk behaviors [43]. This supports the theory that greater HPV prevalence in SOT recipients is due to reactivation of latent infection in the setting of impaired cellular immunity rather than due to a greater number of sexual partners or other traditional risk factors.

Data on anal HPV infection and other anogenital sites is limited for SOT recipients. Small, cross-sectional studies report anal infection rates with any HPV type of 21–48% in RTR [10, 13] and anal infection rates with any HPV type and hr-HPV of 18% and 8%, respectively, in LTR [11]. A larger study is underway to define the prevalence of anal HPV infection in RTR more clearly [44].

For HSCT recipients, the risk of cervical, vaginal, or vulvar HPV infection in female allogeneic stem cell transplant (alloHSCT) recipients increases with time from transplantation, approaching 40% at 10–20 years [45]. As with SOT recipients, the high rates of HPV infection are thought to result from the reactivation of latent HPV post-transplant rather than from an increase in high-risk sexual behaviors. AlloHSCT recipients with cutaneous graft-versus-host disease (GVHD), especially those with severe cutaneous or genital GVHD, are at particular risk. This, presumably, is the result of immune dysregulation and delayed immunologic recovery from GVHD. Moreover, patients with chronic GVHD often require years of immunosuppressive therapy which can lead to long-lasting effects on cellular immunity. Information on the prevalence of anal HPV infection in HSCT recipients, and of genital HPV infection in autologous stem cell transplant (autoHSCT) recipients, is limited.

SIL

SOT recipients are more likely to develop genital warts compared with the general population (Fig. 4a, b). In a registry-based study from the Netherlands, RTR had three times the risk of developing genital warts (LSIL) compared with patients without transplants [46], a finding corroborated by cohort studies from the USA [47] and Australia [48].

The US Transplant Cancer Match Study is an ongoing linkage study between the US nationwide organ transplant registry and 15 state and local registries [49]. In

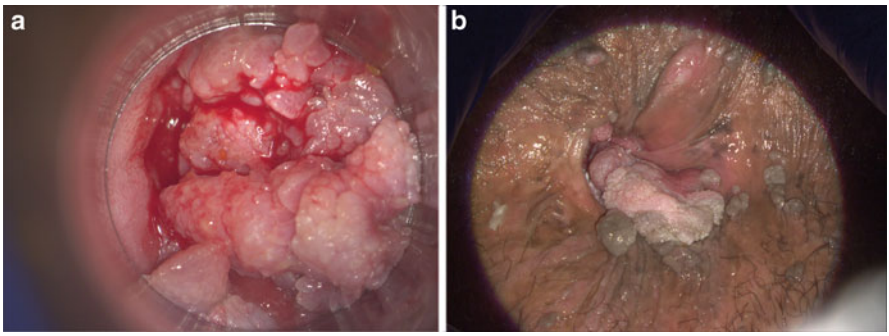

Fig. 4 Bulky condylomata/LSIL in (**a**) anal canal and (**b**) perianus of HIV-negative patient with a history of bilateral orthotopic lung transplant. Thickened micropapillae are typical of LSIL

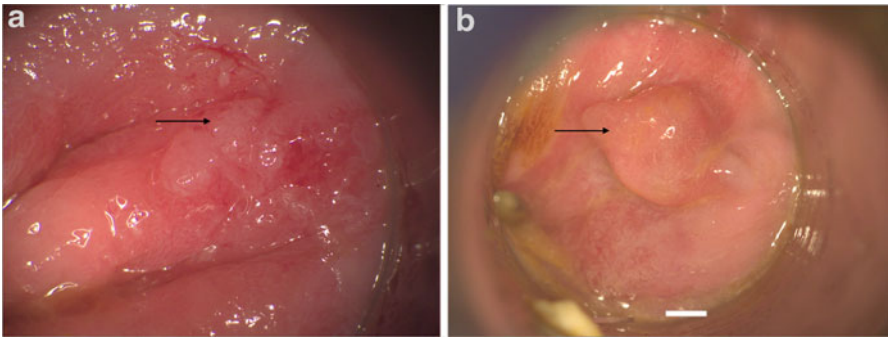

Fig. 5 (**a**) Anal canal HSIL at the right anterior squamo-columnar junction of an HIV-positive patient with a history of renal transplant. Lesion is acetowhite, raised and thickened, with coarse mosaic pattern and punctuation (arrow). (**b**) Follow-up visit with interval development of rubbery polypoid lesion with coarse punctuation suspicious for malignancy (arrow). Surgical excision noted HSIL with features suspicious for superficial invasion

addition to cancer data, this registry captures incidence data for HPV-related in situ *carcinomas,* a term previously used interchangeably with IN 3 and now encompassed by HSIL (Fig. 5a, b) [23]. Data from the US Transplant Cancer Match shows elevated standardized incidence ratios (SIR) for cervical, vaginal, vulvar, anal, and penile HSIL in SOT compared with the general population [49] (Table 1), a finding which is also corroborated by prior smaller and older cohort studies [50, 51].

In HSCT recipients, data on SIL after transplant is limited to several relatively small cohort studies that have evaluated the rates of abnormal cervical cytology before and after transplantation [52–55]. The rates of abnormal cervical cytology in female autoHSCT recipients are similar to that of the age-matched general population [55]. However, a consistent increase in abnormal cervical cytology is seen following alloHSCT [52–56]. As with HPV

Table 1 HPV-related cancers in US organ transplant recipients

	Number	Incidence per 100,000 person years	Standardized incidence ratio	95% confidence interval
In situ cancers (HSIL)				
Cervix	71	144.9	3.3	2.6–4.2
Vagina	34	10.4	10.6	7.4–14.8
Vulva	284	86.5	20.3	18.0–22.8
Anus	53	6.3	11.6	8.7–15.2
Penis	58	11.4	18.6	14.1–24.0
Invasive cancers				
Cervix	52	15.8	1.0	0.8–1.3
Vulva	66	20.1	7.3	5.6–9.2
Anus	103	12.3	5.4	4.4–6.6
Penis	25	4.9	3.9	2.5–5.7
Oropharynx	144	17.2	2.2	1.8–2.5

Source: Adapted from Ref. [49]

infection itself, development of severe cutaneous or genital GVHD is risk factor for abnormal cervical cytology [53, 54]. Data is limited on the actual prevalence of histologic SIL in the cervix as well as on the prevalence of SIL at other genital sites in HSCT recipients.

Progression from HSIL to Invasive Cancer

The rate of progression from HSIL to invasive cancer in SOT and HSCT recipients has not been measured, given that standard of care is to treat HSIL once it is identified. However, data on cervical HSIL progression in the general population and estimates of anal HSIL progression in people living with HIV (PLWH) provide valuable insights into the expected progression of HSIL in SOT and HSCT recipients.

In the general population, the risk of progression to cervical cancer once cervical HSIL is present was studied in New Zealand where cervical HSIL treatment was unethically withheld [57]. For women with persistent HSIL at 24 months, the risk of invasive cervical cancer by 5 years was 20% and by 30 years up to 50%. The study also showed progression of HSIL to invasive cancer after an average of 10–15 years [58].

Although we have not directly measured progression from anal HSIL to invasive anal cancer, combining data on HPV prevalence and anal cancer incidence provides an estimate of 1 in 4196 patients/year in MSM without HIV and 1 in 377 patients/year in MSM with HIV [59], suggesting a possible 10% lifetime risk of anal cancer for those MSM with HIV.

Information on the incidence of progression of HSIL to invasive cancer in other patient populations and at other anatomical sites is unavailable. Given the effects of immunosuppression on cellular immunity, it is reasonable to hypothesize that SOT and certain HSCT recipients (e.g., alloHSCT recipients with GVHD) have rates of HSIL progression to malignancy greater than those of the general population and closer to those of PLWH.

It is worth noting that on a per-HPV infection basis, the estimated rates for progression for cervical HSIL are much higher (approximately 1 in 80 per year) than the measured risk of cancer progression for anal HSIL [57]. While it is unknown as to why the cervix has a higher susceptibility for malignant transformation compared with the anus, contributing factors may include different hormonal milieux and microbiomes.

HPV-Related Malignancies in SOT and HSCT Recipients

The incidence of malignancy in SOT is calculated via the linkage of large transplant and cancer registries. Several such large, population-level studies provide invaluable information about the relationship between SOT and cancer. An Australian study noted a significant increase in the overall incidence of cancer following renal transplantation (SIR 3.27, 95% CI 3.09–3.46) [60]. The SIR was not elevated prior to transplantation, suggesting that immunosuppression itself (rather other traditional risk factors for malignancy like tobacco) was responsible for the results. UK and US linkage studies have similarly noted a twofold increase in the overall risk of malignancy in SOT recipients [15, 61]. Linkage studies also demonstrate a specific increase in the risk of HPV-related malignancies in SOT recipients [15, 49, 60]. In the USA, data from the US Transplant Cancer Match Study showed elevated SIR for vulvar, anal, penile, and oropharyngeal cancer (Table 1) [49]. The SIR of 1 for cervical cancer may reflect the presence of effective screening programs in US SOT recipients rather than an absence of elevated risk for this malignancy.

The risk of vulvar cancer in SOT recipients is particularly elevated with SIRs that range from 7 to 22 [49, 60]. In the general population, vulvar cancers are primarily squamous cell carcinomas (VSCC) and present in two distinct phenotypes. The first occurs in older women and is not associated with HPV infection. The second comprises about 25–40% of cases [62, 63], presents in younger women, and is associated with hr-HPV. A Dutch retrospective cohort of 1253 female RTR detected 6 cases of VSCC of which 5 were associated with HPV: 3 with HPV type 16, 1 with HPV type 53, and 1 with HPV type 58 [12]. Thus, it is plausible and likely that the observed risk for vulvar cancer in SOT recipients is related to a greater proportion of HPV-related VSCC.

Information on solid cancers following HSCT is derived from national and international registries that collect data on health outcomes in HSCT recipients.

Similarly to SOT recipients, HSCT recipients have approximately twice the risk of developing a solid malignancy after transplantation compared with the general, age-matched population [64–66]. However, whether they are at increased risk for HPV-related malignancies has not been clearly established. While smaller studies detected an elevated risk for cervical cancer in female alloHSCT and autoHSCT recipients [67, 68], this has not been replicated in larger studies [64–66, 69, 70]. This discrepancy may result from the smaller sample size in the studies where greater risk was detected. In this setting, a small number of detected cases may drive results toward significance but not be truly representative of the incidence in larger populations [56]. Of interest, registry studies have detected an elevated risk of oral cavity and/or pharyngeal cancer in alloHSCT and combined auto- and alloHSCT recipients, with GVHD as a driving risk factor [64–69]. While it is possible for some of these cases to actually represent oropharyngeal cancer, this has not been confirmed. Only one study specifically calculated the risk for oropharyngeal cancer in alloHSCT recipients and found it to be increased [70]. Two studies have reported increased risk for vulvar cancer in autoHSCT and alloHSCT, respectively [70, 71]; however, these results were only based on a total of one and two cases. Information on risk for anal cancer is limited.

Overall, there is limited evidence for an elevated risk of HPV-related malignancies among HSCT recipients despite greater risk for genital HPV infection and, in females, abnormal cervical cytology post-transplantation [45], although risk for oropharyngeal cancer may be elevated. This may be a result of eventual immune recovery allowing for clearance of HPV, thus decreasing the probability of malignancy. If so, risk likely remains elevated among patients who remain immunocompromised, like alloHSCT recipients with chronic GVHD on immunosuppression. Alternatively, because of the relatively long latent period between HPV infection and development of malignancy [57], patients with HSCT may die from complications related to transplantation before developing HPV-related malignancies. Finally, unlike SOT cancer studies, data from HSCT registries is not linked to cancer registries, and hence detection of malignancies may be undereported.

Non-melanomatous Skin Cancer in SOT and HSCT Recipients

SOT recipients and alloHSCT recipients are also at risk for non-melanoma skin cancer (NMSC) [72–74]. The incidence of NMSC increases with the duration of immunosuppression, ultimately affecting almost 50% of white SOT recipients [72]. While basal cell carcinomas predominate in the general population, cutaneous SCC (cSCC) comprise the majority of NMSC in SOT recipients [72] and an increased proportion of NMSC in alloHSCT recipients [74].

A role for non-anogenital cHPV in the pathogenesis of cSCC has been investigated but not conclusively proven in the healthy, general population [2]. While

cHPV is detected in 30–40% of cSCC from immunocompetent patients, no single HPV type predominates in these specimens, and cHPV is also found ubiquitously on the healthy skin and hair follicles and healthy skin [2]. In SOT recipients, however, cHPV is found in as many as 75–80% of cSCC samples [75, 76], with detection of HPV types 5 and 8 in 50% of specimens [76]. HPV 5 and 8 belong to the beta genus of the papillomaviridae family and are classified as potential carcinogens given their association with epidermodysplasia verruciformis, a rare hereditary skin disorder characterized by susceptibility to cHPV, cutaneous warts, and cSCC [2]. Thus, the greater prevalence of cHPV, particularly of HPV types 5 and 8, suggests a causal association between cHPV and cSCC in SOT recipients. However, most cHPV in cSCC are not transcriptionally active, and, similar to the general population, cHPV are also ubiquitious in healthy skin and hair follicles of SOT recipients [2]. If it is playing a role, cHPV is thought to potentiate the effects of ultraviolet radiation, which remains by far the strongest risk factor for cSCC [2]. The prevalence of cHPV in cSCC of alloHSCT recipients is unknown.

Prevention of HPV-Related Complications in SOT and HSCT Recipients

Until recently, prevention of HPV-related complications consisted of screening to detect and eliminate cervical and anal HSIL before progression to invasive cancer. HPV vaccines were introduced in 2006 to prevent initial HPV infection. Today, both screening and vaccination are important and complementary tools to decrease the risk of complications from HPV infection.

Cervical Cancer Screening

The cervical Papanicolaou (Pap) test, or cervical cytology, was developed by George Papanicolaou in the early 1940s to detect cervical cancer and precancerous lesions like HSIL and is still widely used today [77]. Women with abnormal cytology are referred for colposcopy, where a colposcope microscope and acetic acid are used to examine the cervix and identify HSIL. Affected areas are removed by loop electroexcisional procedure (LEEP), which can be done in the office, or cone conization, which is performed in the operating room [5]. Although no randomized controlled trials exist to establish the efficacy of cervical cytology screening and treatment of HSIL, the rapid decline in US cervical cancer incidence after the 1940s provides compelling evidence of its effectiveness [77]. Molecular techniques to test for hr-HPV have further improved the sensitivity and specificity of cervical cancer screening. Hr-HPV testing can be performed as a “reflex test” (to further risk-stratify in response to an abnormal cervical cytology), a “co-test” (automatically with cervical cytology), or a primary standalone test.

While detailed cervical cancer screening guidelines exist for immunocompetent women (Table 2), it is unclear how well these apply to women at higher risk for cervical cancer like SOT and HSCT recipients. Experts, including the American Society of Transplantation Infectious Diseases Community of Practice, recommend applying screening recommendations for women living with HIV (WLWH) to female SOT recipients [78, 79]. These guidelines are generally more stringent compared with those for the general population; differences include initiation of screening prior to age 21 if women are sexually active, shorter screening intervals, and the extension of screening beyond age 65 even in the absence of risk factors other than immunosuppression itself (Table 2). As with immunocompetent women, hr-HPV testing can be used as a "co-test" in immunocompromised women $\geq$30 years old. However, there is insufficient data to recommend it as a standalone test.

While data on the uptake of cervical cancer screening in SOT recipients from the USA is lacking, international studies suggest that adherence to screening guidelines in SOT recipients is low [80, 81]. A large, population-based cohort study of SOT recipients from Ontario, Canada, determined that only 30% of eligible women were adherent to general cervical cancer screening guidelines from 2000 to 2013 [80]. Furthermore, 31% of eligible women did not undergo any cervical cancer screening during this time period. A previous, smaller study from Northern Ireland in renal SOT recipients had similarly low rates of adherence to general screening guidelines [81].

For HSCT recipients, a large, nationwide, US insurance claims study reported that only 49.1% of alloHSCT and 42.6% of autoHSCT female recipients underwent cervical cytology within 2 years of transplantation [82]. The rate of testing was lower for alloHSCT recipients with GVHD compared with alloHSCT recipients without GHHD (42.5% versus 55.4%, $p \leq 0.01$), perhaps reflecting a sicker patient population less likely to adhere to additional testing, including screening. Uptake was better, but still inferior to that of controls, in an older, cross-sectional survey of HSCT from 40 North American transplant centers, in which 72.6% of women with HSCT reported a cervical cytology within the last year compared with 82.6% of controls ($p = 0.034$) [83]. These numbers are comparable to those reported in a cross-sectional Australian survey of HSCT survivors in New South Wales [84].

Despite variability in methods and results, these studies strongly suggest that SOT and HSCT recipients are less likely to receive cervical cancer screening compared with the general population and highlight the need to improve adherence to guidelines.

Anal Cancer Screening

There is interest in the early detection and treatment of anal HSIL in at-risk individuals. Analogous to the cervical cytology, anal cytology can be used to identify individuals requiring further evaluation. To obtain a specimen for anal

cytology testing, a Dacron swab is moistened with water and gently inserted into the anal canal until it hits the wall of the rectum. The swab is then extracted while rotating it in a spiral motion and gently applying mild pressure to the anal wall, after which it is immersed in preservative solution [85]. Digital anorectal examination (DARE) is performed following anal cytology to detect palpable, early invasive cancers.

The presence of any abnormality on DARE or anal cytology is followed by referral for high-resolution anoscopy (HRA). HRA involves use of a colposcope, the same instrument used to examine the cervix, to carefully examine the anal canal and perianus following the application of 5% acetic acid. The colposcope provides magnification and light, while acetic acid leads to dehydration of the intracellular compartment making cells more refractive to light. Lesions suspicious for HSIL or malignancy are biopsied. Treatment of anal HSIL differs from cervical HSIL in that deep excision of the anal canal causes significant morbidity and is not generally feasible. Instead, therapy typically involves superficial ablation with electrocautery (hyfrecation) or infrared coagulation. These can usually be performed in the office with local anesthesia. Alternatively, topical 5-fluorouracil can be applied to the anal canal and/or perianus for patients with widely diffuse disease. Surgical excision is reserved primarily for diagnosis of suspected malignancy [16].

However, despite our ability to detect and treat anal HSIL, it is unclear which specific patients benefit from this. There are presently no national guidelines for anal cancer screening, largely because of the absence of studies demonstrating that treatment of anal HSIL decreases the incidence of anal cancer, although a large, multi-site randomized-controlled trial is underway to answer this question in PLWH [86]. The HIV Medicine Association (HIVMA) recommends yearly anal cytology testing for the following PLWH: men who have sex with men (MSM), women with a history of receptive anal intercourse or of abnormal cervical cytology, and any individual with a history of genital warts [87]. The New York State Department of Health is the only other health organization to recommend anal HSIL screening in PLWH [85]. Its recommendations are similar to those of the HIVMA in terms of specific subgroups of PLWH who should receive screening [85].

Data to guide screening in SOT and HSCT recipients is lacking. The performance of anal cytology in detecting anal HSIL is unknown, and there is no data on the efficacy or effectiveness of therapy in SOT or HSCT recipients. However, given the elevated risk for anal cancer in SOT recipients and the presence of techniques that may prevent its development, the American Society of Transplantation Infectious Diseases Community of Practice does recommend screening SOT recipients with anal cytology (Fig. 6) [78]. Similar to PLWH, screening efforts should focus on SOT recipients at particular risk for anal cancer like MSM; women with a history of receptive anal intercourse; women with a history of cervical, vulvar, or vaginal SIL; and both men and women with a history of genital warts. It is reasonable to similarly screen HSCT recipients with the above criteria, especially those alloHSCT recipients with chronic GVHD.

Although the test characteristics for anal cytology in SOT and HSCT recipients are unknown, it is worth noting that abnormal anal cytology results are common in

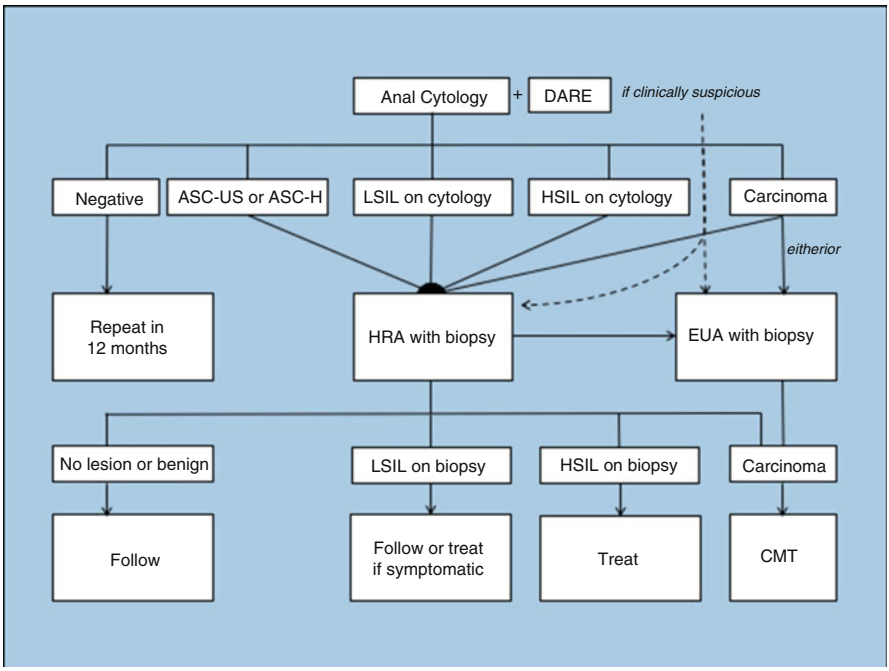

Fig. 6 Anal cancer/HSIL screening algorithm. Abbreviations as follows: atypical squamous cells of undetermined significance (ASC-US); atypical squamous cells cannot exclude high-grade squamous intraepithelial lesion (ASC-H); combined modality therapy (CMT,); digital anorectal examination (DARE); examination under anesthesia (EUA); high-resolution anoscopy (HRA); high-grade intraepithelial lesions (HSIL); low-grade squamous intraepithelial lesions (LSIL). (Adapted from Ref. [118])

the non-transplant population, ranging from 20% in low-risk women to approximately 70% in MSM living with HIV [88–91]. Therefore, it is likely that a substantial proportion of screened transplant recipients will require further evaluation when anal cytology-based screening is offered. Before cytology is performed, patients should be counseled about the high probability of referral for HRA as well as the potential risks and benefits of treating anal HSIL. Cytology should be avoided if the infrastructure to identify and treat anal HSIL is unavailable, and instead, yearly DARE to detect early palpable invasive anal cancer can be performed.

Other HPV-Related Malignancies

No recommendations exist to screen for HSIL at sites other than the cervix or anus in either immunocompetent or immunocompromised patients. Given the elevated risk of vulvar cancer in female SOT recipients, the vagina and vulva should be carefully examined at the time of cervical cytology, with a low threshold to perform vaginal and vulvar colposcopy, particularly if genital warts are noted [78]. This approach is

also reasonable for female alloHSCT recipients with a history of cervical or vulvar SIL or with severe cutaneous or genital GVHD.

Prophylactic HPV Vaccination

Three different vaccines exist to prevent initial HPV infection although only one is currently available in the USA. All three contain virus-like particles (VLP) made up of recombinant L1 capsid subunits but differ in the types they cover. Vaccination generates high levels of neutralizing anti-L1 VLP antibodies, which prevent HPV attachment to the basal cell membrane and, thus, initial infection [1].

Gardasil®, the first HPV vaccine, was approved in 2006. It is a quadrivalent vaccine (HPV4) produced by Merck & Co. that confers protection against hr-HPV types 16 and 18 and lr-HPV types 6 and 11. As previously noted, hr-HPV types 16 and 18 account for 70% of cervical cancers and 85% of anal cancers [7], while lr-HPV types 6 and 11 account for 90% of genital warts [8]. Two large, randomized controlled trials in young women demonstrated excellent efficacy of HPV4 in preventing type-specific cervical HSIL and genital warts in the per-protocol analysis (98% and 100%, respectively) [92, 93]. The per-protocol analysis included women who remained HPV-negative 1 month after completion of a three-dose vaccination series given at 0, 1, and 6 months; efficacy was lower in the intention-to-treat analysis (44% for cervical HSIL and 73% for genital warts). In 2009, GlaxoSmithKline introduced a bivalent vaccine (HPV2), Cervarix®, which protects against HPV 16 and 18. Following a similar three-dose vaccination series, its efficacy against type-specific cervical HSIL is comparable to HPV4 [94]. Subsequent studies also established vaccine efficacy of HPV4 in genital wart prevention among young men [95] and anal HSIL prevention in MSM [96]. Merck introduced a nonavalent vaccine (HPV9), Gardasil®9, in 2014. In addition to covering strains 6, 11, 16, and 18, HPV9 confers additional protection from hr-HPV types 31, 33, 45, 52, and 58 [97] which increases the coverage of cervical cancer to 90%. As of late 2016, only HPV9 is available in the USA.

The lower efficacy in the intention-to-treat analyses of HPV2 and HPV4 highlights a key characteristic of prophylactic HPV vaccines: they work when administered *prior* to HPV exposure. Because initial HPV infection occurs soon after sexual debut [35, 98], vaccination is most effective when given before recipients are sexually active. The US Advisory Committee on Immunization Practices (ACIP) consequently recommends routine vaccination of all males and females 11–12 years old, with immunization starting as early as age 9 years through age 26 years [99]. These recommendations extend to all immunocompromised persons through age 26 years [100]. Based on immunogenicity studies, a reduced, two-dose vaccination series with immunizations at 0 and 6–12 months is recommended for non-immunocompromised individuals less than 15 years old [101].

In October 2018, the FDA approved use of HPV9 in men and women ages 27 through 45 years old [102]. This approval was based on a randomized controlled trial of women aged 27–45 years old that showed vaccine efficacy in preventing

type-specific disease [103, 104]. As with studies in younger women, efficacy was higher in per-protocol analyses, which consisted of women without evidence of HPV exposure after completion of the vaccination series. In the USA, 50% of women and 25% of men aged 27–45 years old have serological evidence of infection by at least one of the HPV types in HPV9; 20–28% of women and 7–14% of men aged 27–45 years have serological evidence of infection by HPV types 16 and/or 18 [105]. Rates of actual infection are presumably much higher given that serological response to infection only occurs in 50–70% of women [106] and 4–36% of men [107]. Thus, a substantial proportion of potential vaccine recipients aged 27–45 years have been exposed to HPV, and it is unclear whether widespread vaccination of this age group would be cost-effective. The most recent ACIP guidelines have not extended catch-up vaccination through age 45. Instead, the ACIP acknowledges that some persons aged >26 years may benefit from vaccination and recommends shared clinical decision-making between these persons and their providers [99].

Data on the efficacy of HPV vaccination in SOT and HSCT is limited. One immunogenicity study of 47 SOT recipients ages 18–35 years old who received HPV4 showed a 47% response rate to all four vaccine HPV types [108]. Response rates were higher in patients who received all three vaccine doses. Factors associated with decreased response included lung transplantation and transplant less than 1 year prior to receipt of vaccine. However, a separate immunogenicity study of 14 RT and 3 liver transplant recipients ages 9–17 years old who also received HPV4 showed a 100% response rate to all 4 vaccine types [109]. This rate is comparable to seroconversion rates in the general, immunocompetent population [110]. The reasons for this discrepancy are unknown and may be due to the variability inherent to small cohort studies. However, it may also reflect real differences in vaccine response due to age given that there was a younger median age in the study with the higher vaccine response. Of note, 6 of 14 RT recipients within the adolescent cohort developed acute rejection during the study period. While this rate was higher than expected, there is no evidence that this was related to HPV vaccination. Neither study evaluated the efficacy of the vaccine in preventing SIL.

For HSCT recipients, there are encouraging preliminary results from a phase 1 study of female alloHSCT recipients who underwent HPV4 vaccination at least 90 days post-transplantation [111]. Response rate to all four vaccine types was 78.3% for female alloHSCT recipients receiving immunosuppression for GVHD, 95.2% for female alloHSCT recipients not receiving immunosuppression, and 100% for healthy female controls. A separate study to assess the immunogenicity of HPV9 in patients after alloHSCT is actively recruiting [112].

Despite the possibility of a suboptimal immune response, we recommend proceeding with HPV vaccination of SOT and HSCT recipients who meet age-specific criteria, particularly since HPV vaccines do not contain live virus and have excellent safety records [78, 113, 114]. Both SOT and HSCT recipients should receive the three-dose vaccination series, ideally prior to transplantation. If vaccination is not performed prior to transplantation, it is reasonable to wait at least 3–6 months in SOT recipients and 6–12 months in HSCT recipients after transplantation to potentially improve seroconversion [113, 114]. Whether or not to vaccinate SOT and HSCT

recipients ages 27–45 years old is unclear; however, vaccination in this age group may help decrease the risk of HPV-related malignancies with relatively little downside. Lastly, vaccination does not substitute for ongoing cervical and anal cancer screening.

Conclusion

In summary, SOT recipients are at high risk for infection with anogenital HPV, development of precancerous lesions (HSIL), and progression to invasive malignancy. This process is thought to be mediated via reactivation of latent HPV virus in the setting of impaired cellular immunity. While there is less data available for HSCT recipients, studies suggest that alloHSCT recipients with a history of GVHD are at particular risk for complications from HPV infection, likely from a mechanism similar to that postulated in SOT. Screening and vaccination are two methods to decrease the risk of HPV-related malignancies. There are specific guidelines for cervical cancer screening for female SOT and HSCT recipients; special efforts are needed to improve their uptake. More studies are needed to determine whether anal cancer screening is effective in SOT and HSCT recipients and whether widespread HPV vaccination should be pursued in these groups. In the interim, anal cancer screening is recommended for high-risk SOT recipients when an adequate infrastructure is available and should be considered in high-risk HSCT recipients. ACIP vaccination guidelines should be followed, with additional consideration of extending HPV vaccination to SOT and HSCT recipients ages 27–45 years old.

Key Points

- Infection with high-risk human papillomavirus (hr-HPV) is associated with cervical cancers (99.9%), anal cancers (90%), and oropharyngeal cancers (70%), as well as a high proportion of vaginal, penile, and vulvar cancers.
- Defects in cellular immunity make solid organ transplant (SOT) recipients particularly susceptible to persistent hr-HPV infection, development of cancer precursor lesions, and progression to malignancy.
- AlloHSCT recipients with GVHD are likely at increased risk for HPV-related malignancies.
- Specific cervical cancer screening recommendations exist for SOT and HSCT recipients, while specific anal cancer screening recommendations exist for SOT recipients. It is reasonable to apply anal cancer screening recommendations for SOT to HSCT recipients, particularly alloHSCT recipients with a history of GVHD.
- HPV vaccination may decrease the incidence of HPV-related complications in SOT and HSCT recipients, particularly when administered prior to HPV exposure and transplantation.

Introduction

Access to solid organ transplantation for the HIV positive recipient has gained acceptance with several studies demonstrating safety and efficacy comparable to HIV negative recipients [1–3]. The early success reported in HIV-infected kidney transplant recipient has subsequently been reported following liver transplantation as well, although early results were compromised by the absence of successful treatment of the HIV positive recipient coinfected with Hepatitis C [4, 5]. With the advent of direct acting agents to treat hepatitis C, this last hurdle to successful liver transplantation has been eliminated. Excellent long-term outcomes following simultaneous pancreas and kidney transplantation have also been reported in people with Type 1 diabetes and HIV [1], despite the more aggressive immunosuppressive regimens required in this group of recipients.

Along with the increased interest in solid organ transplantation in people infected with HIV, waiting lists have expanded. The waiting times to receive a deceased donor kidney are in excess of 7–8 years in many parts of the USA [6]. In most countries, liver recipients require very high MELD scores for organ allocation. Unfortunately, HIV positive recipients have rapid progression to end-stage liver disease and cannot tolerate the high MELD scores required for liver allocation. The use of HIV positive donors has expedited the time to kidney transplant and facilitated liver allocation at significantly lower MELD scores. In South Africa, a transplant

program utilizing HIV positive donors was started in 2008 [7]. In the USA, transplant programs have been using HIV negative donors for approximately two decades, and recently HIV positive donors have been utilized as part of the Hope Act [8].

The evolution of transplantation in people infected with HIV has been remarkable, and gone from HIV positivity being a strict contraindication to solid organ transplantation to broad acceptance. The dramatic evolution is further highlighted by the current practices to use HIV positive organs in HIV recipients to facilitate transplantation and minimize the time on expanding waiting lists. This chapter will provide an overview on strategies which have resulted in successful transplantation in the HIV positive recipient.

Pathophysiology and Organ Involvement

Kidney

The kidney is a known reservoir for HIV, but there are also indirect causes for renal failure associated with HIV infection. The etiology of kidney disease associated with HIV infection has implications for both the recurrence of nephropathy following transplantation, as well as for the choice to utilize an HIV-infected donor kidney. Particularly if a donor has proteinuria, or collapsing FSGS, they are typically not utilized. The spectrum of renal pathology related to HIV infection is diverse, and include lesions directly related to intrarenal HIV gene expression as well as lesions related to co-morbidities, drug effects, immune dysregulation, and other co-infections. Podocytopathy or immune complex-mediated glomerular disease are two common manifestations of HIV in the kidney. A useful approach to classification is based on the major tissue compartment affected by the virus (Table 1).

Liver

Mortality from liver disease impacts up to 18% of people infected with HIV in the current anti-retroviral era and remains a major cause of death in this population [4]. There is no question that HIV infection exacerbates liver inflammation and progression of fibrosis in people with concomitant causes of liver disease. The multiple mechanisms by which this occurs are beyond the scope of this chapter, but are in part related to dysregulation of the immune system as well the direct effect of HIV on activation of hepatic stellate cells [9]. Although the most common etiology remains viral coinfection with either hepatitis C or hepatitis B, enhanced progression of cirrhosis is also seen with liver disease mediated by alcohol abuse as well as non-alcoholic hepatic steatohepatitis.

Table 1 Pathologic classification of HIV-related kidney diseases

I. Glomerular dominant[a]
a. Podocytopathies (all characterized by extensive foot process effacement)[b]
i. Classic HIVAN
ii. FSGS (NOS) in the setting of HIV
iii. Minimal change disease in the setting of HIV
iv. Diffuse mesangial hypercellularity in the setting of HIV
v. Other podocytopathy in the setting of HIV
b. Immune complex-mediated glomerular disease[a]
i. IgA nephropathy in the setting of HIV
ii. Lupus-like glomerulonephritis in the setting of HIV
iii. Lupus nephritis in the setting of HIV
iv. Membranous nephropathy in the setting of HIV
Indicate whether HBV positive, HCV positive, PLA2R positive (should not preclude workup for other secondary causes)
v. Membranoproliferative pattern glomerulonephritis in the setting of HIV
Indicate whether HCV positive (should not preclude workup for other secondary causes)
vi. Endocapillary proliferative and exudative glomerulonephritis in the setting of HIV
Post-streptococcal, staphylococcal-associated, other
vii. Fibrillary or immunotactoid glomerulonephritis in the setting of HIV
viii. Other immune-complex disease in the setting of HIV
II. Tubulointerstitial dominant[a]
a. Tubulointerstitial injury in the setting of classic HIVAN
i. Hyaline droplet tubulopathy
ii. Tubular microcysts
iii. Tubulointerstitial inflammation
b. Acute tubular injury/acute tubular necrosis
i. Ischemic
ii. Toxic (associated with cART vs. other)
c. Drug-induced tubulointerstitial nephritis (other than cART)
i. Antibiotics
ii. Proton pump inhibitors
iii. NSAIDs
iv. Other
d. Direct renal parenchymal infection by pathogens (bacterial, viral, fungal, protozoal, etc.)
e. Immunologic dysfunction-related tubulointerstitial inflammation
i. Diffuse infiltrative lymphocytosis syndrome (DILS)
ii. Immune restoration inflammatory syndrome (IRIS)
f. Other tubulointerstitial inflammation in the setting of HIV
III. Vascular dominant[a]
a. Thrombotic microangiopathy in the setting of HIV
b. Arteriosclerosis
IV. Other, in the setting of HIV infection
a. Diabetic nephropathy
b. Age-related nephrosclerosis

cART, antiretroviral therapy; HBV, hepatitis B virus; HCV, hepatitis C virus; FSGS, focal segmental glomerulosclerosis; HIV, human immunodeficiency virus; HIVAN, HIV-associated nephropathy; NSAID, nonsteroidal anti-inflammatory drug

[a]Indicate the likelihood of HIV causality

Patient Selection for Transplantation for a HIV Positive Transplant

Preoperative Investigations

Most transplant centers require HIV-infected transplant candidates to maintain a CD4+ T-cell count of 200 or more cells/mm^3 and to be on a stable antiretroviral regimen. The CD4+ T cell requirements are decreased to 100 cells/mm^3 for liver transplant candidates, because patients with cirrhosis often have splenic sequestration secondary to splenomegaly and portal hypertension. In order to qualify for a kidney transplant, most centers require the patient to be on a stable antiretroviral regimen, and for the HIV viral load to be consistently less than 50 copies/ml, or at worst, if viral "blips" are occurring, that they are small and readily explainable by concurrent illness. Although undetectable HIV viral loads are preferable for liver transplant candidates, most centers will consider liver transplantation with a detectable viral load if the etiology of the liver disease is related to toxicity from the antiretroviral agents. Especially with more antiquated antiretroviral regimens, they will often have to be stopped because of an exacerbated progression of liver disease. In these cases, the HIV provider needs to review the antiretroviral history and make sure that the virus can be suppressed following the liver transplant. It should be noted that the minimal CD4+ T-cell requirements are based on the higher frequencies of opportunistic infections that were observed in prior eras, and with better prophylactic regimens now available, some centers are beginning to push the boundaries in terms of minimal CD4+ requirements for transplantation.

Someone with a previous history of opportunistic infections or HIV-associated neoplasms may be allowed to progress to transplant if the patient received appropriate acute and maintenance therapy and has no evidence of active disease. A list of these generally acceptable conditions are depicted in Table 2.

All potential recipients must be on a stable cART for 3 months prior to the transplant. For potential liver transplant recipients with hepatotoxicity secondary to cART, an antiretroviral regimen is not required prior to the transplant, provided that the HIV physicians can assure the availability of a suppressive antiretroviral regimen post-transplant. For recipients considering an HIV+ donor, viable alternative cART regimens should be discussed pre-transplant so as to best understand the implications of the viral resistance history of any donor.

Contraindications to Transplantation in the HIV Positive Recipient

Contraindications to transplantation in the HIV positive recipient are outlined in Table 3. Many centers will not treat HCV so that the potential recipient can receive a donor organ from an HCV positive recipient, and elect to treat the HCV post-transplant. With the current direct antivirals available to Hepatitis C positive patients,

Table 2 Opportunistic infections that may be allowed for HIV positive patients on the waiting list

Condition	Comment
Candidiasis of esophagus or vagina	Response to treatment with no recurrence in the last 6 months on cART
Encephalopathy (HIV related)	Diagnosed prior to cART and resolved on cART and no evidence of progression
Isosporiasis (chronic intestinal)	Good response to treatment without history of recurrence in the last 6 months on cART
Human Herpes Virus 8	Potential recipients with a history of Kaposi's sarcoma (KS) can be included, provided that the KS has resolved either with reconstitution of the immune system with antiretroviral therapy or treatment with TOR inhibitors. Based on successful treatment of KS with TOR inhibitors, KS is no longer considered a strict contraindication to transplantation
Mycobacterium tuberculosis	Active disease: Completed treatment with clinical radiological and microbiological response, with no recurrent in >6 months, on cART Latent disease: Ok to progress to transplant, provided INH prophylaxis initiated, ideally at least a month before hand Of note, in hyperendemic areas, such as South Africa, secondary LTBi prophylaxis is universally administered, out of concern for high reactivation
Nontuberculous mycobacteria	Completed treatment with clinical, radiological, and microbiological response, with no recurrence in the last 6 months on cART
Pneumocystis pneumonia	Completed treatment with clinical and radiological response. Must be on/restart cotrimoxazole prophylaxis
Nontyphoidal Salmonella septicemia	Completed treatment with clinical response and no recurrence in the last 6 months on cART
Toxoplasmosis (CNS)	Completed therapy and CT/MRI shows signs of resolution without active disease and is on secondary cotrimoxazole prophylaxis

it might be better to transplant the patient first with a hepatitis C positive donor organ, as the donor pool for this group of patients is bigger.

Donor Options

HIV Negative Donors

Most centers in the USA and South Africa accept HIV positive patients on the waiting list for HIV negative organs, as outcomes have been reported as similar to HIV negative recipients [2]. HIV positive recipients should have access to kidneys and livers from HIV negative living and deceased donors using the standard acceptance criteria. For HIV positive patients co-infected with hepatitis C (HCV), the use of HCV positive kidneys and livers are considered by some centers to expedite the time to transplant. However, with the availability of HIV positive organs for use in HIV positive patients, the demand for the HCV positive donor organs in HIV positive recipients has decreased. Experience with HIV

Table 3 Contraindications for transplantation

Any active opportunistic infection	
Any other current neoplasm *except* for:	Anogenital carcinoma in situ Adequately treated BCC or SCC of skin
A history of a solid tumor between 2 and 5 years ago	
Cytomegalovirus disease	Retinitis or drug resistant disseminated infection, where treatment options may be limited in the event of reactivation
Currently active deep fungal infection	Cryptococcus Histoplasmosis Candidiasis at a site other than the esophagus or vagina Sporotrichosis, Aspergillosis, Fusariosis Any other disseminated fungal infections
Disseminated herpes simplex virus infection	
Tuberculosis	Multi-drug resistant (MDR) or extensively drug resistant (XDR) tuberculosis
Progressive multifocal leukoencephalopathy, at any time	
Hepatitis B and C	Untreated hepatitis B co-infection would be a contraindication for most centers, outside of extreme circumstances Untreated hepatitis C should be treated, either ahead of transplant if viremic control was urgent, or post-transplant with direct acting antivirals. HIV/HCV co-infection is not a contraindication to SOT
Parasitic infections	Chronic intestinal cryptosporidiosis of >1 month duration

transplantation in thoracic organ transplant remains more limited although preliminary experience suggests with modern cART regimens survival mirrors HIV-negative counterparts [10].

HIV Positive Donors

The utilization of HIV positive donors in HIV positive recipients has had a marked effect on expediting the time to transplantation. The use of HIV positive donors, as well as the nearly simultaneous expanded safe use of HCV viremic donors, opened the door to utilize all increased infectious risk donors, for instance, donors who die of intravenous drug usage or have a history of high-risk sexual activities. Furthermore, Nucleic Acid Testing (NAT) as well as HIV antibody assays, both have small percentage of false positive tests results as depicted in Table 4. Recognizing some donors might falsely test positive for HIV, the allocation of these organs to HIV positive patients removes any concern that a recipient contract HIV through transplantation and makes utilizing further donors possible [11]. HIV positive donor organs had been utilized in South Africa for the last 10 years with good clinical results [7].

Based on the success in South Africa, the USA has initiated a similar strategy, and the safety and efficacy of using HIV positive donors is being studied in a NIH multicenter trial (Hope Act) [12]. This strategy has decreased waiting times for HIV infected kidney recipients from greater than 8 years to less than 1 year in parts of the

Table 4 False positive tests amongst different screening tests for HIV

Assay	Company	Sensitivity (%)	Specificity (%)	False positive rate (%)
HIV antibody assays:				
ABBOTT PRISM HIV O PLUS	Abbott	100	99.94	0.06
HIVAB HIV-1/HIV-2 (rDNA) EIA	Abbott	100	99.90	0.1
HIV NAT assays:				
COBAS Amplicreen HIV-1 test v 1.5	Roche	99.1	99.7	0.3
Procleix HIV-1/HCV	Gen-Probe	99.8	99.87	0.13
Procleix Ultrio	Gen-Probe	99.6	99.8	0.2

USA, provided the potential recipients have consented to receiving a HIV positive donor [8]. Early experience with HIV positive donors in HIV positive liver recipients is promising, and suggests the utilization of livers from HIV positive donors will also be a valuable source of donor organs for the HIV positive recipient.

Considerations When Utilizing a HIV Positive Donor

History of HIV Disease

A history of HIV disease (if known) should be obtained from the family member/durable power of attorney giving consent for the transplant. If possible, previous medical records should be obtained using the usual protocols of donor networks. Donors who have not been on previous combination antiretroviral therapy (cART) carry a lower risk of harboring a resistant HIV strain. In resource-rich countries, like the USA, where approximately 10% of the population carry transmitted virus, yet approximately 1 in 7 patients are unaware of their HIV status, and may only be diagnosed during their terminal predonation illness, then transmitted HIV resistance is possible even in the absence of donors taking antiretrovirals. Transplanting a recipient with a resistant viral strain is a major concern. South Africa, where HIV positive donors had been used since 2008, has a unique situation in view of the fact that there are very low ART resistance rates [13]. Most patients who failed second-line ART in South Africa have resistance rates of less than 5% [14]. This unique situation is an important consideration, making the scenario in South Africa for using HIV positive donors more favorable than in many other parts of the world. In the USA, most of the HIV donors are not naïve to antiretroviral therapy. In these cases, the donor networks try to get a detailed history of the ART usage of the donor, and get some sense as to the risk of transmitting a resistant strain. Fortunately, in the early experience of using HIV positive donors, the transmission of a resistant strain has not occurred [8].

Renal Impairment in the Donor

Similar to work-up for HIV negative donors, standard blood tests to assess kidney function should be performed. The propensity of HIV to coexist with other conditions – hypertension, smoking, or viral hepatitis, for example – can amplify subtle renal disease risk. Consequently, urine should be tested for protein, and if more than 2+ proteinuria is present on the dipstick, the kidney should probably not be used because of the risk of HIV nephropathy in the donor. A renal biopsy should be performed on all HIV+ donor kidneys, both to rule out HIV nephropathy but also to assess nephrosclerosis and to establish a baseline for comparison for future biopsy samples. In addition, it is useful to store blood from the donor for resistance testing for donor virus if necessary for later investigations.

Donor Screening for Other Infections

Screening for deceased HIV positive donors should include screening for strongyloidiasis in endemic areas, as well as latent Tuberculosis infection, sexually transmitted diseases like Syphilis, West Nile Virus, and Chagas parasitic disease.

For a more extensive discussion on transplant associated diseases listed here, refer to chapters ▶ Chaps. 18, "*Mycobacterium tuberculosis* in Transplantation," ▶ 40, "West Nile Virus and Transplantation," and ▶ 53, "Strongyloides: Emerging Challenges and Prevention."

Antiretroviral Therapy

The drug–drug interactions between anti-retrovirals and immunosuppressive agents are significant, and attention to these interactions is essential for maintaining sufficient exposure to immunosuppressive drugs, as well as sufficient antiviral activity. The most problematic drug–drug interactions result from the fact that the protease inhibitors utilized in many cART regimens inhibit the cytochrome p450 system, whereas the non-nucleoside inhibitors stimulate the same pathway. The cytochrome p450 system is also the system that metabolizes the calcineurin and TOR inhibitors used in almost all maintenance regimens, as well as many other drugs commonly used in transplant, such as statins, azoles, and neuropsychiatric medications. For that reason, it is very challenging to obtain adequate exposure to the commonly used agents used for maintenance immunosuppression. When feasible, integrase inhibitor (INSTi) based antiretroviral regimens should be preferred to regimens including protease and non-nucleoside reverse transcriptase inhibitors, since the integrase inhibitors do not impact the cytochrome p450 system [15]. Similarly, INSTi resistance in the HIV+ donor population is predicted to be very low, likely $<1\%$. In general, rejection rates in patients who are on PIs are reported to be higher than when on alternative ART, in part related to poor exposure to maintenance immunosuppression [16]. Sufficient exposure to appropriate levels of immunosuppressive agents is facilitated by avoiding the protease inhibitors, and it is for the reason that most US centers are now switching to integrase-based cART regimens for HIV positive recipients on waiting lists for solid organ transplantation. Of course, recipients with resistant strains of HIV

based may require regimens dependent on protease inhibitors, and in these cases close monitoring of drug levels is imperative.

Immunosuppression Choices

Despite the theoretical concerns about HIV+ recipients being functionally more immunocompromised than their negative counterparts, rejection rates following both liver and kidney transplantation in the HIV positive recipient have been unexpectedly high. Although part of the higher rejection rates is undoubtedly related to reduced exposure to immunosuppressive medications based on the drug–drug interactions, part of the higher rates may also be related to immune dysregulation. The reasons behind these higher than expected rates of rejection are beyond the scope of this chapter. With the reality of a twofold higher risk of rejection, many centers choose to give all their HIV positive kidney recipients aggressive induction immunosuppression with lymphodepleting agents, most commonly anti-thymocyte globulin (ATG). Of note, lymphodepleting agents are not recommended in HIV positive liver recipients based on adverse outcomes in the earlier experience, although contemporaneous data are lacking. Although the risk/benefit ratio of lymphocyte depleting regimens has been favorable in the kidney transplant recipients, caution should also be used [17]. Thymoglobulin use were associated with an increased kidney recipient mortality in selected kidney transplant recipients [2].

In some studies HIV-positive patients receiving sirolimus-based therapy had higher acute rejection rates when compared to patients receiving calcineurin inhibitor-based regimens [17]. TOR inhibitors possess anti-HIV properties both in vitro and in vivo. RAPA represses HIV-1 replication in vitro through different mechanisms including, but not limited, to down regulation of CCR5 [18].

CCR5 blockade (maraviroc) is also a logical choice for anti-HIV therapy as it not only blocks the entry port for the HIV virion into the lymphocyte, but also blocks the alloimmune response. Homozygotic carriers of an allele of the gene for the CC chemokine receptor 5 (CCR5) with a 32 bp deletion (CCR5Delta32) leads to an inactive receptor. During acute and chronic transplant rejection, ligands for CCR5 are upregulated, and the graft is infiltrated by CCR5-positive mononuclear cells. Therefore, patients who are homozygous for CCR5Delta32 have a lower risk for graft rejection and the literature reports improved outcomes in terms of rejection rates as well as graft survival compared to homozygous wild type or heterozygous CCR5Delta32 genotype [19, 20]. There is a current NIH trial studying the efficacy of CCR5 blockade in terms of blocking the immune response following kidney transplantation.

Rejection

Rejection remains an important clinical issue in HIV positive patients. The reason for high rejection rates in HIV positive patients is still unclear. As previously discussed, it has been speculated that the rejection rates are related to the drug

interactions affecting the cytochrome P450 enzyme resulting in poor exposure to immunosuppressive medications [21, 22]. In some studies, superior outcomes had been reported with integrase strand transfer inhibitor-based antiretroviral regimens. As these regimens have no interaction with calcineurin inhibitors, it should be preferred to protease and non-nucleoside reverse transcriptase inhibitors [15, 23].

However, a more complex immunological situation might also be responsible for high rejection rates in HIV positive patients. Chronic immune activation and inflammation is known to contribute to the risk of cardiovascular diseases in HIV positive patients [24]. The exposure to co-pathogens may result in heterologous immunity, leading to immunologic memory for HLA antigen in the absence of direct exposure. Furthermore, the loss of T helper cell function in response to antigens and the critical reduction in CD4+ T cell numbers might be responsible for a dysregulated immune response in HIV positive patients [25].

In studies that compared rejection rates between HIV positive and negative recipients, not only the rejection rate was increased, but also the time to first rejection episode was shorter [3]. One important consideration is the impact on the long-term renal function after a rejection episode, clearly visible when comparing the eGFR in patients who did not have rejection with those that did experience one or more episode of rejection in the USA multicenter study [3] (Fig. 1).

Recurrence of HIVAN

The incidence of recurrent HIV nephropathy following transplantation has been reported with variable frequencies. In the South African program, 51 patients received 150 protocol as well as "for cause" biopsies over a 10-year period [26].

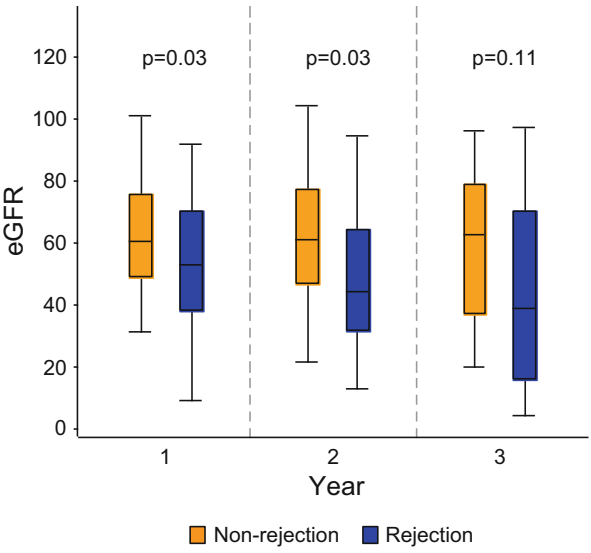

Fig. 1 Comparative eGFR in patients who did not experience rejection with those that had one or more rejection episode

Twelve patients had some features of HIVAN on a protocol biopsy. This included glomerular, interstitial, and tubular findings. In general, the collapsing form of focal segmental glomerular sclerosis (FSGS) is the most common glomerular lesion in HIVAN [27]. Figure 2 represents a histology sample of a South African transplant patient who was diagnosed with plasma cell infiltration, podocyte hypertrophy, as well as FSGS on a protocol biopsy 3 years post-transplant. Despite these changes in the kidney, the patient still had excellent graft function and no proteinuria.

The US NIH multicenter trial reported a 1–2% incidence of HIV nephropathy in the 175 subjects who underwent kidney transplantation. However, biopsies were only performed in this trial for deterioration in the renal function or the development of proteinuria. In this study, proteinuria was an extremely rare event [3]. Unlike the US trial, the French trial reported by Canaud et al. [28] found a much higher incidence of HIVAN in the 19 patients transplanted in this trial. Furthermore, if HIV was detected in the podocytes (5/19), patients had significant deterioration in renal function that often resulted in graft loss. The reasons for the vast disparities between the US and French trials remain unclear, and are the focus of ongoing studies.

Second Viral Strain

A significant concern in the utilization of HIV positive donors is the potential for superinfection with a more virulent or more drug resistant strain than the HIV positive recipient has on board. In a South African study, 24 HIV positive donor and recipient samples were evaluated for HIV drug-resistant mutations pre- and/or post-transplant [26]. Although drug-resistant mutations were found in six recipients, none of these mutations was donor derived. Although a donor virus inoculum was detected in the plasma of eight recipients (32%) at the earliest available time point post-transplant, a long-term sustainable superinfection was absent in all recipients. The ability to detect superinfection was limited by the inherently low proviral loads

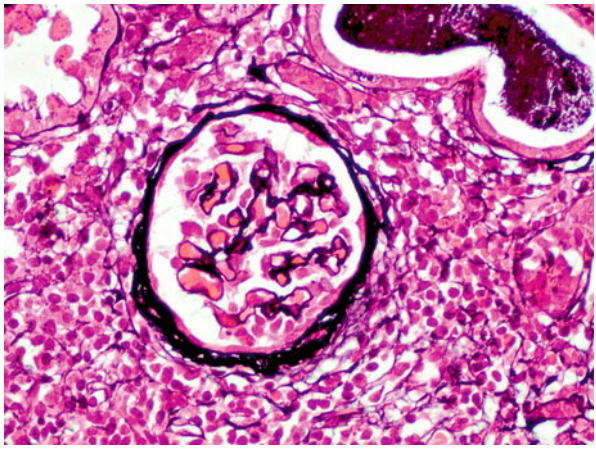

Fig. 2 Example of plasma cell infiltrate, podocyte hypertrophy, end-stage glomeruli, and focal segmental glomerulosclerosis. Despite these changes, patient has excellent graft function

found in ART-suppressed patients, as well as by the ATG-induced T-cell depletion post-transplant. However, superinfection could be detected down to a median of 1% of the viral population. A transient, subclinical superinfection immediately after transplantation suggested lingering viral inoculum and shedding of infected donor cells from the kidney into the recipient's blood. No increases in viral load or new viral resistance have been observed in any of these transplant patients. The favorable clinical outcomes, lack of transmitted drug resistance, as well as the lack of evidence for sustained donor-derived superinfection provides support for the use of HIV+ to HIV+ renal transplants as a treatment option for HIV-infected patients requiring renal-replacement therapy.

Opportunistic Infection

Even in patients with a pre-transplant history of opportunistic infections, recurrent opportunistic infections are not associated with decreased survival. In a large multicenter study of 125 liver and 175 kidney transplants, 55% of liver and 50% of kidney recipients experienced an opportunistic infection. However, these infections did not impact long-term outcomes. Most opportunistic infections occur early, and patients are at the highest risk in the first 6 months after the transplant. Bacterial infections are the most common infective occurrence after a transplant [2]. In some geographical regions, the incidence of tuberculosis and fungal infections seem to be higher in HIV positive recipients than in HIV negative recipients [29]. Prophylaxis strategies against opportunistic infections should provide HIV positive recipients with adequate protection from opportunistic infections, and should be designed with consideration of local donor and recipient epidemiology in mind.

HHV8-related disease, particularly KS, may be exacerbated or reactivated by post-transplant immunosuppression. Importantly, recurrence of effectively treated pre-transplant KS was not observed in the large US multicenter trial [2]. However, the same series reported three cases of de novo cutaneous Kaposi's sarcoma post-transplant, all successfully treated by conversion to TOR inhibitors for immunosuppression. TOR inhibitors down regulate VEGF, and effectively block these highly vascularized lesions from developing. Converting HIV positive recipients to maintenance immunotherapy that includes TOR inhibition has proven to be effective therapy for treating de novo KS in HIV positive transplant recipients. For this reason, KS is no longer considered a contraindication to transplantation, especially if cutaneous only, and especially if it appeared many years prior during phases of more substantial CD4 immunosuppression.

HPV-related cervical and anorectal disease, already accelerated in people with HIV infection, may be exacerbated by post-transplant immunosuppression. It has become apparent that close follow-up with anal and cervical PAP smears is particularly important in the HIV positive recipient, and early detection of atypical cells with aggressive treatment can prevent the need for a major surgical resection. Establishing patients into clinics with robust HPV anogenital screening programs may be beneficial pre-transplant, although they are less commonly available for male patients.

In pediatric patients who had a positive EBV donor, but is negative for EBV before the transplant, EBV viral load monitoring should be done to prevent an opportunistic EBV infection. This is generally not done in adults.

Prophylactic Therapy Against Common Infections

Prophylaxis against fungus, PCP, and CMV is similar to regimens used for HIV negative recipients, with the caveat that *Mycobacterium avium* Complex (MAC) prophylaxis is applied when CD4 counts drop below 75 cells/mm^3, something typically not done in routine solid organ transplantation. A summary of prophylactic therapy is presented in Table 5.

Table 5 Prophylactic therapy recommended for HIV positive recipients of solid organ transplants

Infection	Recommended prophylactic therapy
Pneumocystis pneumonia (PCP)	PCP prophylaxis with trimethoprim/sulfamethoxazole (TMP-SMX) should start immediately post-transplant and continued for 1 year at the discretion of the treating physician. An alternative would be dapsone. If G6PD negative atovaquone is recommended. Some centers use inhaled pentamidine monthly as an alternative approach
Toxoplasmosis	Trimethoprim/sulfamethoxazole (TMP-SMX) prophylaxis should be continued for 1 year at the discretion of the treating physician. An alternative would be Dapsone + Pyrimethamine + Leucovorin if allergic to TMP-SMX
Cytomegalovirus (CMV)	Prophylaxis should continue for 3–6 months after the transplant. Oral valgancyclovir is recommended for 3–6 months after transplant and should be considered again during the treatment of acute rejection for 1–3 months following completion of acute rejection therapy. Donor positive, recipient negative patients should continue prophylaxis for 6 months. Donor negative recipient negative can get Acyclovir as an alternative. Preemptive monitoring with CMV viral loads is less frequently used, but may be acceptable according to center-specific practice
Candidiasis	Center-specific approach, but most centers use prophylaxis with fluconazole 100 mg once a week or nystatin swish/swallow for the first 2–3 months after transplant
Tuberculosis	In endemic areas, all patients receive prophylaxis with INH for 6–12 months after transplant. This can be continued at the discretion of the treating physician
Mycobacterium avium	Azithromycin is initiated when the CD4 counts drop below 75 cells/mm^3 In the general public, if ART is going to be started in a patient with a low CD4 count, clinicians often choose to withhold MAC prophylaxis. In the light of this, a transplant patient with a CD4 count below 50, but with adequate virological control might not need MAC prophylactic therapy
Coccidioidomycosis	Fluconazole is used in endemic areas for 6 months after transplant

Vaccinations Prior to Transplant

Akin to solid organ transplant in HIV negative populations, care should be taken to protect patients before transplant, in line with vaccination recommendations for HIV positive adults. Pneumococcal Polysaccharide Vaccine (PPSV) and Pneumococcal Conjugate Vaccine (PCV) should be given to all patients on the waiting list pre-transplant. Hepatitis A and B immunity should be checked, and if a patient is not immunized, this vaccine should be given before the transplant when the immune response is more robust, and seroconversion more likely. Influenza vaccine should be given once yearly. Recombinant herpes zoster vaccination (Shingrix vaccine) is usually given pre-transplant in selected high-risk patient groups, especially patients over 50 years old. Emerging data suggests it is safe and effective post-transplant also, although not specific to the HIV-infected recipient [30]. Human papillomavirus (HPV) vaccine should be given in selected patients, usually under the age of 45 years. All patients have to be up to date with tetanus, diphtheria, pertussis (Tdap), as well as measles, mumps, and rubella (MMR) vaccinations before transplantation.

Vaccinations Post-transplant

Annual influenza vaccination is recommended post-transplant in all patients. It is usually not recommended to use any live virus vaccine post-transplant. Therefore MMR should not be given post-transplant. It is recommended to wait 3–6 months after transplant before giving vaccines, appreciating theoretical concerns around allostimulation being triggered toward the graft. When a COVID-19 vaccine becomes available, this should be given as well. If a patient received treatment for rejection, vaccination should be avoided for 6 months after this.

Conclusion

Transplantation should be offered to patients living with HIV. Most experience exists in kidney transplant**;** however, liver, heart, lungs, and pancreas may also be safely used. Higher rates of rejection have been observed following liver and kidney transplants in the HIV positive recipient. The drug–drug interactions between immunosuppressive agents and some of the antiretroviral agents have resulted in reduced exposure to the immunosuppressive agents. These interactions can be minimized by switching potential recipients to integrase inhibitor-based regimens before transplant if deemed safe by an HIV provider. Further studies are necessary to determine the additional contribution of the dysregulated immune system to the high rejection rates that have been observed in the HIV positive recipient.

Recurrence of HIV nephropathy was not problematic in the US series, but reports of recurrent disease in France have prompted a re-examination of tissue from biopsies from the US multicenter NIH and Cape Town series. Progression of HIV to AIDS has not been an issue, provided patients remained on a stable antiretroviral

regimen. Prophylaxis against opportunistic infections during the early post-transplant period is essential. Oncogenic viruses mediating cancer development (e.g., Kaposi sarcoma, lymphoma) remain problematic, and HIV positive transplant recipients should undergo screening cervical and anal PAP smears regularly after transplantation. Some anti-retroviral regimens (CCR5 blockade) block the immune response, and some immunosuppressive agents (TOR inhibitors) have an antiretroviral effect and decrease the HIV viral reservoir. Both of these serendipitous findings are being studied in prospective trials in the USA.

Key Points

- HIV positive patients have graft and survival outcome results compatible with HIV negative patients after transplantation.
- Using HIV positive donors have increased the amount of available organs to the HIV positive patient group.
- Rejection rates in HIV positive patients remain higher than in HIV negative patients. Reasons for this include drug interactions as well as inherent immunological differences between HIV positive and negative patients.

Introduction

Though the majority of deaths related to viral hepatitis are attributable to hepatitis B and hepatitis C, hepatitis A (HAV) continues to contribute to a large burden of morbidity. Tens of millions come in contact with HAV annually [1]. In the past it has been one of the most frequently notified vaccine preventable diseases in the USA [2]. In 2016, the Centers for Disease Control and Prevention (CDC) was notified of 2007 cases of acute HAV in the USA, likely to represent only a portion of new cases, with actual estimates likely to be over twice the number of reported cases in any year. In that same year, over 70 death certificates listed HAV as the cause of death [3]. Despite this, most recent publications regarding viral hepatitis focus on hepatitis

B (HBV) and hepatitis C (HCV) and those coinfected with human immunodeficiency virus (HIV), as endorsed by World Health Organization member states and Sustainable Development Goals [4].

In areas of higher endemicity, improving health and hygiene (environment, water supply, and food sanitation) led to a decline in infection in children, resulting in a population of more susceptible teenagers, young, and even older adults at risk of contracting disease [5–7].

This vulnerable population is also increasingly receiving immunosuppressive therapies for various reasons, including solid organ and hematological transplants, making them prone to infections. This, when combined with improved post-transplant morbidity, mortality, quality of life, and increasingly available travel to countries further afield, is a risk for HAV infection. Indeed, immunocompromised travelers are tending to travel to similar destinations and for durations comparable to immunocompetent travelers, highlighting the importance of pretravel care and education to this group [8–11].

While studies on HAV and vaccination have been performed in the immunocompromised host, most data is from those who are healthy. Studies are small, heterogeneous, and variable in results. More robust data from those who are undergoing, or have received a transplant, is needed.

Epidemiology

In countries of high endemicity, seroprevalence rapidly rises in young children, who often have asymptomatic disease [6]. This leads to a difficulty in disease surveillance. As the incidence of HAV decreases in a country, the average age of infection increases [1]. Therefore, as symptomatic disease is more common with older age, there is an increase in case detection despite a decreased overall incidence [12].

Around the world, the prevalence of HAV infection varies and is related to income. Lower-income countries such as Africa and South Asia have higher seroprevalence, while higher-income countries, such as Western Europe, Australia, New Zealand, Canada, the USA, Japan, Korea, and Singapore, have lower rates [6].

Disease continues to occur in the areas of lower endemicity as a result of outbreaks and high-risk groups. Globalization of trade and travel remain important drivers of epidemiological change in HAV infection. Travel to an area of high or intermediate endemicity remains a significant risk for HAV infection. Case reporting from 13 European countries from 2009 to 2015 showed that 28% of cases were associated with travel, and of these 40% were in children less than 15 years of age [13]. The risk of infection is approximately 300 per 100,000 travelers per month in tourist areas in developing countries, and it is five to seven times higher for those traveling off the usual tourist routes [14].

In addition to travel-related risk, other factors for acquiring HAV include close contact with someone known to have the infection, men who have sex with men, and practices associated with intravenous drug use. Exposure to contaminated food and water can lead to common-source outbreaks (See Table 1). Occupational risk

Table 1 Categories of persons with increased risk for hepatitis A virus (HAV) infection or increased risk for complications in the event of exposure to HAV

Type of risk	Risk category	Examples
Increased risk for HAV infection	Close contacts of persons with HAV infection[a]	Household contacts Caretakers Sexual contacts Persons working with nonhuman primates Persons working HAV in a research laboratory
Increased risk for HAV-associated complications	Immunocompromised persons	Congenital or acquired immunodeficiency HIV infection Chronic renal failure/undergoing dialysis Solid organ, bone marrow, or stem cell transplant recipients Persons with diseases requiring treatment with immunosuppressive drugs/biologics (e.g., tumor necrosis alpha inhibitors), long-term systemic steroids, radiation therapy
	Chronic liver disease	Hepatitis B infection Hepatitis C infection Cirrhosis (any etiology) Fatty liver disease (hepatic steatosis) Alcoholic liver disease Autoimmune hepatitis Alanine aminotransferase (ALT) or aspartate amino transferase (AST) level more than twice the upper limit of normal or persistently elevated for 6 months

From Nelson et al. [15]
Abbreviation: HIV = human immunodeficiency virus
[a]Excludes health care personnel using appropriate personal protective equipment

includes those working in research laboratories studying HAV, including those using nonhuman primates [15]. Despite this, the majority of cases have no known or identifiable risk [16].

Sources of foodborne infection and outbreaks include contaminated produce such as fresh fruits and vegetables and shellfish or contamination by food-handlers, at the point of sale, restaurants or social events. Distinguishing a foodborne outbreak can be difficult due to the long incubation time and variability in clinical presentation and location. Some outbreaks have been linked to local and imported foods such as sundried tomatoes, pomegranate arils, frozen strawberries, iceberg lettuce, green onions, sandwiches, bakery goods, oysters, and clams [17–25].

Unfortunately, there is no data on the national rates of HAV infection in transplanted or immunocompromised hosts, particularly in those who travel or may be at risk for other reasons. Reported data is limited to case reports. Despite incremental changes in HAV vaccination recommendations 1996–2006 by the Advisory Committee on Immunization Practices (ACIP) to increase coverage for children and persons at high risk for HAV infection, since early 2017, the CDC has observed an

increase in the number of community-wide HAV outbreaks in multiple states [26] indicating ongoing risk for in the pre- and posttransplant setting but also for potential donor-derived infection.

Structure

Hepatitis A is a 27-nm, single-stranded, non-enveloped RNA virus that is the only member of the genus *Hepatovirus* in the family *Picornaviridae* [27]. Of the seven known genotypes, types I and III are most commonly involved in human infection [27]. Despite genetic heterogeneity of nucleotide sequences, there is only one known serotype [28].

Like other members of the *Picornaviridae* family, the positive sense, linear virus of 7478 nucleotides has a long 5′ untranslated region (UTR) lacking a cap structure, with an additional small covalently bound protein termed VPg.

A polyprotein coding region of 2227 amino acid residues (P1 region) codes for the primary structural proteins in the virion, consisting of, from the N terminus, 3 major viral capsid proteins – VP0, VP3, and VP1-2A (Px). This section of the RNA is followed by a region that translates into nonstructural proteins in the open reading frame (ORF) and finally a short 3′ UTR with a virus-coded poly(A) tail [29, 30]. These nonstructural proteins, P2 and P3, are thought to be involved in RNA synthesis and are termed replicative proteins, with the latter containing a viral protease, 3C, which cleaves the capsid proteins from the precursor polyprotein [27].

The capsid proteins VP0, VP3, and VP1-2A form monomers that combine into pentamers. A provirion is formed when 12 pentamers associate with viral RNA. VP4 is derived from cleavage of VP0 and is essential for capsid maturation from provirion to virion, but is not found in the mature virion [31] (see Fig. 1).

Transmission

Transmission of HAV is predominantly via fecal-oral spread. Presumed enterohepatic circulation after ingestion of virions leads to replication in the hepatocytes with secretion of infectious virions into the bile and subsequently stool. Replication is thought to be limited to hepatocytes and epithelial cells of the gastrointestinal tract, but cell culture has been performed in other cell lines in a laboratory setting [27]. Release of a quasi-enveloped virions [32] from the basolateral surface of hepatocytes leads to contact with dendritic cells, eliciting type I interferon(IFN) release and adaptive cellular responses [33].

Transmission has also been documented via exposure to infectious blood and tissue. Because the presentation of clinical signs and development of IgM lag behind viremia in HAV, donor-transmitted infection may not be detected by routine screening tests. There are documented transfusion-transmitted HAV infections with red

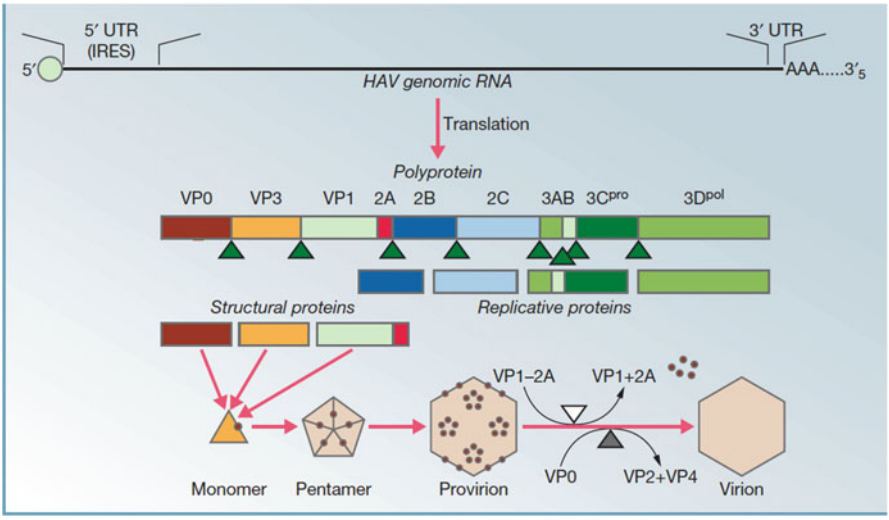

Fig. 1 Organization of the RNA genome of hepatitis A virus (HAV), polyprotein cleavage, and viral assembly. The 7.5-kb positive-strand RNA is covalently attached to VPg (5′ end) and has a poly(A) tail. The 5′ untranslated region (UTR) of 734 nucleotides functions as an internal ribosome entry site (IRES) to initiate translation (*vertical arrow*) of the precursor polyprotein of 2227 amino acids. The single viral protease, $3C^{pro}$, cleaves itself from the polyprotein and subsequently cleaves elsewhere in the polyprotein to yield the structural protein precursors VP0, VP3, and VP1–2A (PX) and replicative proteins 2B, 2 C, 3A, 3B (VPg), and 3D (RNA-dependent RNA polymerase). VP0, VP3, and VP1–2A probably remain associated as a monomer and then form pentamers that are a stable precursor in capsid formation. Assembly of 12 pentamers together with RNA forms the provirion, after which 2A is susceptible to cleavage by host cell protease(s) *(open arrowhead)*. The final maturation cleavage of VP0 to VP2 and VP4 *(solid arrowhead)* is dependent on the encapsidated viral RNA. (Figure 176-3 from Averhoff et al. [179])

blood cells [34, 35], platelets [35], fresh frozen plasma [36], and blood factor donations [37]. HAV has also been transmitted from a whole blood donation and platelets despite the presence of HAV-IgG in the recipient [38, 39]. This highlights the importance of education in donors to ensure notification of later development of clinical symptoms following blood product donation, to allow tracing of recipients potentially exposed.

Various techniques have been utilized to reduce the infectivity of HAV in blood and factor products, particularly factor IX. These include precipitation, diethylaminoethyl cellulose (DEAE-C) absorption and elution, heparin affinity chromatography, and nanofiltration [40]. The virucidal method of solvent detergent fails to effectively inactivate non-enveloped viruses [41] and was the reason for transmission of disease in hemophiliacs [42, 43].

Donor-derived HAV infection has also occurred in both solid organ and stem cell transplantation. There has been one documented case of HAV infection in a 7-year-old recipient of a combined liver-small intestine-pancreas transplant [44]. Interestingly, the recipient was documented to be seropositive prior to transplantation from

prior vaccination. Serum and fecal HAV-RNA was detected at 10 months post-transplantation, but earlier admissions showing elevated ALT results and concerns for acute rejection indicated a likely protracted course of disease. Donor-transmitted infection was confirmed by genetically identical HAV-RNA sequences. The recipients of the donor heart and kidneys were also seropositive prior to transplantation but did not develop infection.

Despite best efforts to minimize transmission, a stem cell transplantation (HSCT) has also been shown to result in HAV infection in the recipient [45]. Due to limited options, an HLA-matched allogeneic HSCT proceeded, despite the donor presenting with acute HAV infection, confirmed by the presence of HAV-RNA. The transplant was delayed for 4 days while the donor biochemical liver tests improved, and the recipient received high-dose intravenous immunoglobulin (IVIG) which was continued on a weekly basis for 2 months posttransplant. Despite the recipient having a transient increase in bilirubin and ALT in the first 2 weeks posttransplant, attributed to the conditioning regime, there were never any signs of symptomatic hepatitis. Detectable HAV virus was found in stools, but not blood, as measured by reverse transcriptase polymerase chain reaction (RT-PCR) at day 32 and was correlated with a transient increase in ALT day 35 to 55. From 15 to 90 days posttransplant, there was detectable HAV-IgG and IgM, of which the latter could not be attributed to IVIG administration. It was postulated that the IgM may have been produced by donor B lymphocytes, therefore suggesting that the transplanted immune system may retain the ability to produce antibodies despite immunosuppression in the early post-transplant period.

Diagnosis

The diagnosis of HAV is made by the detection of infection, by either the presence of HAV-IgM (indicative of recent exposure) or the presence of HAV-RNA. It is not possible to distinguish HAV infection from other types of viral hepatitis on the basis of clinical and epidemiological features alone and therefore requires confirmatory laboratory testing.

Historically, direct examination of the virus occurred through electron microscopy, a difficult and somewhat insensitive technique. Currently, HAV viral antigen may be detected in stools using enzyme-linked immunosorbent assays (ELISA). Detection of antigen in blood using immunoassays is difficult due to fibronectin binding and masking of antigenic determinants [46].

Serological testing remains the mainstay of diagnosis and is very sensitive in the context of clinical cases of acute hepatitis or those recently exposed. Both HAV-IgM and HAV-IgG against capsid proteins are typically present at the onset of symptoms which occurs after a 4-week incubation. IgM, the primary marker for acute infection, typically wanes about 4–6 months postexposure [47]. Numerous commercially available tests rely on either manual or automated enzyme immunoassay platform result. In the absence of a positive IgM result, HAV-IgG corresponds with past infection or seroconversion following vaccination. Some commercially available

assays do not distinguish between IgG and IgM and rely on total HAV antibody levels. A positive result in this circumstance may represent current or prior infection or an immunization response [48].

The arbitrary cutoff for seroconversion or development of immunity has been determined to be HAV-IgG levels of ≥20 IU/mL as determined by ELISA. More recent studies have used a higher cutoff of ≥33 IU/mL, thought to be similar to peak titers of antibodies achieved with a passive immunization strategy utilizing immune globulin (IG) [49, 50]. However, there may be some differences in the affinity of the antibodies between passive and active strategies [51] which may result in differences in resultant immune response. Immunogenicity is measured by the elicited seroconversion rate and geometric mean concentrations (GMC), representing the mean antibody concentration of the group being studied. GMC of antibody to HAV antigen can measured at intervals postvaccine administration and are typically utilized in a research setting [52]. The lower limit of antibody requirement to prevent disease is unknown [53].

Nucleic acid detection is most widely performed by reverse transcriptase polymerase chain reaction (RT-PCR) and may be detectable in blood prior to the presence of HAV-IgM in the so-called window period. It is the most sensitive detection technique and can be both qualitative and quantitative. Nucleic acid detection by other techniques have been utilized, such as restriction fragment length polymorphisms, single-strand conformational polymorphism, southern blotting, nucleic acid sequencing-based amplification, and hybridization and antigen capture RT-PCR [48]. RT-PCR can also detect species-specific viral strains implicated in parenteral transmission of virus [54].

Multiplex RT-PCR platforms provide efficient ways to detect multiple potential causative viral organisms with common simultaneous detection of HAV, hepatitis E (HEV), rotavirus, and poliovirus [48].

Liver biopsies performed in the context of acute HAV show the cardinal features of hepatocellular degeneration, characterized as either ballooning or acidophilic (apoptotic) change, with various degrees of portal and lobular inflammation and hepatocyte regeneration [27].

To date, there are no studies that determine the sensitivity and specificity of any of these diagnostic modalities in the posttransplant setting.

Clinical Presentation

In healthy hosts, typically less than 10–15% of children under the age of 6 years are symptomatic with infection [55, 56], while in adults clinical disease is more common, with symptoms present in over 75% and jaundice in 40–70% [57, 58]. In the immunocompetent, infection is generally self-limiting and does not result in chronic liver disease. As there is only one known serotype, immunity is lifelong following initial infection [28].

Those with symptomatic infection may experience jaundice, nausea, vomiting, diarrhea, anorexia, or abdominal pain accompanied by elevation of the

aminotransferase liver enzymes. Non-hepatic complications are uncommon but include nephrotic syndrome, glomerulonephritis, vasculitis, pancreatitis, Guillain-Barre syndrome, thrombocytopenia, and aplastic anemia [59]. Evanescent rashes, transient arthralgias, and rare cryoglobulinemia complications (cutaneous vasculitis and arthritis) have been documented [60]. Extrahepatic manifestations were seen in around 8% of cases in a US outbreak [61]. Complications more typically occur in those who are older [57] and comorbid, particularly those with chronic liver disease [61–63].

Although the virions replicate in hepatocytes, liver damage is thought to be a consequence of host cytotoxic-T cell response, rather than direct virion cytotoxicity [64, 65]. There have been contrasting studies supporting or refuting the fact that liver damage is related to the degree of viremia [66, 67]. The ambiguity of abnormal liver tests can complicate the diagnosis in the posttransplant setting, as there is often a myriad of reasons for liver abnormalities including organ rejection, graft versus host disease, sinusoidal obstruction syndrome, hepatotoxicity from drugs, and other infections. Despite immunosuppression of T cell responses, there is no current evidence to support reduced severity of liver damage in transplant recipients.

The incubation period from exposure until development of symptomatic infection is thought to be around 28 days (range 15–50 days) [68]. In experimentally infected healthy male subjects, the average duration of viremia prior to peak ALT as determined by PCR was 17 days. Viremia persisted on average for 79 days after this with an average total duration of 95 days [69]. In those with clinical infection, viremia as determined by real-time RT-PCR was found to persist for at least 60 days, with viral load declining with time [70]. Some studies have suggested that peak viremia corresponds with the peak biochemical abnormalities, although this does not necessarily correspond with peak HAV-IgM or IgG [71]. In patients with acute HAV, viral shedding in the stool continues for a median period of 81 days (range 57 to 127) after disease onset [66]. Viral loads are highest in the stool prior to the onset of symptoms [72] (see Fig. 2).

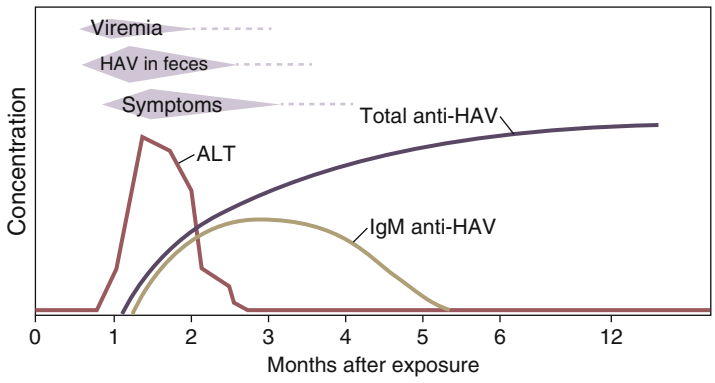

Fig. 2 Clinical, virological, and serological events after hepatitis A virus (HAV) infection. *ALT* alanine aminotransferase, *Ig* immunoglobulin. (Figure 176-5 from Averhoff et al. [179])

It is unclear if those who are immunosuppressed in the transplant setting are viremic, or infectious, for longer durations than immunocompetent hosts. Certainly, those with HIV infection are viremic for a longer period, persisting beyond biochemical and clinical resolution of hepatitis [73]. Children are also known to shed virus for longer periods than adults, at time for periods up to 10 weeks [74]. An infant infected in a nosocomial setting was found to continue to shed virus up to 6 months postinfection [34]. In the transplant setting, there have been two case reports of persistent elevation of HAV-IgM for over 30 months posttransplant and persistent HAV-RNA detection in the stool. Unusually, in both described cases, chronic hepatitis was seen on liver biopsy in the absence of any other hepatitic viral etiology [75, 76]. The lack of cell-mediated immunity, which is important in viral clearance, may contribute to persistence in these scenarios.

A small proportion of patients may develop a relapsing or biphasic course. This biphasic response has been described in infants and the elderly [77, 78]. Typically, these patients initially improve both clinically and biochemically before having a relapse, either with or without symptoms, within 6 months of the initial infection. Incidence of biphasic response varies in reported literature from 3.3% to 20% [79]. Up to 25% of children admitted to hospital may have relapsing disease [80].

Several studies have found that there is a higher case fatality rate in those with underlying chronic liver disease. In a Shanghai outbreak in 1988 of over 310,000 cases, several US outbreaks, and smaller case series, HAV infection in those with chronic HBV was associated with higher peak laboratory abnormalities, more severe disease including fulminant failure, and a higher case fatality rate [81–84]. Fulminant disease is defined by the sudden onset of hepatic encephalopathy of any grade, coagulopathy with international normalized ratio (INR) $\geq$1.5, and jaundice with bilirubin $>$50 μmol/L [38].

One series prospectively followed patients with chronic hepatitis and found that HAV superinfection resulted in increased risk of fulminant disease in patients with pre-existing HCV, compared to those with HBV [63]. Potential reasons for this include coinfection with hepatitis G virus, autoantibodies, or HLA phenotypes.

While increasing age and hepatitis status are associated with worse disease, there is no clear evidence that this is true for immunocompromised hosts [85]. However, in a 2013 outbreak in the USA, a pre-existing chronic medical condition (including pharmacological immunosuppression) was associated with an increased risk of hospitalization [18].

Management of cases is supportive, with a significant role in prevention or spread in the local community. Some early studies have looked at the possibility of the direct acting antiviral (DAA) sofosbuvir being used to prevent relapsing disease posttransplant, but this needs further assessment in both animal and human models [86].

Overall quoted mortality rates vary with the population studied. Historical data from the US states the rate of death associated with HAV is 0.1–0.6% [87, 88]. The most recent data published by the CDC states mortality increases with age, and in those under 40, it is $<$0.01 per 100,000 people, increasing to 0.08 in those over 75 years of age [16]. In a review of the Shanghai outbreak, which predominantly

involved children and young adults, the death rate was 0.015% [89]. In those admitted to hospital in US outbreak in Tennessee, serious illness and death were more common in those over 40 years of age, with a death rate of 5.7%, though the young were not without complicated illness with a mortality rate of 1% [61].

Transplant for HAV

In an attempt to determine risk factors for deterioration and need for referral for transplantation in a pediatric cohort, a single center in France reviewed 24 children admitted with liver failure associated with HAV over the 15-year period from 1980 to 1995. Of these, 11 children either died or had transplantation. Of the nine children who received transplant, two died on the postoperative day with complications of grade 4 encephalopathy, cerebral edema, and subsequent irreversible brain damage. The best predictor of a poor outcome in those with encephalopathy was a prothrombin time 21% below normal and a serum bilirubin >400 μmol/L [80]. Two further cases died within 2 years of transplant with complications of sepsis and chronic rejection.

Prognostic tools can be used to identify the risk of patients requiring consideration for transplantation. The ALFA score is a risk prediction model for death or transplantation associated with HAV-related acute liver failure. It was developed based on the study of a Korean cohort of 294 patients and validated on further patients from Japan, India, and the UK. It utilizes age, INR, bilirubin, ammonia, creatinine, and hemoglobin levels on the day of diagnosis of acute liver failure [90]. The US Acute Liver Failure (US ALF) Study Group reviewed 29 patients enrolled with HAV, a total of 5.6% of total registered. Of those, 55% spontaneously recovered, 31% underwent transplantation, and 14% died. Based on this data, a prognostic index specific for HAV, the HAV-ALFSG, was determined to predict death or transplantation based on four factors on the day that acute fulminant hepatitis is determined – creatinine ≥2.0 mg/dl, ALT ≤2600 IU/L, intubation status, and need for pressor support [91]. Other ALF risk prediction models used include the Kings College Criteria (KCC) for non-paracetamol-related acute liver failure, new ALFSG index, Model for End stage Liver Disease (MELD), and the MELD including sodium (MELD-Na) [92–94]. However, these are not specific for HAV.

Outcomes of transplant for acute liver failure are generally poorer compared with those for chronic liver disease [95, 96]. According to the US ALF Group Registry, HAV-related acute liver failure represents around 3% of cases [97]. Rates of spontaneous recovery range from 25 to 70% [91, 92, 98, 99]. It is suggested that outcomes in those who receive liver transplants for acute liver failure associated with HAV are worse than for those who receive them for HBV. In a single-center review from Korea, 5.6% of patients received liver transplants for acute liver failure. Of these, 14.2% were for HAV, while 16.7% were for HBV [32]. Graft survival was 65.5% for HAV at both 1 and 5 years posttransplant, compared to 88% and 84% for HBV (1 and 5 years posttransplant, respectively). Multivariate analysis showed that

acute pancreatitis and relapse of HAV were independent risk factors for graft failure [100].

Extrahepatic virions, presumed enteric, are suspected to be involved in recurrent HAV infection after liver transplantation. Both protracted and relapsing courses have been identified with detection of either HAV antigens, HAV-RNA, or HAV-specific genomic sequences in graft, serum, or stools, with variable clinical presentation [101–103]. One case even resulted in re-transplantation [104]. Subclinical presentations may suggest recurrent HAV infection following liver transplant is an under-recognized phenomenon, especially when liver test abnormalities are common posttransplant and have a wide variety of causes. The secondary effect of post-transplant immune suppression in limiting the host response to viral infection warrants further investigation.

Prevention

The major goal after both solid organ and stem cell transplants is the resumption of a normal and healthy life, as far as this is possible. Therefore, prevention of any infection, particularly during ongoing maintenance immunosuppression or an immature immune system, is critical. Overall, this involves planning, preparation, and education which commences as early as possible prior to transplantation. The backbone of prevention remains immunization.

In some circumstances immunization must be administered posttransplant, such as emergency solid organ transplant for acute organ failure, or HSCT, which involves the engraftment of a naïve immune system, potentially lacking humoral and cellular immunity. Unexpected travel requirements, or exposure to HAV in an outbreak setting, may also involve unanticipated active immunization or passive immune globulin to prevent disease in the posttransplant setting.

Many regions with active transplant programs tend to have low endemicity of HAV, and later-life infections are usually as a result of outbreaks. In this context, while immunization is the mainstay of HAV prevention, other preventative strategies that target the mechanisms of outbreak should be considered.

Food Precautions

As part of healthy living posttransplant, all recipients should be aware of recommendations for hand hygiene and food preparation to avoid ingestion of HAV virions, as disease occurs predominantly via fecal-oral spread. The recommendations for reducing the risk of HAV infection in the immunocompromised patient are the same as for the immunocompetent individual. Unfortunately, the HAV virion is hardy and survives in the environment for prolonged periods. Virions can survive drying and storage at 25 °C at 42% relative humidity for up to 30 days and still cause infection [105]. Surfaces may be disinfected with a 1:100 dilution of sodium hypochlorite (i.e., household bleach) in tap water [53].

Raw or improperly cooked shellfish cause outbreaks as the virus is not killed unless food is heated to at least 185 °F (85 °C) for 1–2 minutes. This thorough cooking of shellfish is longer than current practices of steaming until the shells open, leaving limited avenues for decontamination [106]. Transplant patients are advised to avoid all raw or undercooked shellfish (oysters, clams, mussels) [107].

For produce, contamination may occur at any step – during cultivation, processing, storage, distribution, or final preparation. Methods to disinfect produce include use of chlorinated water, hydrostatic pressure, and heat [106]. Freezing has little impact on reducing the viability of HAV contamination, particularly seen in frozen produce such as berries and herbs [108]. Rinsing in cold or warm water has little impact on removing enteric viruses from food and chlorine, a common sanitizing agent for produce that has a variable effect on infective risk. Knowledge of uncooked shellfish and produce as source of outbreaks must be included in education posttransplant. However, avoidance of all potential food-based sources of HAV is not possible while maintaining a healthy diet. As a result, immunization remains the key preventative strategy.

Immunization

The backbone of prevention of infection with HAV is vaccination with utilization both before and after exposure to the virus. Inactivated HAV vaccines were first licensed in the USA in 1995 for preexposure prophylaxis. In immunocompetent hosts, seroconversion rates 1 month after a single dose of vaccine are 95.7% rising to 99.8% after a further dose [109]. In 2005 the USA, the Food and Drug Administration (FDA) approved the vaccine in children from age 12–23 months. Initially, HAV vaccines were administered according to a three-dose schedule; however, all vaccines are now given according to a two-dose schedule [110]. Around the world, different countries have adopted varying strategies for vaccination regarding HAV – this approach may be either for universal coverage or based on prevalence or risk stratification [111].

Current vaccine series with doses and intervals that are available on the US market are listed (see Table 2).

In the USA, the ACIP recommends universal vaccination against HAV for children [112]. HAV vaccination has been found to be safe and immunogenic in infants and children from 6 to 21 months independent of the mother's serostatus [113, 114]. Passively transferred maternal antibody persists for at least 6 months and results in a blunted response to HAV vaccination [113], but despite this, infants under 6 months appear to be primed with vaccine despite interference [115, 116]. It is incorporated into the routine schedule, starting from 12 months of age, with either the two-dose series of HAV vaccine or the three-dose series with the combined HAV-HBV vaccine [112].

In adults, vaccination via the same two-dose series is recommended on the basis of risk. This includes persons with chronic liver disease or clotting factor disorders, travelers in countries with high or intermediate endemic HAV, those in close personal

Table 2 Vaccines used to prevent hepatitis A virus (HAV) infection

Vaccine	Trade name (manufacturer)	Age group (years)	Dosage	Route	Schedule	Booster
Hepatitis A vaccine, inactivated	Havrix (GlaxoSmithKline)	1–18	0.5 mL (720 ELU)	IM	0, 6–12 Mos	None
		≥ 19	1 mL (1440 ELU)	IM	0, 6–12 Mos	None
Hepatitis A vaccine, inactivated	VAQTA (Merck and co.)	1–18	0.5 mL (25 U)	IM	0, 6–12 Mos	None
		≥19	1 mL (50 U)	IM	0, 6–12 Mos	None
Combined hepatitis A and B vaccine[a]	Twinrix (GlaxoSmithKline)	≥18 (primary)	1 mL (720 ELU HAV +20 μg HBsAg)	IM	0, 6–12 Mos	None
		≥18 (accelerated)	1 mL (720 ELU HAV +20 μg HBsAg)	IM	0, 7, 21–30 days	12 Mos

From Nelson et al. [15]
Abbreviations: *ELU* ELISA units of inactivated HAV, *HBsAg* hepatitis B surface antigen, *IM* intramuscular, *U* units of HAV antigen
[a]Combined hepatitis A and B vaccine (Twinrix) should not be used for postexposure prophylaxis

contact with an international adoptee in the first 60 days after arrival from a country with high or intermediate endemic HAV, men who have sex with men, homeless persons, persons who use injection or non-injection drugs, and persons who work with HAV in a laboratory or with nonhuman primates infected with the virus. In addition, any person who is not at risk for HAV infection but wants protection against it may be vaccinated [117].

While many studies have given additional doses compared to the recommended schedule, in healthy recipients, booster doses are not thought to be required after a standard two-dose series [110]. A persistent amnestic response lasts up to 12 years postvaccination course [118] with modeling suggesting that antibody levels persist for more than 20 years in immunocompetent adults [119–121]. Similar modeling predicts persistence for an average of 14–20 years for children [122, 123]. Due to the arbitrary threshold for seropositivity, it is unclear if immunity is "lost" despite antibody decline over time and what additional role cellular immunity has in this situation [124]. HAV-proliferative T cell responses have been found to persist for many years postvaccination [125]. There is no difference in recommendations for vaccine dosing for immunocompetent and immunocompromised individuals.

Immunocompromised Hosts

Much of the information regarding HAV vaccination in immunocompromised hosts is based on studies concerning individuals with HIV infection where there is both an impaired response and duration of protection [126]. Much lower rates of HAV

vaccine responsiveness and persistence of antibody response occurred in HIV-positive hemophiliacs compared to those without the infection, with even poorer results in those with evidence of HIV progression [127–129].

In a small systematic review of studies on HAV in immunocompromised hosts, factors that were related to a poorer response to vaccination included the number of immunosuppressive drugs and not completing a vaccine schedule. Those who received the vaccine course with doses only 1 month apart also had poorer responses than those who had 3–6 months between doses [126].

Responses to HAV vaccines were reviewed retrospectively in a heterogeneous group of 85 immunocompromised hosts which included predominantly those on immunosuppressive drugs (n = 65) but also a small cohort post-SCT (n = 13) or with HIV infection who were not on immunosuppression (n = 7). It was found that 76.5% developed HAV-IgG after either one or two vaccine doses. Of the cohort, ten patients had received solid organ transplants and their response rate was 60%. Those on tumor necrosis factor-α (TNF-α) blockers (predominantly those with underlying rheumatic disorders) had better responses, and females were more adherent with postvaccine titer measurements [126].

In HIV patients with hemophilia, use of the standard adult titer vaccine (1440 ELISA units per dose) failed to elicit a vaccine response in those who had already failed to respond following three doses of the lower titer vaccine (720 ELISA units per dose) though numbers were very small [130]. It is unclear the role of booster vaccine in those who fail to respond and knowledge of serostatus postvaccination is important as it highlights a need for those who need protection via passive strategies.

Recommendations of the Infectious Diseases Society of America (IDSA) are that inactivated vaccines should be administered more than 2 weeks prior to immunosuppression [131]. Anticipated immunosuppression should be an indication for HAV vaccination in those at risk.

Pretransplant

Solid Organ Transplant

The American Society of Transplantation (AST) guidelines recommend that both children and adults should undergo a HAV vaccination schedule, ideally completed prior to transplantation [132]. Vaccine titer monitoring is recommended if ongoing risk for exposure, such as planned travel to high-risk areas [132]. Combined HAV-HBV vaccination can be used for solid organ transplant (SOT) candidates aged ≥12 years of age in whom both vaccines are indicated [131]. While it is recommended that children undergo the usual vaccine schedule appropriate for age prior to transplantation, often chronic ill health can impact this, making this population more at risk of vaccine preventable illnesses [133].

HAV vaccine has been extensively studied in candidates with underlying chronic liver disease, particularly those pending liver transplants. It is well tolerated in this population, including those with HBV, HCV, and non-viral etiologies [134]. Though seroconversion after a single HAV vaccine was higher in the healthy adult subgroup, seroconversion rates after two doses, 6 months apart, were comparable in those with

chronic HBV [135]. Safety and immunogenicity have also been determined in a cohort of children who were chronic HBV carriers with rates of seroconversion of 90.0%, 96.9%, and 100%, respectively, after the first, second, and third dose, suggesting a better response than adult counterparts [136], though GMC tended to be lower compared to healthy controls [137].

In those with decompensated liver disease, the antibody response is poorer when compared to the previous group, but better than those who are vaccinated post-transplant. Recommendations therefore support vaccinating as early as possible during the pretransplant course. This is supported by the immunogenicity of the standard vaccine schedule in those with compensated compared with decompensated cirrhosis (Child-Pugh class B/C), with seroconversion rates of compensated patients of 98% compared with 65.7% of those with decompensated disease, 1 month after final dose [138]. In addition, for those on the liver transplant waiting list, the lower the United Network for Organ Sharing (UNOS) score, which is related to the MELD score, the higher the chance of seroconversion with vaccination. However, overall rates were poor with only 48.6% seroconverting [139]. Another small study found that vaccination responses of 24 patients with severe chronic liver disease were compared to those of 8 liver transplant patients vaccinated posttransplant. Using a threshold of $\geq$33mIU/mL for HAV-IgG response, 50% of those with severe liver disease seroconverted (median titer of 34.7mIU/mL), while no liver transplant patients achieved this threshold (median titer of 0.0mIU/mL) [140].

Despite recommendations for vaccinations in those with chronic liver disease, vaccine uptake remains poor [141]. Of a cohort who proceeded to liver transplant, only 45% demonstrated HAV seroconversion when tested after transplantation. Only 26% were vaccinated according to a complete vaccination dose schedule, and these patients had a vaccine response for HAV of 50%. An additional 31% received a single dose of vaccine for HAV-HBV, but not a complete course and unsurprisingly the response rate was much lower among these patients, stressing the importance of completing the vaccination schedule. As supported by prior data, patients seemed to be more likely to respond to a vaccination if they had a lower Child-Pugh score at time of vaccination, further highlighting that patients should be vaccinated as early as possible in the course of their liver disease [142].

Recently, a high-dose accelerated vaccination schedule in those with cirrhosis pretransplant has been found to be effective with a single dose of Havrix 1440 μg repeated after 1 and 2 months and an additional booster for those failing to seroconvert [143]. This has found to be 94.3% effective compared with only 79.5% with the standard schedule of combined HAV-HBV or HAV vaccine.

Stem Cell Transplant

Routine pretransplant testing for HAV in HSCT recipients or donors with normal liver function testing is not necessary as HAV-IgG presence in the absence of IgM has no impact on transplant outcome [144]. One guideline states that there are higher rates of sinusoidal obstruction syndrome (SOS) post-HSCT in recipients who present with HAV-IgM and subsequently undergo myeloablative conditioning. This indicates that if a recipient presents with acute hepatitis prior to transplant, this should be

tested and transplant delayed, though this seems to be based more on expert opinion rather than primary data [144].

Pre-donation vaccination benefit is limited to T cell-dependent vaccines, and a durable humoral and cell-mediated immune response is not seen in the recipients. Overall risk-benefit ratios do not therefore support the use of pretransplant vaccination in clinical practice currently [145, 146]. There are no HAV-specific studies looking at this, and therefore, pre-donation HAV vaccination is not recommended as any potential benefit is unknown [147].

Posttransplant

Solid Organ Transplant

If HAV vaccination did not occur prior to transplant in at-risk recipients, it should be completed posttransplant. This includes all liver and renal transplant patients who have underlying HBV or HCV or are at risk of acquisition by other modalities [148]. Posttransplant vaccination should not be withheld for concerns regarding organ rejection [131].

Posttransplant HAV vaccination has been found to be safe, though studies report conflicting seroconversion compared to healthy controls with widely varied results ranging from 0% to 97% in different studies [140, 148]. Some have found statistically less immunogenicity compared to those vaccinated pretransplant and healthy controls [149], while others have found sufficient vaccine response even in as long as the vaccination series is completed [148]. Studies are often small and based on heterogeneous groups with variations in results between studies, likely due to discrepancies in patient selection, severity of liver disease, immunosuppressive medications, and type of vaccine used [150].

Though well tolerated, after a standard HAV vaccine series following liver transplant, only 8% seroconverted 1 month after the first dose, while 26% seroconverted after the second. Vaccine responders presented with higher total white blood cell and lymphocyte count at vaccination compared to non-responders and started vaccination series further in their posttransplant course [149]. In a similar study after kidney transplantation, only 26.9% seroconverted after a full series, with multivariate analysis showing that higher hemoglobin and lower serum creatinine levels were better prognostic factors for seroconversion. There was a trend for higher response rates with cyclosporine over tacrolimus and with lower prednisone doses [151].

There is no clear data on the level of protection or duration of response to vaccination in the pediatric solid organ transplant population. Historically, this population has low rates of vaccination prior to transplantation [152] . Overall, HAV vaccine response in immunocompromised children is suboptimal [133]. In a cohort of pediatric heart transplant children traveling to the World Transplant Games who had not received either HAV or HBV vaccinations prior, only 25% developed titers consistent with HAV seroconversion following vaccination. However, the type of vaccine and the number of doses administered were heterogeneous across the whole cohort [153].

Some have postulated that there are unique features regarding renal transplantation with poorer seroconversion rates. In a study that had higher levels of immunogenicity, only 72% of renal transplant recipients seroconverted after a standard series compared to 97% of liver recipients and 100% of healthy controls. In addition, the renal recipients also had lower GMC, with an inverse association with the number of immunosuppressive drugs patients were receiving [148]. In healthy donors, immunity is presumed after a single dose because of seroconversion rates of >90%. However, this can't be assumed in transplant recipients where in 68% a single dose did not result in protection [148].

Rates of antibody decline postvaccination are also greater in liver and kidney transplant recipients compared with normal controls [154]. In a follow-on study looking at posttransplant antibody decline, after 2 years, only 59% of liver transplant and 26% of renal transplant patients showed persistent seroconversion compared with 100% of control subjects. In the liver transplant group, decline in antibody level was greatest in those on cyclosporine compared with tacrolimus, even after adjustment for time posttransplant which contrasted to prior studies showing trends for higher responses with cyclosporine [151]. In the renal transplant group, type of immunosuppression did not alter antibody decline [154]. It remains unclear if there is something unique about the transplant type and seroconversion rates or if this is related to the underlying immunosuppression regime.

In those with immunity from prior infection, there is significant loss of HAV-IgG post-liver transplantation. Though numbers were small, one study showed 18% became seronegative at 1-year posttransplant while 29% were seronegative at the 2-year posttransplant mark [155]. In contrast, a study of renal transplant patients with underlying HCV, HAV-IgG levels remained over 90% at a median of 3 years posttransplant. However, pretransplant HAV-IgG levels were not determined, so the degree of loss could not be correlated [156]. The presence of antibodies after natural infection is higher than with immunization, so the decline may be faster in the latter. As in adults, the duration of protection after vaccination is not known in pediatric transplant patients [111].

Further studies are also required to determine if postvaccination antibody decline in immunocompromised patients warrants booster vaccinations. The association of an arbitrary antibody level defining persistence of humoral immunity is even less clear in the immunocompromised, as is the role of maintained T memory cells.

Hematopoietic Stem Cell Transplant

There are a number of studies that follow HSCT patients seropositive for HAV prior to transplantation as a result of infection earlier in life, rather than vaccination. The effects of HSCT upon their immune response to HAV indicate a role for posttransplant vaccination. In Brazil, in a study showing pretransplant seroprevalence of 92.2%, survival analysis showed rates of the probability of becoming seronegative were 4.5% at 1 year, 7.9% at 2 years, 10.1% at 3 years, and 23.4% at 4 years [157]. Loss of antibody was significantly associated with longer follow-up, GVHD, and younger age. An Argentinean cohort of 36 non-vaccinated patients receiving a peripheral-HSCT for heterogeneous indications demonstrated that 31 patients (86%)

remained seropositive on retesting an average of 12 months posttransplant (range 1–51) while the remaining patients became seronegative. There was no clear correlation with age, sex, diagnosis, type of transplant, timing of follow-up testing, or the amount of CD34+ cells that were given on univariate or multivariate analysis [158]. In another high-endemicity setting, the Ankara University Pediatric HSCT Unit evaluated 30 patients ranging in age from 1 to 18 for loss of HAV-IgG posttransplant. Seventy-six percent (n = 23) of patients were seropositive for HAV prior to transplant, and received transplants from donors, of whom 66% were seropositive. Ten patients (43.5%) became seronegative posttransplant with the median time of 12 months (range 12–32 months). Age, sex, diagnosis, GVHD, and follow-up time were not found to have a statistically significant contribution though numbers were very small. Although those with negative donor serology appeared to have a greater loss of antibody (75% vs. 26%), the results were not statistically significant. Interestingly, two of the three recipients who seroconverted posttransplant received transplants from seropositive donors [159]. Overall, recommendations are that those undergoing transplant in countries of high endemicity should undergo pretransplant seroprevalence testing and receive posttransplant vaccination if negative. The role of a booster vaccination in this setting is unclear, given the loss of antibody titers in the months following transplant.

The IDSA suggests that all HSCT recipients are to be considered unvaccinated after transplant with some experts recommending revaccination even if there are protective antibody titers [131]. After HSCT, most vaccinations are recommended based on local vaccine schedules, in the context of travel to endemic areas, occupational or personal risk. Despite regional differences with recommendations, there is often poor adherence to guidelines posttransplant [160]. As HBV vaccination is also required, administering the combined three-dose HAV-HBV vaccine course with an additional booster dose can be considered. If giving the standard monovalent vaccine, a routine two-dose schedule is sufficient. Expedited vaccination schedules using the combined HAV-HBV vaccine on a schedule of 0, 7, and 21 days and 12 months for rapid seroconversion have been studied with evidence that this is as immunogenic as the monovalent vaccine two-dose schedule [161].

Based on expert opinion, in the absence of posttransplant graft versus host disease (GVHD), persistent chemotherapy, and anti-CD20 monoclonal antibody therapy within the past 6 months, routine vaccination schedules may commence from 6 months posttransplant with evidence of immune reconstitution (131, 160). Within local schedules, HAV vaccination is often delayed until 1 year after transplantation, when the immunosuppression is even lower [160]. Vaccines should be delayed in the context of ongoing treatment for GVHD or administration of intravenous immunoglobulin (IVIG) replacement therapy. GVHD is independently associated with reduced T cell and antibody responses to vaccination and is also a marker for infectious risk [144, 162, 163]. IVIG is given in the context of profound hypogammaglobulinemia (IgG <400 mg/L) and recurrent infections, highlighting delayed humoral immune reconstitution [144]. However, recently administered IG products are not thought to inhibit the immune response to inactivated vaccines, unlike live vaccines, and should not be an excuse for a missed opportunity to

administer vaccines to those who are seen infrequently [160]. IVIG is likely to provide a period of protection against HAV, which may allow for later, perhaps more immunogenic, HAV vaccination.

Vaccine responses have been studied in a cohort of patients who underwent autologous HSCT for multiple myeloma, of whom 75% were on lenalidomide maintenance therapy. Of the 120 patients studied, 56 received vaccination post-transplant for HAV. Of the HAV vaccinated patients, 30% ($n = 17$) seroconverted, 29% ($n = 16$) retained immunity measured prevaccination, 21% ($n = 11$) did not respond, while 20% ($n = 11$) were non-evaluable (defined as missing results or titers being performed beyond 6 months postvaccination) [164]. Of those who received HAV vaccination, there was no statistical difference in vaccine response in those on maintenance therapy versus those who were not, though numbers were small. While it appears response rates to vaccination were high with other vaccines, the responses to HAV, HBV, and polio were poor in patients evaluable for response. Further studies are required determining exact response by titer and the rates of decline over time.

Travel Recommendations

Recommendations for HAV prevention in the circumstance of travel into areas of high endemicity varies depending on several factors. The main preventative strategies are the administration of either HAV vaccine or immune globulin (IG).

Ideally travel to HAV risk areas should be delayed until at least 1 year post-SOT and after 2 years in HSCT after resolution of GVHD or intensive immunosuppression – corresponding with the time of highest risk of infection [165]. The optimal approach for the traveling immunocompromised patient is a review at least 6–12 months prior to departure. If indicated based on destination, the first dose of HAV vaccine should be administered with repeat dosing after 6 months as per the routine schedule [131]. This is in comparison with healthy travelers who have high levels of seroconversion after a single dose [166]. Poor seroconversion after a single dose of vaccine has also been seen in patients with rheumatoid arthritis [167]. Use of a double dose, or repeat vaccine 4 weeks apart, gave patients with rheumatoid arthritis similar seroconversion rates to healthy controls after a single vaccine (85), and it may be considered if this approach may be utilized in transplant patients. Ideally, seroconversion should be assessed 4–8 weeks prior to departure with administration of IG (given as intramuscular gamma globulin) if seronegative [168, 169]. If seronegative, and travel is for more than 2 months duration, repeat doses should be given every 2 months [112, 170]. For less than 2 months of protection, a dose of 0.1 mL/kg is recommended; for more than 2 months of protection, a dose of 0.2 mL/kg is recommended and should be repeated every 2 months for long-term travel with no maximum dosage limitations [170]. GamaSTAN S/D, the only IG product approved by the Food and Drug Administration (FDA) for hepatitis A prophylaxis, is supplied in 10 and 2 mL units; therefore, rounding up to avoid wasting of product is recommended [150].

Often pretravel planning is not feasible with emergency travel, so those planning on departing in under two weeks should receive simultaneous administration of HAV vaccine and IG, administered at separate anatomical sites [15]. When

HAV vaccine and IG are administered simultaneously in the immunocompromised, the antibody titer achieved is lower, but not the proportion classified as seropositive, and is therefore not thought to have clinical relevance. How this affects the duration of protection is unclear [171]. In addition to the immunocompromised host, those who are over the age of 40 years and with underlying chronic liver disease should receive similar treatment based on risk [15]. This approach is in contrast to the immunocompetent aged between 12 months and 40 years who can receive a single dose of vaccine prior to travel and complete as per the schedule on return [15]. In immunocompetent children given simultaneous IG and three-dose vaccine strategy (0, 1, 6 months), there was a twofold lower antibody response as determined by GMC than if vaccine was given alone. There was immediate protection as determined by antibody response at 5 days when giving the combined active/passive vaccination strategy. In those who received IG alone, levels waned to around 66% seropositive at 2 months and 11% at 5 months with none of them being seropositive at 6 months [49].

There are no specific different recommendations for immunocompromised children traveling prior to the standard vaccination schedule, but care should be taken in this situation and delayed if possible. In immunocompetent children, if travel is occurring prior to the standard schedule vaccination of commencing at 12 months, HAV vaccine may be administered from 6 to 11 months though this should not be counted toward the routine two-dose series [15]. This approach was developed due to the fact that IG cannot be administered at the same time as MMR due to inhibition of the immune response to this vaccine for up to 3 months [170, 172] with prevention of measles, mumps, and rubella being the priority in traveling infants which can cause more severe illness than HAV in this age group [173]. Infants less than 6 months of age or those in whom vaccination is contraindicated should receive a single dose of IG before travel.

Adequate vaccination requires education of both patients and health practitioners to present or refer to travel clinics or vaccine providers within the adequate time frame. Despite efforts, uptake of recommendations is poor. In a North American transplant clinic survey, 36% of attenders revealed that they had recently traveled outside Canada and the USA (10). Despite 66% of travelers seeking pretravel advice, primarily from their transplant physician, 63% traveled to areas where HAV was endemic, but only 5% had received HAV immunization. This further highlights the importance of the transplant infectious disease physician within the posttransplant setting.

Postexposure Prevention

Postexposure prophylaxis with either HAV vaccine or IG prevents infection when given within 2 weeks of exposure [15, 53, 174]. Initial recommendations supported the primary use of IG which, when administered within 2 weeks of last exposure, is 89–90% effective in preventing clinical disease [175]. However, a large study of over 1090 immunocompetent people in an outbreak setting between the ages of 2–40 years found that vaccine administration was non-inferior [174]. The effectiveness beyond this time period was not determined. The combination HAV-HBV vaccine should not be used as postexposure prophylaxis, due to the duration of the vaccine course. Prior recommendations by the ACIP have determined the

postexposure strategy on the basis of age – those between 1 and 40 years have been recommended vaccination, while, if available, IG has been recommended to those under 1 or over 40 years [166, 176]. But, HAV vaccine has multiple advantages over IG administration, with a longer duration of protection, ease of administration, and greater acceptability and availability [176]. This postexposure prophylactic regimen, however, is not applicable to the transplant recipient or immunocompromised host.

While there are no studies that specifically assess the risk in the immunocompromised host postexposure to HAV, the vaccine is clearly less immunogenic in this population, and therefore a combined IG and vaccine approach is recommended for a potentially more durable response [15]. Transplant recipients with hypogammaglobulinemia or receiving routine immunoglobulin repletion with IVIG for other indications do not need additional protection against HAV (or measles and varicella) [150, 177].

Increased doses of IG (0.1 mL/kg) have been recommended since 2017, due to declining HAV-IgG potency, presumed from reduced prevalence in the donor pool [170, 178]. Dosing strategies for other IG indications such as measles, varicella, or rubella pre- and postexposure are unchanged (see Table 3).

Conclusion

While much progress has been made on a worldwide front in reducing rates of HAV infection, we continue to have a group of susceptible hosts at risk of more severe disease, who are often unprotected despite known risk factors for HAV acquisition. In practice, HAV vaccination rates are poor among the immunocompromised.

While there is obviously limited and heterogeneous information on HAV infection and vaccination in transplanted and immunocompromised hosts, it is clear that much of our information on immunocompetent hosts cannot necessarily be applied to transplant patients. Further study, particularly on improving immunogenicity and durability of both humoral and cellular responses to vaccination in transplant recipients, is required.

From the perspective of those involved in transplantation and the care of immunocompromised hosts, knowledge of the importance of the timing of vaccination remains key. Ensuring our patients are educated and seek further medical opinion prior to travel or other risk factors is critical.

Key Points

- Hepatitis A is non-enveloped RNA virus with predominantly fecal-oral spread.
- It is associated with typically foodborne outbreaks in areas of low endemicity, such as the USA and Western Europe, but there is higher transmission in other areas such as South Asia and Africa.
- Immunity to HAV occurs after infection or vaccination – the persistence of this is unclear after transplantation.

Table 3 Recommendations for postexposure prophylaxis and preexposure protection, by age group and risk category

Indication/age group	Risk category/health status	Hepatitis A vaccine	Immune globulin
Postexposure prophylaxis			
<12mos	Healthy	No	0.1 mL/kg[a]
12 Mos–40 years	Healthy	1 dose[b]	None
>40 years	Healthy	1 dose[b]	0.1 mL/kg[c]
≥12mos	Immunocompromised or chronic liver disease	1 dose[b]	0.1 mL/kg[d]
≥12mos	Vaccine contraindicated[e]	No	0.1 mL/kg
Preexposure prophylaxis[f]			
<6mos	Healthy	No	0.1–0.2 mL/kg[g]
<12mos	Healthy	1 dose[h]	None
12mos–40 years	Healthy	1 dose[i]	None
>40 years	Healthy	1 dose[i]	0.1–0.2 mL/kg[g, j]
All ages	Immunocompromised or chronic liver disease	1 dose[i]	0.1–0.2 mL/kg[g, j]
≥6mos	Persons who elect not to receive vaccine or for whom vaccine is contraindicated	No	0.1–0.2 mL/kg[g]

From Nelson et al. [15]

[a]Measles, mumps, and rubella vaccine should not be administered for at least 3 months after receipt of IG

[b]A second dose is not required for postexposure prophylaxis; however, for long-term immunity, the hepatitis A vaccination series should be completed with a second dose at least 6 months after the first dose

[c]The provider's risk assessment should determine the need for immune globulin administration. If the provider's risk assessment determines that both vaccine and immune globulin are warranted, HAV vaccine and immune globulin should be administered simultaneously at different anatomic sites

[d]Vaccine and immune globulin should be administered simultaneously at different anatomic sites

[e]Life-threatening allergic reaction to a previous dose of hepatitis A vaccine or allergy to any vaccine component

[f]IG should be considered before travel for persons with special risk factors for either HAV infection or increased risk for complications in the event of exposure to HAV

[g]0.1 mL/kg for travel up to 1 month; 0.2 mL/kg for travel up to 2 months, 0.2 mL/kg every 2 months for travel of ≥2 months' duration

[h]This dose should not be counted toward the routine two-dose series, which should be initiated at age 12 months

[i]For persons not previously vaccinated with HAV vaccine, administer dose as soon as travel is considered, and complete series according to routine schedule

[j]May be administered, based on providers' risk assessment

- HAV vaccine is recommended universally for children in the USA and on the basis of risk in adults, which includes many transplant recipients, particularly those with chronic liver disease.
- In SOT recipients, vaccine strategies to prevent HAV should be commenced as early as possibly in the pretransplant period for increased immunogenicity.

- Post-HSCT, recipients should be considered as unvaccinated and receive HAV vaccine as per their local schedules after transplant.
- Solid organ and hematopoietic stem cell transplant recipients are increasingly traveling to high-risk countries, and awareness of this fact before and after transplant can help protect patients from HAV.
- In those traveling to areas with increased HAV endemicity, a full HAV vaccine course must be completed or given with IG if vaccination is unable to occur in a timely manner.

Introduction

The hepatitis E virus (HEV) is a leading agent of viral hepatitis worldwide [1]. HEV is a member of *Hepeviridae* family. The strains that infect humans belong to *Orthohepevirus A* species for which eight genotypes have been identified [2]. Genotypes 1 and 2, which are restricted to humans, are responsible for acute hepatitis transmitted by fecal-oral route, principally via contaminated drinking water in low-income countries. Both genotypes are involved in epidemics and sporadic cases in resource-poor areas and are associated with severe manifestations in pregnant woman and patients with a preexisting liver disease [1]. In industrialized countries, HEV genotypes 3 and 4 are predominately observed, with a zoonotic reservoir mainly composed of pigs, wild boars, and rabbits [1]. HEV3 is widespread, whereas HEV4 is mainly found in Asian countries, such as China and Japan [3], although it was recently detected in Europe [4]. HEV genotypes 5 and 6 are known to infect wild boars, but no human infections have been reported to date. Finally, genotypes 7 and 8 were recently identified in camels and could infect humans occasionally [1, 5].

HEV is a small (27–34 nm) single-stranded, positive-sense RNA virus with an icosahedral capsid [1]. The HEV genome, which is approximately 7.2 kb long, is capped at the 5′ end and poly-adenylated at the 3′ end. It contains three or four open reading frames (ORFs) depending on the HEV genotype [6]. ORF1 encodes a nonstructural protein of approximately 1,700 amino acids containing the RNA-dependent RNA polymerase [1]. In genotype 1 strains, ORF4, the translation of which is promoted by endoplasmic reticulum stress, stimulates RNA polymerase activity [6]. ORF2 encodes the 660-amino acid capsid protein, which holds the immunogenic epitopes [1]. ORF2 protein is associated with infectious particles but is also massively secreted as free glycoproteins by infected cells [7]. The soluble form of ORF2 protein, which is the majority of ORF2 protein detected in patient serum, could inhibit antibody-mediated neutralization and participate in immune evasion [8]. Finally, ORF3 encodes a small phosphoprotein, which is 113 residues in genotype 3 and 114 residues in other genotypes, and is involved in virus egress [1]. While HEV virion is naked in the environment and feces, it was found be associated with a lipid membrane in the blood and urine of infected patients and in culture supernatants [9]. Therefore, like the hepatitis A virus, HEV is considered to be a quasi-enveloped virus [1].

Although most HEV3 and HEV4 infections cause self-limiting hepatitis in immunocompetent subjects, they can progress to chronic hepatitis in immunosuppressed patients such as solid organ transplant recipients [10, 11], stem cell transplant patients [12, 13], human immunodeficiency virus-infected patients with low CD4 T-cell count [14], and patients receiving chemotherapy or immunotherapy [15]. In this comprehensive review, we summarize current knowledge regarding HEV epidemiology, diagnosis, clinical manifestations, and treatments in transplant recipients.

Disease Epidemiology: Transmission

HEV prevalence in transplant recipients is not easy to determine because of the significant variability of HEV prevalence within countries and the different serological assays used. HEV seroprevalence in solid organ transplant recipients obtained from endemic and non-endemic areas is between 8.3% and 43%, depending on the HEV endemicity in the areas studied and the eating habits of populations [16–18]. The prevalence and incidence of replicative HEV infection, attested by HEV RNA detection in blood, range from 0% to 3.2% and 1–3.2/100 person-years, respectively [16].

HEV is mainly transmitted enterically. The discovery that porcine HEV also infects humans revealed that hepatitis E is a zoonosis [19]. Therefore, HEV 3 and 4 contaminations are principally linked to direct contact with the animal reservoir, which mainly consists of domestic pigs, wild boars, rabbits, and deer, or the consumption of undercooked meat or offal [20]. In addition to zoonotic transmission, blood products have been identified as a potential source of HEV [21]. Only a minority of the recipients of contaminated blood products develops symptomatic hepatitis E. Nevertheless, when administered to immunosuppressed patients, the risk of developing chronic HEV infection increased [22]. The risk of blood-derived HEV infection correlates with the incidence of HEV RNA among blood donors according to the country (Table 1). Moreover, recent data suggests that HEV viremia could be prolonged by more than 2 months in healthy blood donors, thereby increasing the risk of transmission through multiple donations [23]. Transplant patients often receive red blood cell transfusions during the perioperative period or fresh plasma administered in desensitization protocols. In solid organ transplant recipients, several cases of transfusion-transmitted HEV infection have been already published [21, 24]. The minimal total infectious dose of HEV virions through transfusion seems to be approximately 1×10^4 international unit (IU) [21]. More recently, plasma exchange, including with pathogen-reduced plasma, has been associated with HEV infection in kidney transplant patients [25]. Consequently, countries with a high HEV prevalence are now evaluating the general screening for HEV RNA in blood products so that they can provide HEV-negative products for organ transplant recipients [21].

Rare cases of graft-transmitted HEV infections have been reported for genotype 3 in kidney and liver recipients [26, 27]. For genotype 4, multiple HEV transmissions that have affected five transplant recipients have been recently described from the same donor with HEV viremia [28]. The incubation period ranged between 34 and 67 days. In this case, all the HEV infections evolved to chronic hepatitis [28].

No reactivation of HEV infection was noted after solid organ transplantation for anti-HEV IgG-positive patients [16]. Moreover, low anti-HEV antibodies (<7 IU/ml) did not seem to protect solid organ transplant recipients from HEV reinfection or from the development of chronic infection [29]. Similarly, in rhesus macaques, a mean anti-HEV IgG level of 7.1 IU/ml only led to partial protection against reinfections. This leads to the notion that serum IgG level is correlated with

Table 1 HEV RNA detection in healthy blood donors

HEV hepatitis E virus

the degree of protection and that HEV reinfection can occur despite preexistent humoral immunity [30].

In bone marrow transplant recipients, few data are available concerning HEV infection epidemiology. In the Netherlands, a retrospective cross-sectional study showed that the incidence of HEV infection in allogeneic hematopoietic stem cell transplant recipients was 2.4% (8/328) [31]. Reactivation of HEV infection in anti-HEV IgG-positive patients seems to be anecdotal after bone marrow transplantation [32, 33]. The mode of transmission of HEV has not been well studied in this population. However, one case of transmission via a hematopoietic stem cell donor has been reported [13].

Most chronic HEV infections that have been reported are genotype 3-infected immunocompromised patients [10]. Recently, 12 cases of genotype 4 chronic infections were also published [11, 28, 34]. Moreover, one case of chronic HEV genotype 7 infection was reported in a liver transplant recipient from the Middle East who consumed camel-derived food products including milk and meat [5].

More recently, rat hepatitis E virus has been implicated in chronic hepatitis in liver transplant patients, which required antiviral treatment [35]. Therefore, *Orthohepevirus C* could also be a source of zoonotic hepatitis in immunosuppressed patients. Further studies are needed to define the pathogenicity of rat strains in humans and the mechanisms that lead to the zoonotic capacities of *Orthohepevirus*.

Clinical Impact on Transplant: Both Solid Organ and Bone Marrow/Stem Cell

Clinical Manifestations

In immunocompetent subjects, hepatitis E infections are mostly asymptomatic or self-limiting illnesses [1]. The main symptoms associated with acute hepatitis E are jaundice, weakness, and weight loss. In immunocompromised subjects, two-thirds of the infected HEV patients are also asymptomatic [36]. Fatigue and diarrhea are the main symptoms observed at diagnosis, while jaundice is rare [36]. Fulminant hepatic failure is exceptional in the case of acute hepatitis E in transplant recipients [37]. The increase in liver enzyme levels is usually low in transplanted patients, sometimes less than twofold the upper limit of the normal value, and can mimic drug-induced liver injury. Consequently, the diagnosis of HEV infection may be delayed in some cases.

Chronic Infections

Solid organ transplant patients are the immunocompromised patients among whom chronic HEV infections are most often reported. Typically, patients with resolving hepatitis eliminate the virus within the first month following infection. Without any modification of the immunosuppressive regimen, no case of spontaneous HEV clearance has been reported beyond 3 months after infection [38]. Therefore, patients with persistent HEV replication beyond 3 months are considered to be chronically infected [38]. Approximately two-thirds of HEV-infected solid organ transplant recipients develop chronic HEV infection [36, 39]. Rapid progression of liver fibrosis can result in cirrhosis in ~10% of chronically infected transplant patients within a few years [10, 36, 40]. The histological aspect of HEV hepatitis is nonspecific, with inflammatory infiltrates within both portal tracts and the lobules [10, 40, 41]. Mixed lymphocytic and neutrophil polymorph cholangitis are also reported [41]. Strong immunosuppression is associated with an increased risk of chronic development, specifically, an impaired adaptive T-cell immune response [42]. Chronic infections were associated with the use of tacrolimus-based

immunosuppressive therapy, rather than cyclosporine A [36]. In vitro studies have shown that mTOR inhibitors and calcineurin inhibitors promote HEV replication [43]. Conversely, mycophenolic acid inhibits HEV replication in vitro, with additional antiviral potency when associated with ribavirin [44]. Nevertheless, clinical studies do not strongly support such effects, probably due to the significant level of T-cell inhibition induced by mycophenolic acid [36]. In fact, low lymphocyte subset counts have been clearly associated with increased chronic development [10, 39]. Similarly, low liver enzyme levels during infection and a shorter delay after transplantation or after the last treated acute rejection episode have been associated with chronic hepatitis E, which highlights the deleterious impact of a decreased immune response [10, 36]. Finally, greater quasispecies heterogeneity has been associated with persistent HEV infection whereby the emergence of viruses with an enhanced ability to persist is promoted [45].

Few data are available concerning the course of HEV infection in HSCT recipients. Most infected patients are asymptomatic but usually show a high increase in liver enzyme levels [12]. Liver histological analyses show active hepatitis with T-cell infiltrates which can be associated with severe fibrosis [12, 31]. The rate of progression to chronicity is ~60%, similar to that of solid organ transplant recipients [31]. In general, patients cleared HEV during the cessation of immunosuppressive therapy introduced to treat or prevent graft versus host disease [31].

Extrahepatic Manifestations

HEV can cause extrahepatic manifestations, as suggested by its ability to replicate in a large number of cell types in vitro, including neuronal-derived cells and kidney cells [1]. The most common extrahepatic manifestations reported in both immunocompetent and immunocompromised HEV-infected patients are neurological disorders, mostly Guillain-Barré syndrome, [46] neurologic amyotrophy, and encephalitis [47, 48]. Therefore, 5–11% of patients with Guillain-Barré syndrome have signs of very early HEV infection [46, 49]. In patients with acute hepatitis E, a high frequency of neuropathic pain suggesting small fiber neuropathy and painless sensory disorders has been recently reported [50]. All neurological manifestations were more frequent in immunocompetent subjects compared to immunocompromised patients, suggesting pathophysiological mechanisms involving the immune system [50]. Moreover, in some patients, HEV variants characterized in cerebrospinal fluid differed from those found in serum, suggesting the appearance of neurotropic variants [48].

Acute hepatitis E has been associated with decreased kidney function in both liver and kidney transplant recipients [51]. In solid organ transplant patients, HEV infection is associated with a high frequency of cryoglobulinemia, ranging from ~35% at the acute phase to ~50% in chronically infected patients [52]. Most cases of cryoglobulinemia are asymptomatic and disappear after viral clearance, but some cases of HEV-induced cryoglobulinemia are associated with membranoproliferative glomerulonephritis or rheumatologic symptoms [51–53]. Other specific

nephropathies have been identified during HEV infection, including membranous nephropathy and relapsing IgA nephropathy after kidney transplantation [51, 54]. The mechanisms responsible for renal damage have been poorly studied; HEV RNA and antigen have been detected in the urine of HEV-infected transplant patients [9].

Diagnosis Including Clinical Evaluation and Available/Emerging Diagnostics

Serological Tests

Despite a significant genetic variability, only one serotype is described for HEV. Therefore, anti-HEV antibodies cross-react between genotypes [30]. Acute HEV infection can be diagnosed by detecting specific anti-HEV antibodies by various commercial enzyme immunoassays. For acute infection in solid organ transplant recipients, anti-HEV IgM assays have a sensitivity of approximately 85% but a high specificity of >99% [55]. In the same phase, the sensitivity of anti-HEV IgG antibodies is only 45% and usually indicates a past infection. The detection limits of commercial assays for anti-IgG vary between 0.25 and 2.5 IU per ml. Although it does not improve the diagnostic performance of serological tests at the acute phase of infection, the quantification of anti-HEV IgG could be useful to assess the risk of reinfection in immunocompromised patients in high endemic areas [18]. For bone marrow transplant patients, the sensitivity of serological tests seems to be lower, which argues for direct HEV RNA detection [56].

Antigen Detection

The secreted form of ORF2 capsid protein can also be detected in the serum and urine of immunocompromised patients during acute hepatitis E [9]. The sensitivity and specificity of commercial assays in serum are, respectively, 94% and 100%, and seem to be similar in urine [9, 57]. Considering that this is more sensitive than anti-HEV IgM testing, it could be an alternative to RNA detection in laboratories without molecular diagnostic devices. It is interesting to note that a high level of serum HEV antigen during acute hepatitis E has been associated with an increased risk in the development of chronic HEV infection in solid organ transplant recipients [9]. Further studies are needed to clarify the role of soluble ORF2 protein in chronically infected patients and its importance in patient follow-up.

Molecular Diagnosis

Molecular detection of HEV RNA is the gold standard for active hepatitis E diagnosis. DNA primers are targeted in regions that are highly conserved across genotypes, generally ORF3 [58]. The performance of RT-PCR tests varies widely,

and assays that include the WHO international standard should be used [58, 59]. With recent commercial testing, the lower limits of detection are approximately 7–80 IU/ml [59]. The serum and stool samples of immunocompromised patients should be tested for HEV RNA to confirm the diagnosis of hepatitis E and to assess the progression of HEV infection and the response to antiviral therapy. However, the presence of PCR inhibitors in a feces-derived matrix can make detecting HEV RNA difficult, and the extraction protocol should be strictly validated in each laboratory [60].

HEV genotypes and subgenotypes can be determined by sequencing a part of the ORF2 region. This could be a useful tool for epidemiological monitoring and to identify the source of infection. Some mutations in the ORF1 region (RNA-dependent RNA polymerase) have been associated with a decrease in susceptibility to ribavirin in vitro [61, 62]. Nevertheless, their detection in clinical practice does not seem to have any impact on the therapeutic response or the management of antiviral therapy [63, 64].

Natural History and Diagnostic Algorithm

After contamination, 2–4 weeks of incubation are usually described during which HEV RNA and antigens can be detected in blood samples. Subsequently, HEV RNA persists in blood and feces for ~4 and ~6 weeks, respectively, in immunocompetent patients [1]. Capsid antigens could persist longer than detectable viremia in immunosuppressed patients. Anti-HEV IgM appears during the symptomatic period, mainly revealed by elevated liver enzyme levels. It then persists for several months [1]. In general, specific IgG develops secondarily but persists several years. The persistence of HEV RNA in blood and stool for more than 3 months characterizes a chronic HEV infection [38]. The diagnostic algorithm for the suspicion of HEV infection in immunocompromised patients is summarized in Fig. 1.

Management Including Emerging Treatment Modalities and Options for Prophylaxis/Prevention

Immunosuppressive Regimen Management

No data is available concerning the optimal management of acute HEV infection. In chronically infected patients, reducing immunosuppressive therapies that target T-cells is the first therapeutic option [39]. In fact, tacrolimus levels and steroid doses were lower in solid organ transplant recipients who eliminate the HEV compared to those who remained viremic [39]. Approximately, one-third of patients achieve viral clearance after immunosuppressive drug doses are reduced, especially calcineurin and mTOR inhibitors [39]. Effective antiviral therapy is needed for patients who remain viremic and for those whose immunosuppressants cannot be reduced.

Ribavirin Monotherapy

Ribavirin, a guanosine analogue, has shown anti-HEV activity both in vivo and in vitro [65]. Its pleiotropic antiviral activity against HEV is not fully understood but has been associated with cellular GTP pool depletion and mutagenesis [65, 66]. Several studies have demonstrated the efficacy of oral ribavirin alone in the treatment of chronic hepatitis E [67, 68]. Overall sustained virological response (SVR) rates range from 63% to 78% after 3–6 months of monotherapy. Nevertheless, no statistically significant difference has been noticed between patients who were treated for 3 months or less and those who received ribavirin for more than 3 months [67]. Consequently, a 12-week long ribavirin treatment is currently recommended as first-line drug therapy for immunosuppressed patients with persisting HEV replication (see Fig. 2 for treatment algorithm) [18]. In chronically HEV-infected transplant recipients, a fall in HEV RNA of >0.5 $\log_{10}$IU/ml at day 7 of treatment predicted SVR with a positive predictive value of 88% [69]. However, ribavirin trough levels that were checked at day 7 or at steady state had no impact on SVR [69]. Relapses after ribavirin cessation have also been associated with lower liver enzyme levels or low lymphocyte counts at the

initiation of treatment, which probably indicates deeper immunosuppression and a lower T-cell immune response [64, 67]. Persistent HEV shedding in stools at the end of ribavirin therapy leads to systematic relapse [64]. Therefore, patients on antiviral therapy should be tested for HEV RNA in both serum and stools before ribavirin withdrawal. In the case of persistent HEV excretion in feces, ribavirin should be prolonged for 12 additional weeks [64]. Finally, HEV clearance can be established 12 weeks after ribavirin cessation if HEV RNA in both blood and stools remains undetectable [70].

Ribavirin treatment can be associated with side effects, mostly dose-dependent anemia [67]. Ribavirin doses should be carefully adapted to kidney function [71].

Cases of ribavirin treatment failures despite multiple retreatments have been reported. A G1634R mutation has been identified in the RNA-dependent RNA polymerase in patients who relapse [61]. This mutation does not provide ribavirin resistance in vitro but increases the replicative capacity of HEV [62]. Nevertheless, in clinical practice, the presence of the G1634R mutation before treatment had no impact on the early virological response, SVR, or virological response after retreatment [63, 64]. Other mutations have also been recently described including Y1320H, K1383N, Y1587F, V1479I, and D1384G [62, 66]. Their impact on ribavirin treatment response in vivo remains speculative.

In stem cell transplant recipients, only few case series have been published on the treatment of chronically HEV-infected patients. A 3-month course of ribavirin showed good efficacy in this setting, enabling continuation of cytotoxic treatments for underlying malignancies [56].

Other Antivirals

Despite only moderate in vitro anti-HEV activity [72], pegylated interferon has been successfully used to treat some chronically infected liver transplants [73, 74]. Nevertheless, interferon is usually considered contraindicated in other organ transplant patients because of the increased risk of acute rejection due to the immunostimulatory effect [75].

Some in vitro studies show an antiviral effect of sofosbuvir against HEV [76]. Sofosbuvir, a nucleotide analogue, is a direct-acting anti-hepatitis C virus drug that targets HCV RNA-dependent RNA polymerase. Data suggests that a combination of sofosbuvir and ribavirin provides an additive antiviral effect against HEV replication in vitro [76]. Nevertheless, pharmacological data suggest that an inhibitory concentration of sofosbuvir for HEV is tenfold that for the hepatitis C virus (HCV), theoretically requiring major dose adjustment [77]. Finally, no convincing in vivo data support the use of sofosbuvir, as highlighted by several treatment failures [78].

Some chronically HEV-infected immunosuppressed patients do not achieve SVR even after repeated ribavirin treatment. For these patients, further research is warranted to find new antivirals to cure HEV infection.

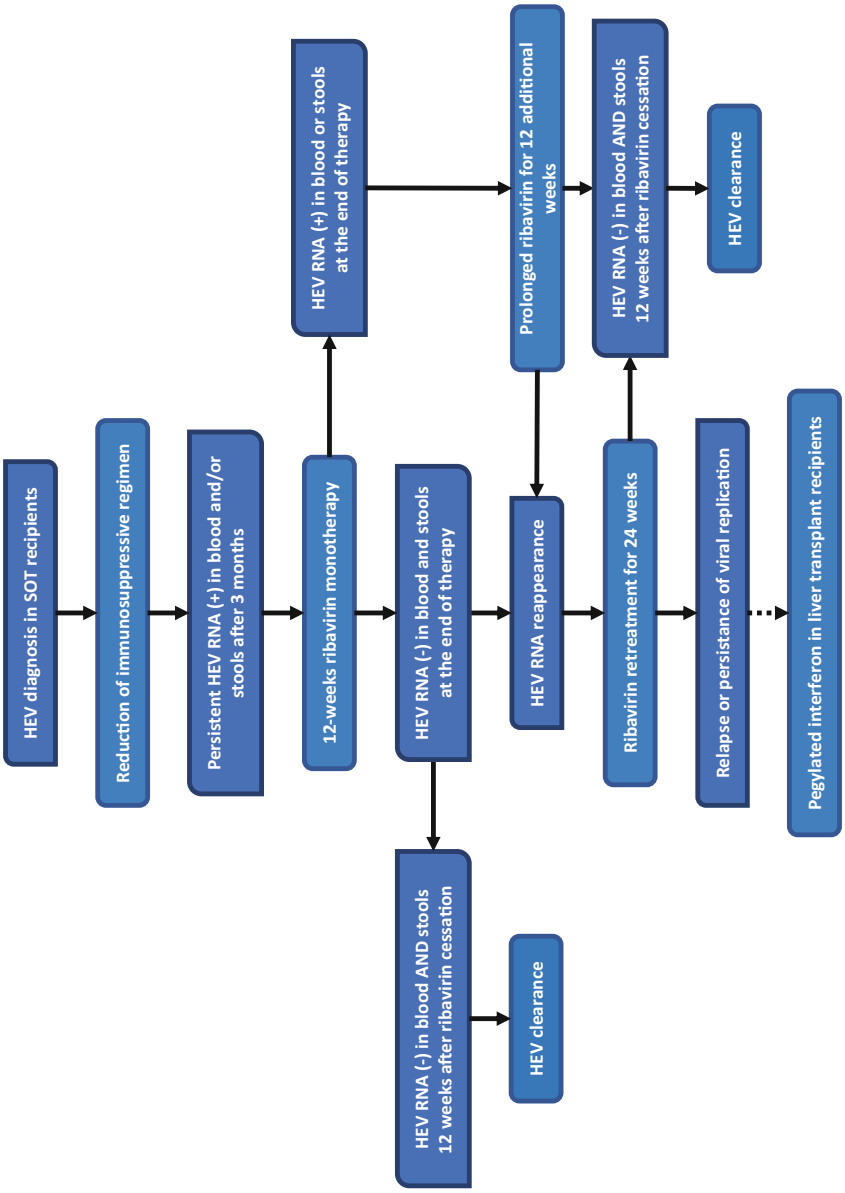

Fig. 2 Management of chronic HEV infection in solid organ transplant recipients. Abbreviations: HEV, hepatitis E virus; SOT, solid organ transplant

Prevention

HEV transmission could be prevented by avoiding the consumption of undercooked meat, game products, or offal in populations at risk for chronic infection. One effective vaccine candidate has been developed but is only licensed in China [79]. Its efficacy has not been evaluated in immunosuppressed patients with a risk of a decreased immune response to a vaccine.

Conclusion

HEV has been recognized as a major causative agent of acute viral hepatitis worldwide. In immunocompromised patients, especially transplant recipients, HEV causes acute and chronic infection with a high risk of rapidly progressive liver fibrosis. Ribavirin monotherapy has shown good efficacy in the treatment of chronic HEV infection. However, cases of HEV infection that are refractory to ribavirin have emerged, requiring the development of new antiviral therapies.

Key Points

- The hepatitis E virus is responsible for acute and chronic hepatitis in solid organ transplant recipients.
- Approximately two-thirds of HEV-infected transplant patients develop chronic infections.
- A 12-week ribavirin treatment is recommended as first-line drug therapy for immunosuppressed patients with persisting HEV replication.

Introduction

Hepatitis B virus infection (HBV) is one of the most significant causes of liver-related morbidity and mortality across the world, accounting for more than 620,000 deaths annually, predominantly from complications of cirrhosis and hepatocellular carcinoma (HCC) [1]. An estimated 248 million individuals are positive for hepatitis B surface antigen (HBsAg) worldwide with higher prevalence found in regions of Africa and Asia [2]. Nearly one-third of the global population or two billion people have serologic evidence of past or present HBV infection [3]. An estimated 5% of patients with chronic hepatitis B (CHB) have coinfection with hepatitis D virus (HDV) with higher prevalence found in the Mediterranean Basin, Middle East, and Central and Northern Asia [4, 5]. The mode of transmission of HDV is similar to that of HBV but can only occur in the presence of HBsAg. In the United States, the majority of individuals with CHB are foreign-born, reflecting the endemicity rates of HBsAg positivity in their countries of origin [6]. However, new HBV infections are on the rise among Americans, in part, related to the opioid epidemic and spread of HBV among those who inject drugs [7]. As a result, all organ transplant recipients and donors require evaluation of current or prior HBV infection.

Approximately 5% of all liver transplants (LT) are performed for patients with complications of CHB in the United States [8, 9]. Accurate data on the frequency of HDV coinfection are lacking. Among LT recipients with HBV, HCC is the most common indication for LT, with decompensated cirrhosis and acute liver failure (ALF) being less common [8, 9]. Among other solid organ transplants (SOT), HBsAg-positive recipients account for only 1–2% of recipients [10], with kidney transplant (KT) recipients being the best studied among non-liver transplant recipients.

HBV and HDV can have a significant impact on patients undergoing transplantation. In the setting of immunosuppression, the natural history of HBV and HDV can be accelerated and carry significant morbidity and mortality. Even for those who have cleared HBsAg, a risk for reactivation remains in the context of immunosuppression. Clinical awareness is key to identifying those patients at risk for hepatic complications associated with HBV and HDV and for providing appropriate prophylactic and therapeutic interventions to prevent liver-related complications.

The natural course of hepatitis B infection is characterized by the fluctuations in the levels of viral replication, measured by HBV DNA, and the host response, indicated by levels of alanine transaminase (ALT). HBV is not inherently cytopathic to hepatocytes (except in very unusual circumstances) but induces innate and adaptive immune responses in the host [11, 12]. A robust immune response yields resolution of infection (defined by HBsAg loss), but an inadequate immune response leads to chronicity and sets the stage for ongoing liver inflammation and injury.

While effective anti-HBV therapies are available, they are suppressive and not curative. Achievement of HBsAg loss either spontaneously or with treatment is the

best means of minimizing the risk of CHB complications. Unfortunately, in patients with CHB, the likelihood of spontaneous and treatment-associated clearance of HBsAg is very low – approximately 1% per year [13, 14]. New drug therapies, currently in early phase development, are increasingly focused on HBsAg loss as the endpoint of therapy [15]. However, even patients who achieve HBsAg seroconversion remains at risk for HBV complications due to the persistence of covalently closed circular DNA (cccDNA), a stable minichromosome inside the hepatocyte nucleus [16]. If host immune control is compromised, as occurs in the setting of transplantation, there is risk for reactivation of HBV.

The goals of therapy in the transplant setting are similar to those in the non-transplant setting – to prevent liver-related complications. Longitudinal assessment of HBV replication is essential to ensure treatment is provided when needed [17]. Antiviral therapy reduces the risk of clinical liver disease progression, can reverse symptoms of decompensation, improves indices of liver function (including model for end-stage liver disease score), and reduces HCC incidence [18, 19]. Most importantly for patients listed for LT, achieving a low or undetectable HBV DNA level prior to LT is associated with lower risk of HBV recurrence post-LT [20].

Diagnostic Evaluation of Organ Recipients and Donors

All transplant candidates and donors undergo serologic testing for HBV. Testing establishes whether there is evidence of current versus prior infection and current immune status (Table 1).

Table 1 Interpretation of screening tests for HBV infection in transplant candidates

Screening test results			
HBsAg	Anti-HBc	Anti-HBs	Interpretation
+	+	–	Chronic HBV
+	–	–	Very recent vaccine administration
–	+	+	Resolved HBV infection, naturally immune
–	–	+	Vaccine-induced immunity
–	–	–	Uninfected, not immune
–	+	–	(1) Resolved HBV infection, with loss of anti-HBs[a] (2) False positive anti-HBc (3) Recovering from acute HBV infection (4) Passive transmission from recent blood products (especially with IVIG)

HBV hepatitis B virus, *HBsAg* hepatitis B surface antigen, *anti-HBc* antibody to hepatitis B core antigen, *anti-HBs* antibody to hepatitis B surface antigen, *IVIG* intravenous immunoglobulin
[a]Note HBV DNA may be intermittently detected at low levels (referred to as occult HBV infection)

- HBsAg is the serologic marker of acute and chronic HBV infection. HBsAg usually appears in the serum 1–10 weeks after acute exposure to HBV, and its persistence in the serum for more than 6 months generally defines CHB. Transient HBsAg detection can occur after vaccination [21].
- Hepatitis B surface antibody (anti-HBs) is the marker of immunity. Anti-HBs can develop in response to HBV exposure (natural immunity) or through vaccination (vaccine immunity).
- Antibody to hepatitis B core antigen (anti-HBc) indicates prior exposure to HBV and remains positive even if anti-HBs may wane. After an acute HBV exposure, a window period may exist during which time the HBsAg is declining and anti-HBs is rising. During this period, both HBsAg and anti-HBc may be undetectable, and IgM anti-HBc and HBV DNA are used to diagnose acute HBV in this window period. The presence of isolated anti-HBc in the absence of HBsAg and anti-HBs can be seen in several settings, but it most frequently represents past exposure to HBV with resolved or resolving infection. Rarely, an isolated anti-HBc can represent occult infection with detectable HBV DNA [22]. Transient detection of anti-HBc can also be seen in patients who have recently received blood products, especially intravenous immunoglobulin infusion [23].

For transplant candidates with CHB, as evidenced by a positive serum HBsAg, HBV DNA level should be obtained to determine the need for HBV antiviral therapy and, if antiviral therapy is initiated, response to therapy. For those patients on the waiting list who do not meet the criteria for antiviral therapy, serial monitoring of ALT and HBV DNA levels every 3–6 months is recommended [17]. HDV antibody testing should be performed for those with positive HBsAg, regardless of HBV DNA level. If anti-HDV antibody is positive, HDV RNA testing should be measured to assess for active chronic HDV infection.

For those transplant candidates who are HBsAg-negative and anti-HBc-positive, no further testing is needed unless ALT levels are elevated. HBV DNA will help to rule out occult HBV infection. In this setting, if HBV DNA is detected, levels are typically low (<100 IU/mL) [24] and may not warrant treatment unless the patient is immunosuppressed. HBsAg-negative and anti-HBc-positive patients (with or without antibody) are not at risk of HBV-related complications unless HBV reactivation occurs (see below), and antiviral therapy can be used to prevent reactivation in the setting of immunosuppression.

The current Organ Procurement Transplant Network (OPTN) policy in the United States requires that all deceased organ donors are tested for HBsAg and anti-HBc (Table 2). OPTN policy also requires all potential living donors to be tested for HBsAg, anti-HBs, and anti-HBc [25]. Additional testing, including donor IgM anti-HBc or HBV DNA using sensitive nucleic acid test (NAT), may be performed by the individual organ procurement organizations to further guide decisions about accepting these potential organs and should be done in high-risk donors [26]. Rare HBV transmission and de novo hepatitis B infection (DNB) have been described in recipients who receive organs from donors with negative anti-HBc, HBsAg, and

Table 2 Interpretation of screening tests in donors

Screening test results			Interpretation of donor's HBV status	Donor status for transplantation
HBsAg	Anti-HBc IgG/IgM	HBV DNA		
–	–	–	No HBV	Acceptable
+	+	+/–	Chronic HBV	Reject – though rarely centers may use in life-threatening situations
–	IgG+	+	Occult HBV	Reject – though rarely centers may use in life-threatening situations
–	IgG+	–	Prior HBV exposure or false positive (if DNA negative)	Acceptable, with high-risk consent
–	IgM+	+	Acute HBV	Reject – though rarely centers may use in life-threatening situations
–	IgG-/ IgM-	+	If PHS high-risk donors, may be early acute infection	Reject – though rarely centers may use in life-threatening situations

HBsAg hepatitis B surface antigen, *anti-HBc* antibody to hepatitis B core antigen, *HBV* hepatitis B virus, *PHS* public health service

HBV DNA but with high-risk behavior, including injection drug use [27]. The recent opioid crisis and increasing number of deaths due to overdose have resulted in an increase in donors with Public Health Services high-risk profiles from 8.9% in 2010 to 26.3% in 2017. Given this statistic, all donors should be tested for HBV DNA by NAT.

In the United States, 4.8% of donors from 2010 to 2017 were from anti-HBc-positive donors, while 0.1% of donors were from HBsAg-positive donors [28]. Donors who are HBsAg-positive are high risk for transmission of HBV and are rarely used for transplantation. Donors who are anti-HBc-positive or HBV DNA-positive (but HBsAg-negative) may transmit HBV but with the risk varying by organ type and HBV serologic status of the recipient. These donors may be used in recipients in urgent need of transplantation after detailed review of the risks [29].

Evaluation of Stage of Liver Disease

Assessment of hepatic fibrosis severity and liver function is essential in HBsAg-positive non-liver transplant candidates, to both exclude the need for dual transplantation as well the need for antiviral therapy. Advanced hepatic fibrosis and/or hepatic decompensation may preclude a safe non-liver transplant and lead to consideration of dual organ transplantation. The presence of cirrhosis is an indication for antiviral therapy regardless of HBV DNA and ALT levels [17].

Historically, a liver biopsy was used to determine fibrosis stage, but noninvasive options are available, allowing most patients to avoid a liver biopsy. Measurement of

liver stiffness using transient elastography or magnetic resonance elastography is the primary mode to noninvasively assess fibrosis. However, limitations of these noninvasive assessments in certain patient populations are important to recognize. As an example, elevated central venous pressure and passive hepatic congestion that occur in end-stage renal disease and heart failure may lead to an overestimation of fibrosis stage by elastography measures [30]. Nevertheless, elastography measurement can be useful even in this population given that a low stiffness score, with its high negative predictive value for cirrhosis, may effectively rule out the presence of cirrhosis [31]. Serum blood tests, such as Fibrosis-4 (FIB-4) and AST to Platelet Ratio Index (APRI), combined with liver stiffness measurements can increase the accuracy of excluding cirrhosis [32]. If the noninvasive tests indicate the presence of advanced fibrosis (stage F3 or F4), a liver biopsy is recommended to assess further. If done via the transjugular route, the hepatic venous pressure gradient can also be measured concurrently, providing information on whether portal hypertension is present.

HBV Reactivation and Implications for Transplant Recipients

Reactivation of HBV is defined as one of the following: (1) $\geq$2-log$_{10}$ increase in HBV DNA level, (2) detection of HBV DNA in a patient with previously undetectable DNA, or (3) reverse HBsAg seroconversion (reappearance of HBsAg in previously HBsAg-negative patient) [17]. HBV reactivation can be followed by an ALT flare, defined as the abrupt increase in ALT to $\geq$100 IU/L and $\geq$3 times baseline level. Flares are preceded by increasing HBV DNA levels. In response to the increased levels of HBV DNA and antigen expression, the immune response is enhanced resulting in hepatocellular injury [33].

The clinical outcome of HBV reactivation with flare in the setting of immunosuppression can range from asymptomatic to severe hepatitis. Severe hepatitis can potentially lead to ALF, characterized by severe hepatic dysfunction with coagulopathy and encephalopathy. According to the United States Acute Liver Failure Study Group, of the 156 cases of HBV-associated ALF from 1998 to 2015, 28 cases (18%) occurred in the setting of immunosuppression use. Immunosuppression-induced ALF from HBV was associated with lower 21-day transplant-free survival [34]. Even in those patients that avoid the development of ALF, the presence of active CHB portends poorer long-term outcomes in the setting of post-transplant immunosuppression with increased rates of histologic progression, development of cirrhosis, and diagnosis of HCC [35, 36].

Thus, clinicians should be aware of two distinct, “at-risk” populations of transplant recipients. First are the HBsAg-positive recipients, whose chronic infection can be exacerbated by immunosuppression and lead to a rapid progression of hepatitis. Second, are recipients with resolved HBV infection (HBsAg-negative, anti-HBc-positive, $\pm$anti-HBs) who may experience reactivation of HBV

in the setting of transplant-related immunosuppression. Additionally, donors with prior exposure to HBV may potentially transmit the virus to uninfected recipients, leading to DNB.

Natural History of Post-Transplant Recipients with Chronic Hepatitis B

Liver Transplant Recipients

Historically, patients with CHB undergoing LT had worse long-term survival than patients without HBV. For LT recipients, recurrence of HBV was frequent and associated with 5-year survival of only 50% as compared to 80% seen in those transplanted for other types of liver diseases [37, 38]. Factors associated with recurrence were high HBV DNA levels and presence of hepatitis B envelope antigen, whereas as those with ALF and HDV coinfection had lower rates of recurrence [39]. A unique variant of recurrent HBV called severe fibrosing cholestatic hepatitis (FCH) occurred in less than 5% of transplant recipients but was associated with rapidly progressive hepatitis leading to graft loss. Histologically, FCH is characterized by cholestasis, ballooned hepatocytes, a paucity of inflammatory cells, and pericellular fibrosis [40]; HBV DNA levels are very high (both in serum and in liver) leading to the conclusions that the injury is related to the direct cytopathic effects of HBV, rather than injury from the immune response [41]. In the current era, FCH is rarely seen, as safe and effective antivirals can effectively prevent and treat recurrent HBV infection in LT recipients.

Other Solid Organ Transplant Recipients

The outcomes of non-liver SOT recipients with CHB are best studied in KT recipients. Prior to the availability of safe and effective antivirals, KT recipients positive for HBsAg had higher rates of mortality and graft failure than recipients negative for HBsAg [36]. Liver-related complications were the primary cause of death [42, 43]. However, with routine use of antiviral therapy after KT, this risk has been mitigated, and excellent outcomes have been observed [44, 45]. Frequent HBV reactivation has been reported after heart transplantation, but with antiviral therapy, the outcomes for HBsAg-positive recipients have been excellent without increases in HBV-related morbidity and mortality [46].

SOT recipients with CHB are at risk for HCC. In a review of 178,367 non-liver SOT recipients, the reported HCC incidence was 6.5 per 100,000 person-years with a hazard ratio of 9.7 (95% CI 2.8–33) for those with HBsAg positivity [47]. Standard criteria for HCC surveillance apply to SOT recipients with CHB including all patients with cirrhosis and those in high-risk subgroups such as HDV coinfection (Table 3). Surveillance for HCC with ultrasound (with or without serum alpha-fetoprotein levels) every 6 months is recommended.

Table 3 Indications for hepatocellular carcinoma surveillance in transplant recipients with chronic HBV[a]

Who to screen?
• All HBsAg-positive persons with cirrhosis • HBsAg-positive adults without cirrhosis if: 1. Asian or black men over 40 years of age 2. Asian women over 50 years of age 3. First-degree family member with a history of HCC 4. HDV coinfection
How to screen?
• Surveillance should be performed with ultrasound with or without serum AFP levels, every 6 months

HBV hepatitis B virus, *HBsAg* hepatitis B surface antigen, *HCC* hepatocellular carcinoma, *HDV* hepatitis D virus, *AFP* alpha-fetoprotein
[a]Excludes recipients with HCC pre-transplant

Hematopoietic Stem Cell Transplant Recipients

A systemic review of 42 studies described a more aggressive behavior of HBV in the setting of hematologic malignancy and hematopoietic stem cell transplant (HSCT) [48]. The use of cytotoxic chemotherapy enhances the immunosuppressive state in these patients, and patients with CHB are at high risk for HBV reactivation [49]. Prophylactic antiviral therapy significantly reduces rates of HBV reactivation in patients with hematologic malignancies [50] and is recommended for all HBsAg-positive HSCT recipients [51].

Anti-HBc-Positive, HBsAg-Negative Transplant Recipients

While HBsAg-positive transplant recipients are the minority of SOT recipients, a larger proportion of transplant recipients will have evidence of resolved HBV infection (HBsAg negative, anti-HBc positive ± anti-HBs). Such recipients have a potential risk of HBV reactivation post-transplant, under the effects of immunosuppression [52, 53]. However, reactivation after transplant is rare in the reports of liver, kidney, and heart transplants published to date, and when managed well, outcomes post-transplant appear to be similar to recipients without prior HBV exposure [52–54]. In contrast, reactivation in HSCT recipients is more frequent and associated with risk of liver complications, and thus antiviral prophylaxis is recommended in anti-HBc-positive HSCT recipients [51].

Management of Hepatitis B in the Transplant Setting

Given the potential impact of HBV on patient outcomes after transplant, management strategies should focus on (1) prevention of HBV recurrence in LT recipients; (2) reducing risk of HBV disease progression post-transplant in those with CHB; and

(3) prevention of HBV transmission from donor to recipient. These goals can be achieved through the combination of prudent vaccination, observation, and pharmacologic therapy. Additionally, prevention of DNB infection in the pre- and post-transplant settings through comprehensive vaccination programs is essential.

Overview of HBV Therapies

First-line antiviral therapy for treatment of active HBV includes the oral nucleoside analogue, entecavir, and nucleotide analogues, tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF) (Table 4). These nucleos(t)ide analogues (NA) have excellent tolerability and achieve high rates of viral suppression with low risk of viral resistance. Older NAs including lamivudine, adefovir, and telbivudine are not preferred owing to their higher risk of resistance. In patients with renal dysfunction or bone disease, entecavir or TAF is recommended over TDF given the risk of decline in bone density and renal function with chronic TDF use [17]. TAF is more stable in plasma than TDF and delivers the active metabolite to hepatocytes more effectively at a lower dose. In phase 3 studies, TAF caused significantly less decline in renal function and bone density as compared to TDF at 48 weeks of treatment [55, 56]. This is especially relevant in transplant recipients, where concurrent use of calcineurin inhibitors increases risk for renal dysfunction post-transplant, and chronic steroids use decreases bone density. In patients with prior lamivudine exposure, TDF or TAF should be used as there is greater risk of entecavir resistance in these patients (up to 50% after 5 years) [57]. Resistance is very rare with TDF and TAF, though recently, a quadruple mutation that conferred high-level tenofovir resistance was described [58]. In any adherent patient with virologic breakthrough on antiviral therapy (defined by >1 $\log_{10}$ increase in HBV DNA or >100 IU/mL if

Table 4 Antiviral therapies for transplant recipients with chronic HBV

[a]Unless on fully suppressive ART

previously undetectable), resistance testing should be considered and a change in antivirals made. For patients on entecavir with virologic breakthrough, the NA therapy should be switched to TDF or TAF. If tenofovir resistance is noted, the NA therapy should be switched to entecavir. In case of multidrug resistance, the combination of TDF or TAF with entecavir can be used [17].

Pegylated interferon is also considered a first-line therapy for HBV and is the only available therapy for HDV [17]. However, its use in transplant recipients with CHB is not recommended since well-tolerated, safe, and highly effective oral therapies are available. Moreover, pegylated interferon is associated with bone marrow suppression and risk of graft rejection [59, 60]. However, for transplant recipients with severe or progressive liver disease due to HDV infection, pegylated interferon may still need to be considered.

Vaccination to Prevent De Novo HBV in the Transplant Setting

For those with serologies negative for HBsAg, anti-HBc, and anti-HBs, vaccination is indicated. In patients with positive, isolated anti-HBc with negative HBsAg and anti-HBs, the serologies may indicate occult HBV, prior exposure to HBV with low, undetectable anti-HBs titer, or false-positive anti-HBc test. To avoid a missed opportunity to protect susceptible individuals (i.e., those with false-positive anti-HBc test), any patient with absent anti-HBs should be vaccinated [17]. In immunocompetent patients, the protection is generally considered life-long, and postvaccination serologic testing is not routinely recommended. However, in immunocompromised patients, as in patients with end-stage diseases awaiting transplant, measurement of anti-HBs titer after vaccination may be important to determine protection [61]. Annual anti-HBs titer is recommended in immunocompromised patients or patients undergoing hemodialysis. If titers fall below 10 IU/L, booster vaccination is recommended. Whenever possible, the vaccination series should be given prior to transplant since the vaccine response is less effective after transplant [62, 63]. In patients with cirrhosis, hemodialysis patients, and post-transplant patients, strategies to increase vaccine responsiveness include the use of high dose or four (versus three doses) series [64]. The recently approved HEPLISAV-B vaccine, which includes a Toll-like receptor-9 as adjuvant and is given as 2 doses 1 month apart, has shown superior response rates compared to three-dose Engerix® in healthy adults and those with diabetes so may offer advantages in patients with end-stage disease awaiting transplantation [65].

Prevention of Recurrent HBV in Liver Transplant Recipients

Guidelines recommend antiviral therapy for all HBsAg-positive patients with cirrhosis, regardless of HBV DNA or ALT levels; thus, all LT patients on the waiting list should be on antiviral therapy (Fig. 1) [17].

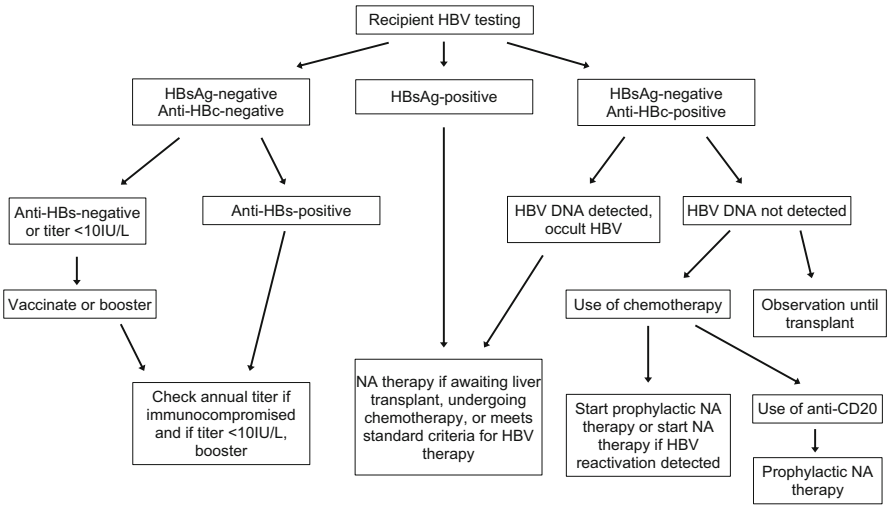

Fig. 1 Management of recipients prior to organ transplantation. Abbreviations: *HBV* hepatitis B virus, *HBsAg* hepatitis B surface antigen, *anti-HBc* antibody to hepatitis B core antigen, *anti-HBs* antibody to hepatitis B surface antigen, *NA* nucleos(t)ide analogue

In HBsAg-positive LT recipients, reinfection and recurrence of HBV are frequent unless prophylactic therapy is provided. Reinfection is defined by the reappearance of HBsAg in the recipient after LT and is almost always followed by recurrence of HBV liver disease if untreated. Prophylactic strategies include treatment with NA with and without hepatitis B immune globulin (HBIG). HBIG is a polyclonal preparation of anti-HBs from plasma donors that binds and neutralizes circulating virions, reducing liver graft reinfection. Prior to the availability of NA, the use of post-LT HBIG prophylaxis alone dramatically improved outcomes of recipients undergoing transplant for HBV complications [66, 67]. The combination of NA and HBIG post-LT has further reduced HBV recurrence rates to less than 10% [68]. HBIG helps to prevent reinfection of the graft, while NA prevents HBV disease and recurrence through viral suppression. While many LT centers utilize HBIG in the early post-LT setting, oral NA alone appears to be equally effective with low rates of recurrent HBV disease with active viral suppression [69, 70] There is currently no consensus on the dose and duration of HBIG therapy after LT. It is a reasonable strategy to give daily HBIG in the immediate post-LT setting for 5–7 days and transition to NA therapy alone afterward [71]. Long-term HBIG with NA can be considered if the patient has higher than average risk for HBV recurrence including the presence of drug-resistant HBV, high DNA at time of LT, and lack of access to NAs with high barrier to resistance (entecavir, TDF, and TAF) [72] (Table 5). HBIG should not be used alone without NA given higher rates of HBV recurrence. Post-LT, NA should be continued indefinitely.

Special consideration for long-term HBIG can also be made for patients with HDV or human immunodeficiency virus (HIV) coinfection with HBV. Oral NA

Table 5 Factors influencing the choice of antiviral prophylaxis after liver transplantation in HBsAg-positive recipients

Indefinite NA alone or with short-term HBIG	Indefinite NA with long-term HBIG
Absence of drug-resistant HBV	Drug-resistant HBV
Undetectable to low HBV DNA at time of transplantation	High HBV DNA at time of transplantation
Lack of access to HBIG	Lack of access to high-potency NA (entecavir, TDF, or TAF)
HBsAg-positive liver graft	HIV coinfection
	HDV coinfection

HBsAg hepatitis B surface antigen, *NA* nucleos(t)ide analogue, *HBIG* hepatitis B immune globulin, *HBV* hepatitis B virus, *TDF* tenofovir disoproxil fumarate, *TAF*, *HIV* human immunodeficiency virus, *HDV* hepatitis D virus

has no direct efficacy against HDV. Given that HDV requires HBsAg for infection, post-LT combination therapy with NA and long-term HBIG to optimize HBsAg clearance may be ideal. In patients with HIV and HBV coinfection, low-level viremia without detectable HBsAg was detected in approximately 50% of recipients despite combination NA and HBIG therapy, suggesting that long-term HBIG may have an added role in this population to reduce HBV reinfection [73].

Prevention of De Novo Infection in Recipients of Anti-HBc-Positive Donors

Donors with anti-HBc (with or without anti-HBs) pose the highest risk of HBV transmission to liver graft recipients [74]. Recipients of non-liver SOT are at low risk, and thus, prophylactic strategies are primarily determined by the type of transplant recipient. However, further modification of risk is dependent upon the HBV status of the recipients. As a general strategy, use of these organs in recipients who already have markers of HBV exposure is preferred (HBsAg- or anti-HBc-positive) as it simplifies post-transplant management [26]. However, given the current organ shortage, this option is not always available, and recipients who are HBsAg- and anti-HBc-negative are often given these organs, placing them at risk for DNB.

Liver Transplantation

The majority of data on use of anti-HBc-positive donors derive from experience in LT. Without prophylaxis, the risk for DNB, defined by the appearance of HBsAg or detectable HBV DNA, can be substantial but varies with the immune status of the recipient [75]. In a review of 90 cases of DNB in 194 liver recipients, the risk of transmission was highest in anti-HBs-negative recipients (76.6%), lowest in anti-HBs-positive, anti-HBc-positive recipients with natural immunity (0%), and modest (18.2%) in patients with vaccine-induced immunity (HBsAg-negative, anti-HBs-positive, and anti-HBc-negative) [76].

Combination antiviral therapy with NA and HBIG has been used and associated with reduction in the DNB rate from 58% to 11% in HBV nonimmune recipients. In patients with vaccine immunity, the rate dropped from 18% to 2%. Prophylaxis did not further reduce the risk of transmission in recipients with natural immunity (3–4%) [73]. Subsequent studies have shown HBIG alone did not confer a significant benefit, and NA alone is effective in lowering DNB rates [76, 77]. High-potency NA (entecavir, TDF, or TAF) is recommended in this setting over lower-potency NA (lamivudine, adefovir, or telbivudine). In a retrospective study of 964 LT recipients in Hong Kong, anti-HBc-positive grafts did not adversely impact long-term outcomes. Of the HBsAg-negative recipients that received anti-HBc-positive organ, the risk of DNB was overall low at 2.8%. However, all DNB occurred in the group receiving lamivudine prophylaxis, while none occurred in the entecavir prophylaxis group [78]. Lamivudine may be an acceptable choice where cost influences decision-making.

Nonimmune LT recipients without prior exposure to HBV (anti-HBs-negative, anti-HBc-negative) and recipients with vaccine immunity (anti-HBs-positive, anti-HBc-negative), who receive an isolated anti-HBc-positive liver graft, should receive indefinite NA therapy alone without HBIG [17]. NA therapy is not recommended if the recipient has natural immunity to HBV (anti-HBs-positive, anti-HBc-positive), but monitoring with HBV DNA and/or HBsAg every 3 months for the first year and during periods of intensified immunosuppression, as with treatment of acute graft rejection, is recommended (Fig. 2). Additionally, if abnormal liver tests develop post-LT, testing of HBV serologies and HBV DNA should be considered.

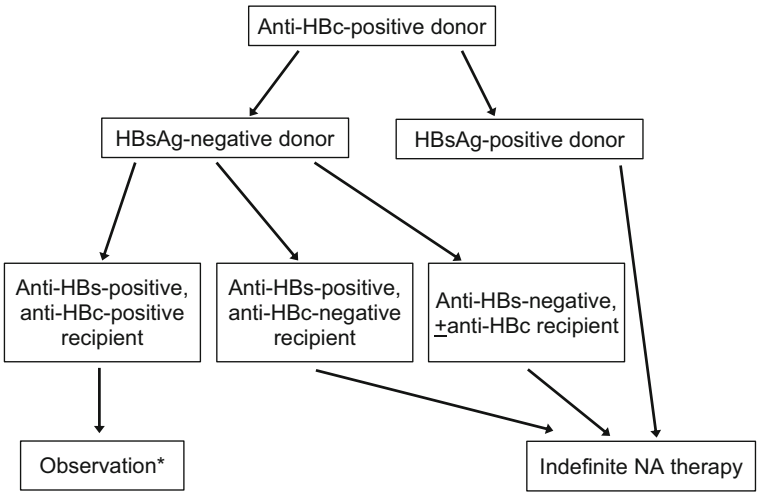

Fig. 2 Algorithm for the use of liver grafts from anti-HBc-positive donors in recipients with and without chronic HBV. ∗Monitor with HBsAg or HBV DNA every 3 months for the first year and during any period of intensified immunosuppression (i.e., treatment of acute rejection). Abbreviations: *anti-HBc* antibody to hepatitis B core antigen, *HBV* hepatitis B virus, *HBsAg* hepatitis B surface antigen, *anti-HBs* antibody to hepatitis B surface antigen, *NA* nucleos(t)ide analogue

Non-liver Transplantation

The reported risk of DNB from isolated anti-HBc-positive donor in non-LT recipients is much lower than compared to LT recipients, about 0.3% in KT [79]. As in LT recipients, the risk of DNB depends on the recipients' HBV immune status. In non-liver transplant recipients who are immune (vaccine or natural immunity), the DNB risk is negligible, and no antiviral prophylaxis is required [80, 81]. Close monitoring with HBV DNA and/or HBsAg should be performed every 3 months for the first year or when immunosuppression is most intensive such as with treatment of acute graft rejection. In nonimmune recipients (anti-HBs-negative, ±anti-HBc), DNB risk is presumably due to the presence of HBV DNA in the plasma of the donor organ. Thus, if donor serum HBV DNA is undetectable, no antiviral therapy is warranted. If donor serum HBV DNA is positive or unknown, prophylaxis with either NA or HBIG in the early post-transplant period and for up to 6–12 months should be considered (Fig. 3) [82].

Managing Anti-HBc-Positive Transplant Recipients (HBsAg-Negative)

Presence of anti-HBc indicates prior exposure to HBV; false-positive tests can occur, albeit very infrequently. Such recipients may or may not have anti-HBs, but if anti-

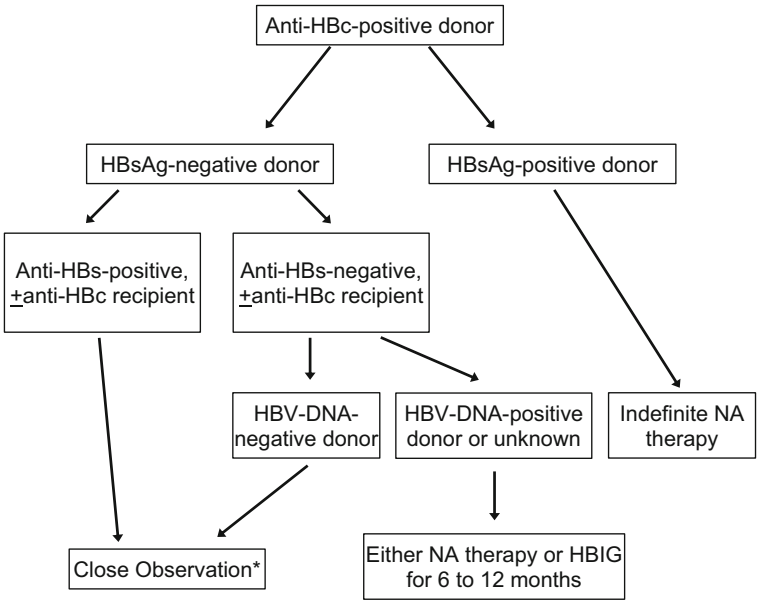

Fig. 3 Algorithm for the use of non-liver grafts from anti-HBc-positive donors in recipients without chronic HBV. ∗Monitor with HBsAg or HBV DNA every 3 months for the first year and during any period of intensified immunosuppression (i.e., treatment of acute rejection). Abbreviations: *anti-HBc* antibody to hepatitis B core antigen, *HBV* hepatitis B virus, *HBsAg* hepatitis B surface antigen, *anti-HBs* antibody to hepatitis B surface antigen, *NA* nucleos(t)ide analogue, *HBIG* hepatitis B immune globulin

HBs is present, this confirms prior exposure and is less likely to be associated with occult HBV infection, defined as presence of viremia in HBsAg-negative patients with prior HBV exposure. HBV DNA should be obtained pre-transplant to identify the rare patient with occult CHB, and if HBV DNA is positive, these patients should be treated similarly to patients with CHB.

The majority of transplant recipients with positive anti-HBc will have undetectable HBV DNA pre-transplant but are at variable risk for HBV reactivation post-transplant. In HBsAg-negative, anti-HBc-positive liver recipients receiving HBV-negative grafts, HBV replication has been demonstrated on liver biopsy, but none of the LT recipients became HBsAg-positive post-transplant [54]. Presumably, the source of HBV in these patients is from extrahepatic reservoirs but is not of clinical consequence. Thus, HBV prophylaxis and routine monitoring of HBV reactivation are not required in HBsAg-negative but anti-HBc-positive LT patients.

In non-liver transplants, the risk of post-transplant HBV reactivation in anti-HBc-positive donors is estimated to be at most 5% [52, 83]. Here, the source of HBV is cccDNA from the recipient's liver that reactivates under the effects of immunosuppression. Routine HBV antiviral therapy is generally not indicated. However, the risk is increased during intense immunosuppression. Rituximab, a monoclonal antibody that targets the B-cell marker CD20, is often used in KT recipients for desensitization and is associated with high rates of HBV reactivation [84]. In these patients, prophylactic, antiviral therapy with entecavir, TDF, or TAF is recommended. Cessation of therapy can be considered after 6 months of therapy with high-dose immunosuppression or 12 months after anti-CD20 therapy [85]. Repeat HBsAg and HBV DNA testing is not required in patients managed with antiviral prophylaxis unless there are concerns regarding medication adherence.

Reactivation occurs due to the loss of protective anti-HBs (if present at baseline) followed by a rise in HBV DNA and reverse HBsAg seroconversion. Therefore, in patients who do not start antiviral prophylaxis, close monitoring for HBV reactivation can be performed with HBV DNA and HBsAg every 3 months for the first year or in the context of intensification of immunosuppression as in treatment of acute graft rejection. If a patient has reverse HBsAg seroconversion or HBV DNA progressively rises, a high-potency NA (entecavir, TDF, or TAF) should be started [82]. Additionally, evaluating for HBV reactivation should be considered if unexplained ALT elevations develop.

Management of Recipients of HBsAg-Positive Donors

The risk of DNB is high in nonimmune, HBsAg-negative recipients who receive organs from HBsAg-positive donors [86]. Therefore, risks and benefits of accepting such organs should be carefully weighed, especially in nonurgent transplants. For transplant candidates who already have CHB, the risk associated with a HBsAg-positive donor is negligible for non-liver organ recipients but may be significant for LT recipients without appropriate prevention.

Liver Transplantation

Livers from HBsAg-positive donors have been donated to recipients with CHB. Comparison of recipients with CHB who received livers from HBsAg-positive and HBsAg-negative donors have shown no difference in postoperative morbidity and mortality. All recipients received oral NA postoperatively. HBsAg persisted after transplant in all recipients who received HBsAg-positive donor livers despite HBIG use [87, 88]. This is not surprising since the liver had established HBV infection at the time of transplantation, so HBIG has no role. Thus, CHB recipients who receive liver grafts from HBsAg-positive donors should be treated with indefinite NA alone after LT (Fig. 2). To minimize any risk for virologic breakthrough, the NA with high barrier to resistance should be used. Moreover, since prior NA exposure history may not be available for the donor, it is prudent to use TDF or TAF and not entecavir as the latter has lower efficacy if there has been prior lamivudine exposure [57].

Care should be taken during liver procurement to ensure that the donor liver does not have significant fibrosis that might impact long-term post-LT graft survival. Both the recipient and donor need to be tested for HDV coinfection. HDV coinfection is a contraindication to the use of organs from HBsAg-positive donors due to the lack of safe and effective therapies for HDV after LT. As HBsAg universally persists after HBsAg-positive liver donation despite prophylaxis, HDV can establish in the liver graft and can cause active necroinflammation, potentially leading to graft failure despite the control of the HBV with NA [89].

Non-liver Transplantation

Successful transplants of kidneys from HBsAg-positive donors to HBV immune (anti-HBs-positive) recipients have been described. Although potential transmission risk is present, the combination of HBIG and oral antiviral therapy have been effective in preventing HBV-related complications with similar graft and patient survival. In a study of 129 KT recipients with anti-HBs titer above 100 IU/L, no difference in patient survival, graft survival, and HBV transmission was seen between the HBsAg-positive and HBsAg-negative donor groups, even in the absence of HBV prophylaxis, suggesting that high-titer anti-HBs may lower DNB in this cohort [90]. Thus, organs from HBsAg-positive donors can be considered in patients who are immune to HBV. All patients should receive indefinite NA therapy with high barrier to resistance (entecavir, TDF, or TAF) post-transplant [26]. Monitoring with HBV DNA and HBsAg should be performed every 3 months in the first year and 6 months indefinitely thereafter, plus as indicated clinically (Fig. 3) [26, 82].

Managing Transplant Recipients with Chronic Hepatitis B

Post-transplant recipients with CHB include those with pre-transplant HBV infection and those who acquire HBV post-transplant from donor or other sources. All HBsAg-positive patients who are the waiting list should be evaluated to determine the need for pre-transplant antiviral treatment (Fig. 1). As highlighted above, all LT

candidates should be on antiviral therapy. For other transplants, the decision to treat while on the waiting list is based on levels of HBV DNA and the stage of liver fibrosis (Table 6). Entecavir, TDF, and TAF are preferred NAs. Surveillance for HCC should also be initiated in individuals with cirrhosis, positive family history for HCC, HDV coinfection, or prolonged duration of infection (ethnicity and age based) (Table 3) [17].

Post-transplant, all non-liver recipients with pre-transplant CHB should be on antiviral therapy with NA to prevent HBV reactivation and/or progression, at least for the first year and potentially indefinitely. As mentioned previously, patients with CHB on post-transplant immunosuppression are at risk for accelerated progression of their liver disease. The primary goal of patients with CHB post-transplant is sustained virologic suppression to prevent HBV-related hepatitis and progression to cirrhosis and/or HCC. The ideal duration of therapy has not been established, and since most post-transplant recipients receive life-long immunosuppression, indefinite antiviral therapy provides the surest means of preventing HBV-related complications. As in the pre-transplant setting, entecavir, TDF, and TAF are preferred NAs. Entecavir and TAF are the preferred NAs in patients at risk for renal insufficiency. Dose adjustment may be required for all of the NAs, based on the patient's creatinine clearance (Table 4).

For patients who acquire DNB during or after transplant, progression of liver disease can be rapid in the face of concurrent immunosuppression. These patients need NA therapy to be started as soon as the diagnosis is made and continued on antiviral therapy indefinitely to minimize risk of future liver-related complications.

Table 6 Indications for antiviral therapy in transplant candidates and recipients with chronic HBV

Type of transplant	Indications for treatment	When to start pre-transplant	When to stop post-transplant	Comments
Liver	All patients, due to underlying cirrhosis	Immediately upon recognition of cirrhosis	Treatment is indefinite	Monitor HBV DNA every 3 months to ensure response and no evidence of virologic breakthrough
Non-Liver	Presence of cirrhosis	Immediately upon recognition of cirrhosis	Treatment is indefinite	
	HBV DNA quantifiable	Pre-transplant	Consider long-term treatment	
	HBV DNA < LLOQ	At time of transplant	At least 1-year post-transplant; can consider long-term therapy HSC: indefinite treatment	If treatment is stopped, life-long monitoring for HBV reactivation is necessary with HBV DNA tests every 3-6 months

HBV hepatitis B virus, *LLOQ* lower limit of quantification, *HSCT* hematopoietic stem cell transplant

Hepatitis D Virus

Hepatitis D virus is a defective RNA virus that requires the presence of HBV for its lifecycle. Consequently, HDV infection can only be found in HBsAg-positive patients. All patients with CHB, undergoing consideration for SOT or HSCT, should have screening performed for HDV infection with antibody testing for HDV [17]. If anti-HDV is positive, confirmation with HDV RNA testing should be performed. In patients with HDV coinfection, HBV DNA may be low or undetectable [91]. In HDV-infected patients, the annual rates of progression to cirrhosis and HCC are 4% and 2.8%, respectively [92]. There appears to be a 2.2-fold increase in hepatic decompensation and 3.2-fold increase in the development of HCC as compared to those with HBV infection alone [93].

Liver Transplant Recipients

Despite increased risk of pre-transplant decompensation and HCC development, overall outcomes after LT for HDV coinfection are generally better than in patients with HBV infection alone [39]. This is likely due to HDV suppression of HBV replication, leading to lower rates of HBV reinfection after LT [94]. If both HDV and HBV reinfection does occur after LT, clinical hepatitis is often seen with elevated ALT [95]. In a study involving serial liver biopsies of patients with HDV and HBV reinfection after LT, four of nine patients progressed to cirrhosis during a mean follow-up period of 20 months without antiviral therapy [96].

Antiviral therapy with NA does not have any efficacy against HDV infection. Interferon alfa is the only currently approved treatment for HDV but is generally poorly tolerated in the pre- and post-transplant settings and typically requires years of treatment due to the high risk of relapse [97]. Thus, the goal of therapy in the transplant setting is to prevent reinfection of a liver graft after transplant. Post-LT combination therapy with NA and long-term HBIG to optimize HBsAg clearance is recommended to reduce the risk of reinfection with HBV and HDV (Table 4).

Currently there are no published cases of donor-derived HDV transmission in non-liver transplants. OPTN does not currently recommend routine donor HDV serologic testing. Nevertheless, care and consideration for HDV coinfection should be made in donors with positive HBsAg. When possible, additional donor testing (anti-HDV and, if positive, HDV RNA) should be considered.

Conclusion

Hepatitis B virus and hepatitis D virus infections can have significant impact on transplant recipients. The evaluation and management of these patients begin well before the transplant event itself. Serologic testing of recipients and potential donors is crucial to risk-stratify patients for HBV- and HDV-related complications. With the

combination of appropriate vaccination, close observation, and pharmacologic therapy, significant morbidity and mortality can be avoided.

Key Points

- De novo hepatitis B infection, reactivation of hepatitis B during immunosuppression, and donor transmission of hepatitis B are all potential complications that can occur in the transplant setting.
- If managed appropriately, patients with chronic hepatitis B infections can have similar post-transplant outcomes to those without chronic hepatitis B infection.
- All donors and recipients with chronic hepatitis B infection should have serologies checked for hepatitis D virus infection.
- With the opioid epidemic and shortage of available organs, there will be a continued rise in use of HBV-exposed donor organs, but risk-based antiviral prophylaxis can achieve excellent outcomes in these transplants.
- Treatment with high-potency nucleos(t)ide analogues is indicated for all chronic hepatitis B-infected patients with cirrhosis who are on the liver transplant waiting list and for all transplant recipients on immunosuppression.
- Depending on the type of transplant, donor immune status, and degree of immunosuppression, prophylactic treatment with antiviral therapy may be warranted in cases where either the donor or recipient has evidence of prior hepatitis B exposure without active infection.

Introduction

Chronic hepatitis C virus (HCV) infection affects about 71 million people worldwide, two-thirds living in Europe, South Asia, and North Africa. Seven countries (China, Pakistan, India, Egypt, Russia, USA, and Nigeria) account for half of the global population of HCV infected persons [1]. Each year, Hepatitis C is responsible for approximately 399,000 deaths worldwide, mostly from cirrhosis and liver cancer [1]. HCV-related advanced liver disease and HCV-related hepatocellular carcinoma (HCC) are leading indications for liver transplantation (LT) worldwide representing 20% of all LT performed in Europe and the United States (USA) [2]. Recently, the proportion of HCV-induced cirrhosis requiring liver transplant has begun to decline in the United States, as more people gain access to high effective antiviral agents.

Sustained virological response (SVR), defined as undetectable HCV-RNA 12 months posttherapy [3, 4], represents the cure of the infection. In the interferon (IFN) era, treatment was rarely feasible in LT candidates due to their advanced liver insufficiency, and in the posttransplant setting results were modest with high toxicity [5–7]. For practical purposes, three time-periods can be identified based on HCV-treatments availability: prior to 2010 when only IFN-based regimens were available (IFN-era), from 2010 to 2013 when the first generation of direct-acting antivirals (DAAs) – boceprevir and telaprevir – two nonstructural protease inhibitors (PIs) combined with IFN and ribavirin were available (PI-IFN era) and after 2013 when all-oral DAAs combinations were approved (DAA era). Currently, pangenotypic regimes are available and represent the standard-of-care recommended by general guidelines [4]. IFN-free regimens based on these specific drug combinations are characterized by shorter treatment duration, typically 8–12 weeks. They have SVR rates greater than 97%, both in transplanted populations and nontransplant groups, pangenotypic activity, are exclusively oral administration, and generally possess an excellent safety and tolerability profile, with limited drug-drug interactions [4].

The present review provides an overview of chronic HCV infection current management and focuses on the use of DAA treatment in the field of transplant, both in the pretransplant and the posttransplant period.

Pretransplant HCV Management

Treatment Efficacy in Patients with Decompensated Cirrhosis

Several studies have investigated the efficacy of DAAs in patients with different degrees of hepatic decompensation, generally based on Child-Turcotte-Pugh (CTP) classification's classes A, B, and C (Table 1). Based on these studies, it has become clear that: (i) protease inhibitors should not be used in HCV-patients with decompensated cirrhosis (CTP-B or C); (ii) patients with decompensated cirrhosis, particularly those with CTP class C achieve lower rates of SVR; and (iii) ribavirin

(RBV) is required in some of these patients to increase efficacy [8–12]. In brief, rates of viral eradication decrease as liver function worse with SVR rates ≥90% in patients with CTP class A cirrhosis, 80–90% in patients with CTP class B cirrhosis, and only 60–80% in those with CTP Class C cirrhosis.

Functional and Clinical Evolution Following DAAs

Viral eradication results in histological and clinical improvement [13], also in patients with advanced decompensated disease, with reversal of disease severity as assessed by the model for end-stage liver disease (MELD) and Child-Turcotte-Pugh scores, and/or decreased portal hypertensive complications, eventually leading to "re-compensation" and LT avoidance. Two European studies, each one including more than 100 patients, found a significant reduction in portal hypertension following successful antiviral therapy with an overall medium reduction of hepatic venous pressure gradient (HVPG) between 2.2 and 2.6 mmHg after SVR [14, 15]. HVPG reduction though was less likely among patients with more advanced liver dysfunction (CTP B class) and clinically significant portal hypertension (HVPG ≥10 mmHg) persisted in many patients despite HCV eradication indicating a persisting risk of morbidity from portal hypertensive complications. Similarly, several studies reported liver function improvement after SVR with DAA therapy [8–10, 16, 17], quantified as reductions in MELD and CTP scores from baseline to posttreatment (Table 2); a significative reduction in rates of serious decompensation events, sepsis, or hospitalizations beyond 6 months following viral clearance was also reported [18]. Moreover, the impact of HCV eradication on the waiting list for LT was investigated in a large European study which included 103 consecutive listed patients without HCC. Delisting was feasible in about one out of five patients after a mean follow up of 60 weeks [19]. Extended follow-up to 2 years after delisting showed that DAA treatments result in long-term improvement of liver synthetic

function with a low risk of liver-related complications requiring relisting. Two years after delisting, a new HCC was diagnosed in only 4.5% (2/44) of patients previously removed from the LT waitlist [20].

Potential Harms of Treating Patients on the Waiting List

Efficacy, safety, and tolerability of DAA treatments worsen as the severity of liver disease increases. This reduction in antiviral therapy success is due to an increment in the number of nonvirologic failures (death from underlying disease progression) and virologic failures (those related to the development of long-term drug resistances which may difficult retreatment options following LT) [21]. Although retreatment options are currently available for patients who fail previous DAA therapies (glecaprevir/pibrentasvir and sofosbuvir/velpatasvir/voxilaprevir), their use is limited in patients with decompensated cirrhosis as both combinations include a protease inhibitor (NS3 PI). Furthermore, many patients in the waiting list have concomitant renal insufficiency, and the best DAA therapies in terms of security for patients with advanced liver disease, sofosbuvir-based [21], should still be used with caution in patients with severe renal impairment (estimated glomerular filtration rate [eGFR] <30 ml/min/1.73 m^2) or end-stage renal disease in hemodialysis because of residual concern about cumulative toxicity concerns regarding sofosbuvir and its renal excreted metabolite GS-331007 [22, 23]. Results from a recently ended phase 2b clinical trial, which evaluated two sofosbuvir combinations (sofosbuvir 400 mg + RBV 200 mg during 24 weeks; and ledipasvir + sofosbuvir during 12 weeks) in HCV infected patients with severe renal insufficiency, concluded that no dose adjustments can be suggested in this population, and that its use remains beyond license recommendations (https://www.ClinicalTrial.gov: NCT01958281).

Another potential limitation to treat waitlisted patients is the eventual lack of significant clinical improvements despite SVR. The "point of no return" that defines a limited hepatic repair capacity in the sickest patients is still unknown [21]. Furthermore, improvement in MELD scores after viral clearance may not reach a sufficient cut-off for delisting, leaving patients with a lower MELD score than before therapy with therefore lower LT access, according to the current organ allocation system [24]. This is referred as the "MELD limbo or purgatory" which is more likely to affect patients with high MELD scores as the magnitude of improvement in liver function from baseline ("delta-MELD") needs to be significantly higher to achieve real clinical benefits [19]. Particularly, *Belli and colleagues* showed that in patients with a MELD score >15, a delta MELD greater than 4 was required to result in meaningful improvement in the medium-long term [19]. Thus, both major Liver Transplant Societies (The European Liver and Intestine Transplant Association -ELITA- and the International Liver Transplant Society -ILTS-) recommend DAA therapy for waitlisted patients with HCV-decompensated cirrhosis and MELD score lower than 20 while in patients with higher MELD score the decision to treat should be individualized after carefully weighing the risk of a MELD purgatory effect related to an expected prolonged waiting time [21, 25]. In reality, the drive to treat HCV ahead of transplant is also balanced against the wait times for liver allocation in

that patient's region, and their willingness to also take a HCV-viremic donor. In many cases in the United States, the time taken to allocate a viremic organ is significantly less, hence waiting to initiate DAA treatment until after transplant, as a means of facilitating more rapid transplant, may be preferred.

Objective tools to assess whether the benefits of treating patients with HCV-decompensated cirrhosis outweigh the previously mention risks have been recently investigated. A study from Spain [26] which included 43 patients with cirrhosis treated with new DAAs explored baseline liver volume obtained through imaging assessment and adjusted by body surface area, as a noninvasive instrument to predict improvement of liver function over time after viral eradication. In addition, a clinically based tool to predict liver repair capacity following DAA therapy was recently published, consisting in a predictive score (BE3A score) based on 5 clinical and analytical variables; so that a body mass index <25 kg/m^2, serum levels of albumin >3.5 g/dL, and alanine aminotransferase (ALT) >60 IU/L together with absence of encephalopathy and/or ascites predict a greater probability of achieving re-compensation (reduction of CPT score to class A) and thus future benefit from DAA treatment before LT [16].

DAA Benefits in Patients with HCC on the Waiting List for Liver Transplant

Although initial studies suggested a potential increase in the risk of aggressive tumor recurrence and/or development of de novo HCC in patients treated with DAA therapy [27, 28], recent and more properly designed studies have demonstrated that these therapies are not harmful for LT candidates with HCC. Results from the French ANRS collaborative study group on HCC, prospectively including more than 6000 patients from three different cohorts, did not show a higher risk of HCC recurrence after DAA therapy than that historically observed in HCV-patients not treated with DAA combinations [29]. Concordantly, in a retrospective single center study of 149 waitlisted patients for HCV-related HCC in the United States from 2014 to 2016, DAA therapy had no impact on rates of HCC recurrence after local-regional treatment and was associated with a reduction in waitlist dropout due to death or tumor progression and with a trend towards increased likelihood of survival [30]. Several recent very large studies as well as meta-analyses have confirmed that both de novo and recurrent HCC are significantly reduced following SVR. Finally, in a large recent North American study which included 62,354 patients who initiated antiviral therapy in the Veterans Affairs national healthcare system from 1 Jan 1999 to 31 Dec 2015, viral eradication was associated to an overall HCC risk reduction of 70%, which confirms DAA therapies' benefits in terms of HCV-related HCC [31].

Impact of DAA on LT Waiting Lists

The main consequence of these therapies has been the significant reduction in new registrations for HCV-indications (Table 3) [2, 32–34]. This reduction has been more

Table 3 Impact of Direct -Acting Antivirals (DAA) on LT waiting lists (WL)

[b]Non applicable

significant in patients with HCV-decompensated cirrhosis than in those with HCV-related-HCC [2, 32–34]. This fact has been postulated to be related to (i) an increased residual risk for HCC versus decompensation in HCV-patients after viral eradication, (ii) aging of LT candidates with the consideration of old candidates with HCV-decompensated cirrhosis to be worse candidates than those with HCV-related-HCC, and (iii) possibility of delisting for clinical improvement following SVR in HCV-patients with decompensated cirrhosis unlike patients with HCC who cannot avoid LT indication in spite of decompensation reversal [35]. On the other hand, as the proportion of LT procedures for HCV-related diseases decline, the rate of LT indications for nonalcoholic fatty liver disease (NAFLD) and for alcohol-associated liver disease increases thus maintaining the number of LT performed in Europe and USA, stables over time [2, 34, 35].

Posttransplant HCV Management

DAA Regimens After Liver Transplantation

In LT recipients for HCV-related disease, HCV recurrence is nearly universal [36]. In the posttransplant setting, the natural history of HCV infection is accelerated compared to the pretransplant phase mostly due to immunosuppression. The proportion of HCV recipients that evolve to cirrhosis within 5 years after LT is approximately

15–30% [37, 38] with a subset of subjects developing a rare but severe form of recurrence, which leads to liver failure and death in only few months, so-called fibrosing cholestatic hepatitis (FCH) [37, 38]. Such events are now considered rare with efficacious early posttransplant administration of DAA therapy.

Treatment of HCV recurrence in LT recipients has been traditionally challenging because of the poor efficacy, high toxicity, and risk of rejection associated to IFN-based regimens [39]. A variety of oral DAA combinations have shown very high success rates and excellent safety profiles in patients with HCV without cirrhosis or with compensated cirrhosis post-LT (Table 4) [8, 9, 40–45]. Excellent SVR rates have also been reported in subjects with FCH, the most uncommon and life-threatening form of HCV recurrence (Table 5) [8, 9, 46, 47]. However, similarly to what has been published in nontransplanted subjects, worst results are observed in HCV recipients with decompensated graft cirrhosis and portal hypertension (Table 5) [8, 9, 46, 47].

In terms of timing of therapy post-LT, most experts recommend starting therapy as early as possible once the complications from the LT surgery have subsided, to improve tolerability and reduce drug-drug interactions. Indeed, an exquisite evaluation of drug-drug interactions is needed in all patients, but particularly in transplant recipients given the potential effect on immunosuppression trough levels. Strict monitoring of drug levels with adjustments as needed is required both during and after antiviral therapy [21, 25].

Impact of DAA on Posttransplant Outcomes of HCV-Positive Recipients

The advent of newer DAA therapies has dramatically changed post-LT outcomes of HCV recipients. In the large European study based on the ELTR database, authors showed a significant improvement of 3-year survival in patients transplanted for HCV-decompensated cirrhosis, from 65.1% in the IFN-era to 76.9% in the DAA era, results that are now equal to those achieved by LT recipients with chronic hepatitis B virus (HBV) infection [2]. Concordant results were observed in the recent USA-Scientific Registry of Transplant Recipients study where 52,526 LT recipients were included. In the DAA era, the 3-year graft survival was found to have increased four-fold more for HCV-positive recipients than for non-HCV recipients, with both groups of patients currently obtaining similar outcomes following LT [48].

Early studies in the modern DAA era assessed recurrent HCV infection after LT. SOLAR-1 was a randomized, multicenter trial, run out of the United States, with 223 liver transplant recipients with genotype 1 and 4, across all stages of fibrosis and cirrhosis. SVR12 rates using ledipasvir, sofosbuvir, and ribavirin for 12 or 24 weeks were 96–98%. SOLAR-2 trial had a similar design in an international setting and resulted in SVR12 rates ranging from 87% to 100% depending on the genotype and degree of liver fibrosis. More contemporaneous regimens, including the pan-genotypic DAA cocktails, have equally proven effective. Glecaprevir/pibrentasvir was evaluated in the MAGELLAN-2 trial, where 80 liver recipients

and 20 kidney recipients were treated. 98% achieved SVR12, with excellent tolerability and generally low rates of rejection [49–51].

Impact of DAA on the More Extensive Use of HCV-Positive Donors

According to estimates, there are around 110 million people worldwide with positive anti-HCV antibodies and around 80 million with active infection (detectable HCV-RNA) which correspond to a prevalence of HCV among organ donors between 1.4% and 5.5% with a wide variability depending on the geographical area [25, 52, 53].

Grafts from HCV-positive patients have been classically used in HCV-positive LT recipients with detectable HCV-RNA with good outcomes [54–57]. However, in the last 5 years, the high efficacy and safety of DAA therapies both in immunocompetent and in organ transplant recipients, including kidney, cardiac, and pulmonary recipients [58–67], has lead health authorities to encourage the use of HCV-positive donors, in HCV-negative patients, in order to increase their transplant options by reducing their time on the waiting list [21, 25, 68–70]. The transmission of HCV infection to the recipient from any HCV-positive graft is not universal as it mainly

depends on the detection of active viral replication in the donor. Depending on the geographical area and the recent use of DAA, the percentage of those viremic among serologically positive individuals may vary substantially. If the donor is viremic (positive HCV-RNA), transmission of HCV infection is the rule. Conversely, the risk of transmission of a nonviremic HCV donor (negative HCV-RNA) is very low, although not null, in cases of very low levels of viremia or in the case of window period of infection (very recent infection) [57]. From a clinical point of view, the expected transmission of HCV is manageable with new DAA used early after transplantation before liver injury has taken place. Caution remains within most Societies, with guidelines still suggesting caution when using HCV-viremic donors. In particular, limiting the use viremic organs in HCV-negative recipients, particularly if the latter had previously been successfully treated with DAA, so as not to require a second treatment course. Also transplant centers should be especially careful about using viremic donors for transplant in the absence of guaranteed access to DAA therapy post operatively, given a desire to start treatment as early after transplantation as possible to avoid fibrosis cholestatic hepatitis risk [21, 25, 68–70]. Finally, liver donors with extensive fibrosis (F3-4) should be declined preferentially using those with no or mild fibrosis. It is still debatable whether HCV-positive F2 donor grafts should be accepted for transplantation. Interestingly, liver grafts from HCV positive donors may differ in terms of quality with those coming from young donors, possibly in the setting of drug overdose and recent infection being typically of high quality whereas those from older donors, generally infected for years and decades, showing significant inflammation and fibrosis, and thus not qualifying for liver donation.

Use of Viremic Donor Organs for Transplant into HCV-Negative Recipients

Seropositive organ donors can be safely used for transplant into HCV negative organ recipients with no additional risk of developing HCV. In areas of the globe where drug overdose, particularly intravenous, results in a high proportion of the suitable donors, there remains a low but not zero risk of window period HCV infection.

Kidney transplantation was the first clinical area to highlight the potential for using HCV viremic donors and transplanting them into HCV negative recipients (D+/R−). The THINKER trial reported their experience with 20 patients, who were transplanted with donors who had HCV genotype 1. Each recipient was treated with elbasvir/grazoprevir for 12 weeks. While each recipient was found to be viremic by day 3 posttransplant, and DAA therapy was then initiated, all patients achieved SVR12, and a 12-month follow-up report noted HCV cure, excellent renal function, and a good quality of life off dialysis for all concerned. The EXPANDER trial similarly enrolled 10 kidney transplant recipients, although attempted a “prophylactic” strategy, also using elbasvir/grazoprevir, although dosing began preoperatively

on the day of the transplant. A number of other centers have since described experience with D+/R− kidney transplantation, all with comparable success.

In the interest of being rational with DAA use, some centers have also begun to explore variations in treatment duration. One United States report, of the DAPPerR study, describes the immediate day zero initiation of sofosbuvir/velpatasvir. In the initial group, patients received their first dose of drug 6 h prior to kidney implantation and then a single postoperative dose. Transmission of HCV occurred in 3/10 patients. A second phase of the study enrolled a further 40 patients, with additional doses on day 2 and 3. Three patients became HCV-viremic, yet all were successfully treated with regular length of DAA treatment afterwards. The study demonstrated that shorter courses of DAA therapy might be possible, if initiated very early on after a D+/R− transplant [71–74]. The exact ideal length of therapy remains unknown.

For heart transplants, undergoing a D+/R− transplant offers a rapid pathway towards a lifesaving organ. An early report from the United States demonstrated high SVR12 rates with 70 HCV D+/R− donors in 2016 and 2019. Waiting times for transplantation in the initial phase fell to a median of just 3 days postconsent (although this likely reflects organ availability and lack of competition for HCV-viremic hearts at the time). HCV viremia developed in 96% of patients and yet 100% achieved SVR12 ([70, 75]. Treatment was "delayed," initiated after discharge from hospital, yet SVR was still achieved and no fibrosing cholestatic hepatitis or significant graft damage (e.g., accelerated transplant coronary angiopathy) was noted.

Additional thoracic transplant experience was observed in HCV D+/R− heart and lung transplants performed in Boston. The DONATE HCV study included 8 heart and 36 lung transplant recipients, who each received only 4 weeks of sofosbuvir/velpatasvir, initiated within a few hours of transplantation. The primary outcome was a mixture of both SVR12 and graft survival at 6 months. 35/35 (100%) of patients met the primary endpoint with undetectable viremia. Although increased rates of rejection were noted in the lung transplant group compared to a non-HCV cohort, potential confounding limited evaluation of whether rejection was more significant or not.

Cost remains a significant barrier to D+/R− transplantation. In North America, a course of DAA therapy is typically many thousands of US$ per month. By contrast, however, the additional cost of waiting on dialysis is usually more over the space of a 2-year period, thereby making D+/R− transplants financially viable in many circumstances. Such models have not been put forward outside of a US context. Having a center with capable transplant pharmacy support to manage drug interactions that come with pan-genotypic regimens is important. Similarly, being aware of rare but important complications is key. In recipients who elect to wait for DAA treatment, there remains a small risk of rapidly progressive fibrosing cholestasis. Similarly, inadvertent secondary infections to caregivers should be discussed and mitigation techniques espoused. Finally, nonhepatic complications, such as membranous or immune deposition nephritis, or cryoglobulinemia, have been rarely described.

In summary, direct acting antivirals agents have allowed exploration of safe and effective HCV therapy after transplantation with HCV-viremic donor organs. Regardless of the organ involved, numerous studies have now demonstrated viable pathways to more rapid transplant, although more work is required to delineate the best time to begin DAA therapy (immediately before, during or after transplant), and the duration of therapy required. It should be noted, however, that most of these studies are in North America, where the epidemiology of the opiate epidemic has driven up the number of otherwise suitable donors who are actively infected with HCV. It is not clear whether the advantages offered in these trials can be extrapolated to other parts of the world.

Conclusion

The availability of newer and highly effective DAAs therapies has facilitated the management of HCV infection in the field of solid organ transplantation, leading to viral eradication in a classically considered "difficult to treat" population. In the pretransplant setting, functional and clinical improvement following DAAs treatment has been reported in patients with HCV-decompensated cirrhosis allowing 1 out of 4 patients to avoid LT. However, a small group of patients with HCV-decompensated cirrhosis will not derive clinical benefit despite viral eradication, indicating a limited hepatic repair capacity, a situation which is more common in the sickest patients where the risks and potential benefits of therapy in the waiting list need to be carefully weighted. Similarly, HCV-viremic patients on the kidney, heart, and lung waiting lists can generally be moved to transplant with confidence, knowing posttransplant SVR12 and cure rates are now outstanding, comparable to presurgical. Equally relevant are the DAA benefits in subjects awaiting LT for HCV-related HCC with a decrease in waitlist drop out due to death or tumor progression. In the posttransplant setting, DAA treatments have excellent efficacy and low toxicity and have dramatically improved outcomes of HCV recipients. Moreover, the new therapies have opened the door to a more extensive use of HCV positive donors, including into HCV-negative recipients, allowing an important expansion of the donor pool with subsequent benefits both at an individual and community level.

Key Points

- Hepatitis C infection
- Direct-acting antivirals
- Impact on the Waiting list
- Donor pool expansion

Acknowledgments The funding organization Instituto de Salud Carlos III supported the research of both Lorena Puchades (Grant number: CM17/00006) and Marina Berenguer (Grant number PI19/01360).

Epidemiology

West Nile virus (WNV) takes its name from the first identified case of a woman with fever in the West Nile district of Uganda in 1937 [1]. The virus is a single-stranded RNA virus in the *Flaviviridae* family and is related to other flaviviruses including St. Louis encephalitis virus, dengue, yellow fever, Japanese encephalitis virus, and hepatitis C (Table 1). It is an avian zoonosis that is maintained in an enzootic cycle

between mosquito vectors, predominantly of the *Culex* species, and over 330 species of birds. The birds serve as amplifying hosts and may remain viremic for up to 100 days, providing ample time for other mosquitoes to become infected during blood meals [2]. In the United States, WNV peaks during the midsummer and fall (Fig. 1) when mosquitoes are most infectious for humans. Following mosquito bites, humans and horses generate only lower levels of WNV viremia [3] and are considered dead-end hosts.

Since 1937, epidemics of WNV infection developed intermittently in the Mediterranean basin [4], but the Western Hemisphere was generally free until 1999, when 59 individuals presented with WNV encephalitis and/or meningitis in Queens, New York [5]. Over the ensuing years, WNV quickly spread westward with an intermittent predominance of infection based on the migratory pattern of the infected birds and predominantly *Culex* spp. mosquitoes. Between 1999 and 2017, there were 48,183 confirmed cases of WNV disease reported to the Centers for Disease Control and Prevention (CDC), 22,999 cases of which were neuroinvasive [6]. West Nile virus has become endemic and the leading cause of arboviral disease in the continental United States [7].

Concern for WNV in transplant recipients came shortly after its spread to the United States with donor transmission via blood or organs in 2002 when WNV was recognized in four recipients who received organs from a woman who had sustained a fatal motor vehicle accident [8, 9]. Three of the four recipients developed encephalitis, while the fourth had a fever with mild cognitive impairment; one of the patients died. The donor was subsequently documented to be infected by WNV with positive reverse transcriptase polymerase chain reaction (RT-PCR) and positive culture from blood obtained on the day of organ procurement. The donor had a negative RT-PCR and WNV IgM results on samples obtained 1 and 2 days prior to procurement [9]. The infection was eventually confirmed to have originated from

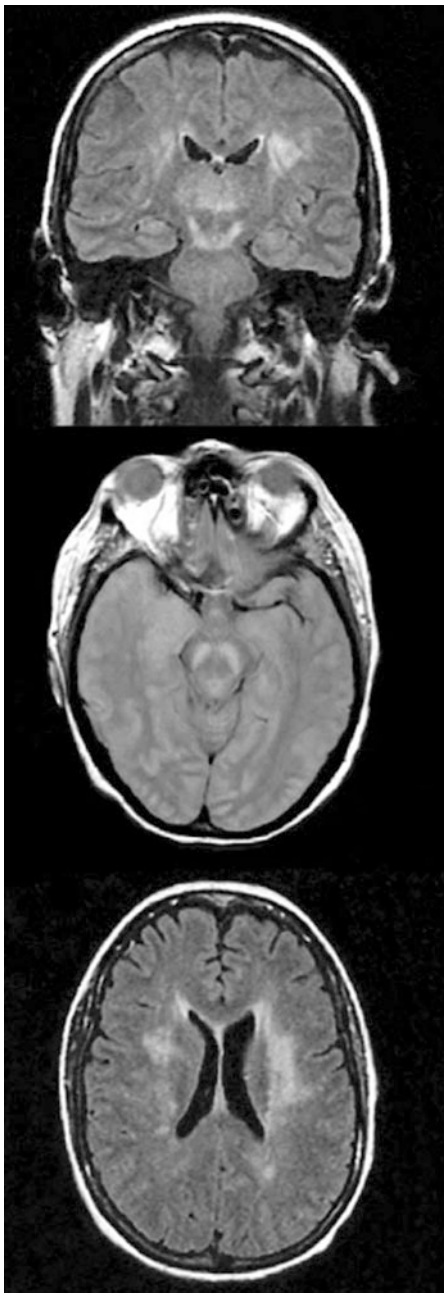

Fig. 1 Coronal fluid-attenuated inversion recovery (FLAIR) image shows an area of abnormally increased signal in the thalami, substantia nigras (extending superiorly toward the subthalamic nuclei), and white matter. (Figure reproduced with permission from Ref. [34])

1 of 53 units of blood products given to the donor prior to procurement [8, 9]. The Food and Drug Administration provided guidance for donor blood screening starting in 2002, and screening of all blood donors for WNV RNA was implemented by the summer of 2003 [10]. Mosquito-borne community-acquired WNV in organ transplant recipients was also recognized early in the spread to the Western Hemisphere [11, 27].

West Nile virus is now considered endemic within the Western Hemisphere.

Disease Manifestation

In immunocompetent individuals, WNV infection is asymptomatic in 80% of individuals with an incubation period typically of 2–14 days. Only 20–25% develop symptoms predominantly manifesting as an acute febrile illness (WNV fever) often accompanied by nonspecific symptoms of headache, myalgia, arthralgia, vomiting diarrhea, or rash, with <1% developing West Nile neuroinvasive disease (WNND) [6, 7, 12–16]. Increasing age was found to be a particular risk for the development of WNND [12–14]. West Nile neurologic features can be manifold presenting with encephalitis, meningitis, acute flaccid paralysis, Parkinsonian-like cogwheel rigidity, or a combination of these symptoms [15, 16]. Involvement of the brain stem, basal ganglia, thalamus, or anterior horn cells of the spinal cord can account for variable clinical presentations. In comparison to healthy individuals, immunocompromised patients may have a more prolonged incubation period with symptoms developing between 4 and 20 days after donor-derived infection [9, 17–25]. In addition, transplant recipients appear to have an increased incidence of WNND occurring in up to 40% with mosquito-acquired infection and over 50% with donor-derived infections [9, 17–27]. However, these data must be taken with consideration that mild or asymptomatic infections may not undergo diagnostic evaluation so that neuroinvasive and severe disease may be overestimated.

The cerebrospinal fluid findings are similar to other viral meningoencephalitides with mild leukocytosis (usually <500 cells/mm^3), normal glucose, and elevated protein [12, 15, 26–28]. Similar findings were noted in transplant recipients [9, 11, 17–25]. MRI of the brain and spine may identify anterior horn cell signal changes and enhancement of the ventral nerve root (as shown in Figs. 1 and 2) [27].

Prognosis and recovery in transplant patients with neuroinvasive disease varies but has a high rate of sustained morbidity and mortality [17]. In 23 reported donor-derived infections after organ transplantation, 13 (56%) had encephalitis, 3 died, and at the time of reporting, 5 were noted to still be in a coma or requiring rehabilitation [17–25]. In a more recent series of 11 kidney transplant patients, 7 had altered mental status, while 4 had fever and headache; 9 had a full recovery, but 2 had ongoing neurologic deficits [29].

Recipients of bone marrow transplantation are less frequently reported to have WNV [27, 30–36]. In a review of ten cases, only one was proven to be donor-derived despite negative routine testing 3 weeks prior to donation [36]. In this review, one pediatric

Fig. 2 MRI of a patient with WNV encephalitis, acute flaccid paralysis of the upper extremities, and respiratory failure. Increased T2 signal involving the anterior cervical spinal cord. (Courtesy of Dr. Lyle Peterson, Centers for Diseases Control, Fort Collins, Colorado)

recipient developed fatal encephalitis and repeat testing of the donor documented seroconversion. In three cases, the acquisition was felt most likely to be environmental from mosquitoes, and in six it was not known if it was due to blood transfusions or natural acquisition [30–35]. In total, seven of the ten died with WNV encephalitis; two of the surviving recipients were over 9 months after transplant and on minimal to no immunosuppression which may have accounted for their better outcomes [34].

Diagnostic Considerations and Laboratory Testing for WNV

Arboviral infections particularly WNV should be considered when transplant recipients present with fever, headache, and viral-like symptoms especially with altered mental status, flaccid paralysis, Parkinson-like cogwheel rigidity, or other neurologic symptoms during mosquito season, especially in regions of reported cases in humans, birds, or other animals.

Geographic Regions at Higher Risk for WNV

Of great importance is for clinicians to also consider the epidemiology of the donor particularly if the symptoms are within a month after transplantation. Consideration

of possible donor associated infection is important not only for the individual patient but also to rapidly inform other recipients of organs from the same donor so that evaluation and management can be optimized. The CDC maintains up-to-date tracking of WNV activity by state both in humans and in nonhumans including veterinary cases and infections of mosquitoes, birds, or sentinel animals [6].

Laboratory Testing

Testing of recipients can be multipronged as one method may not always be accurate particularly in immunocompromised hosts. Interpretation of WNV laboratory testing is dependent on the stage of the patient's illness. Upon human infection, a period of asymptomatic West Nile viremia is detectable by nucleic acid amplification testing (NAT) usually starting 1–2 days after a bite from an infected mosquito, lasting for 5–7 days in immunocompetent individuals with negative testing generally by the time symptoms develop [37]. Serum WNV IgM seropositivity develops 3–5 days after viremia develops and generally 2 days within the onset of symptoms, so it is commonly considered consistent with acute infection lasting on average 156 days [37]. However, IgM persistence for at least 3 years has been reported in healthy adults [38].

In cases of WNV neuroinvasive disease, IgM may be detected in the CSF before serum and is pathognomonic for central nervous system disease, as the antibody does not penetrate the blood-brain barrier [36]. Positive nucleic acid testing of CSF is also pathognomonic for WNND but is less sensitive. If the clinical presentation is concerning for WNV with an initial negative serum or CSF IgM assay, repeat testing may be performed after 1 week. Serum WNV IgG becomes detectable generally several days after IgM and may be persistent for years. Cross-reactivity with other arboviruses, particularly St. Louis encephalitis [39] may occur, and laboratory confirmation with plaque reduction neutralization test (PRNT) may be obtained through local and state health department laboratories and the CDC Division of Vector-Borne Diseases. Commercial assays for WNV-specific antibodies are available but may vary in sensitivity and specificity. Table 1 lists all flaviviruses given the need to consider serologic cross-reactivity with WNV.

In transplant recipients, antibody response to WNV may be delayed or absent, and viremia may persist particularly in the presence of severe immunosuppression or use of B-cell-depleting agents such as rituximab [35, 40–42]. Both serum and CSF WNV NAT, IgM, and IgG should be obtained when WNND is suspected in a transplant recipient. Delay in serum WNV IgM seropositivity has been reported in several transplant recipients maintained on tacrolimus with initial negative serology upon neurologic presentation. Seroconversion was noted with repeat testing [18, 43]. Accordingly, if initial testing is negative for WNV and diagnostic workup does not identify other sources to account for the patient's symptomatology, repeat testing for WNV by serology and NAT after 4–7 days are warranted. This was highlighted in a case report of severe West Nile virus infection in a kidney transplant recipient who presented with neurologic involvement, thrombotic microangiopathy,

pancreatitis, and irreversible loss of kidney function, where the standard US Centers for Disease Control and Prevention diagnostic serology criteria did not initially identify WNV. Due to persistent symptoms, a subsequent plaque reduction neutralization test confirmed the diagnosis months later, with additional diagnostic and therapeutic procedures performed that contributed to morbidity and graft loss [44]. More recently, newer methodologies such as metagenomic deep sequencing of nucleic acids have been noted in a case report to identify WNV encephalitis in a 14-year-old renal transplant recipient whose CSF and serum antibody and NAT tests were initially negative and may become a technologic advance to consider in cases that are diagnostic dilemmas [43]. However, in this case report, subsequent testing documented the development of a positive antibody; for now, issues including significant cost, limited availability, and potential contaminating microbes may be problematic with this technique.

Diagnostic Imaging

Imaging studies including MRI images with T2-weighted imaging should be considered for all transplant patients with neurologic symptoms. However, here too significant variation in findings may occur, and brain MRI scans may be normal in the presence of severe WNV encephalitis particularly early in the course [45]. Examples of MRI imaging are shown in Figs. 1 and 2. While positive findings are suggestive of neuroinvasive viral diseases such as enhancement of the thalamus, basal ganglia, and anterior horn cells of the spinal cord, they are not diagnostic for WNV over other etiologies.

Management of West Nile Virus Infection

There are no WNV-specific antiviral therapies or adjunctive therapies that have been shown to be definitively effective for the treatment of WNV. Accordingly, supportive care and minimizing immunosuppression as tolerated are the mainstay of management. However, in a series of 11 kidney transplant patient with WNV infection and who all had immunosuppression reduced, 3 had acute rejection within the following year, and the entire cohort had a mean drop in estimated glomerular filtration rate of 8.4 ± 13 mL/min/1.73 m^2, suggesting a need for careful immunosuppression management after clearance of WNV [29]. Hospital protocols used in many institutions for the prevention of secondary bacterial infections in patients with compromised respiratory function should be implemented such as elevating the head and suctioning. Long-term care in nursing facilities may be required for further rehabilitative care as well and should be planned early in the course as an expectation for infected patients and their families.

Several agents have been used with variable results in case reports and case series. While ribavirin had in vitro activity, a retrospective review of a large outbreak in Israel noted an increased mortality risk for those treated with ribavirin [46]. Likewise,

while interferon alpha-2b had some anecdotal success, a clinical trial has not as yet reported definitive clinical benefit [17, 47] and carries a concern for potentially triggering organ rejection after SOT. Intravenous immunoglobulin products have been most widely used in an attempt to treat WNV disease particularly in immunocompromised patients with both standard preparations of intravenous immunoglobulin (IVIG) and high titer IVIG against WNV (Omr-IgG-am™, OMRIX Biopharmaceuticals) that have been anecdotally reported to be of benefit [18, 21–25, 31–36, 48, 49]. A phase I/II randomized, double-blind, placebo-controlled study failed to show a benefit of a single dose (500 mg/kg) of high-titer anti-WNV IVIG (Omr-IgG-am™) compared to placebo (standard WNV-negative IVIG or normal saline) in a study conducted by the NIAID Collaborative Antiviral Study Group in 55 adults with confirmed WNV neuroinvasive disease (personal communication Richard Whitley [50]). However, the majority of the patients in the study had been symptomatic for several days before receiving the investigational therapy which may have impacted efficacy.

Predictors of death or persistent neurologic deficits included age over 65 years and presenting with coma [50]. High-titer WNV IgG (OMR-IgGam) is no longer available in the United States; over time polyclonal immune globulin intravenous (IVIG) from plasma-derived immunoglobulin in the United States has been shown to have measurable WNV-neutralizing antibody although its efficacy is not proven [51, 52]. Multiple case reports in the literature have described the use of US polyclonal IVIG for patients with varying results in neurologic sequelae and survival. Dosing regimens are not standardized, but if there is efficacy, it is suggested that early treatment may improve the outcome and decrease mortality. Further studies are needed to assess this as well as to determine dosage and timing.

A WNV recombinant humanized monoclonal antibody, MGAWN1 (Macrogenics Inc., Rockville, MD) was also evaluated in a clinical trial from 2009 to 2011 but terminated due to inability to adequately enroll subjects [53]. Deaths occurred in 2 of 6 patients receiving study drug compared to 1 death in 7 placebo recipients. In addition, a phase 1 safety and pharmacokinetic study of MGAWN1 in 40 healthy adults (30 received study-drug) noted adverse reactions in 6 (20%) subjects ranging from neutropenia, leukopenia, diarrhea, chest discomfort, dizziness, and somnolence; 1 subject was diagnosed with schizophrenia [53]. This agent is no longer available.

Finally, corticosteroids have been used in some case reports with varying results [54, 55] regarding neurologic improvement; there is one report of topical corticosteroids for the treatment of ocular signs of WNV in four patients also with varying results [56].

Prevention

Preventive strategies for WNV in transplant patients can take two forms, screening of blood products and donors and environmental protection from mosquitoes for living donors, candidates, and recipients.

Blood Donor Screening in the United States

Since the middle of 2003, blood banks in the United States and Canada have been screening all blood donations for WNV using NAT platforms, and since 2005 the FDA has two approved NAT assays that can be used to combine samples from 6 to 16 individuals (mini-pool, MP-NAT) or to test individual donor samples (ID-NAT) for WNV RNA [20, 57, 58]. Due to the great variability of WNV circulation in a specific geographic locality, blood banks in the United States either test all specimens by ID-NAT or use an algorithm to use MP-NAT testing until a reactive result is found indicating that WNV may be circulating in that local region. Once a reactive mini-pool is found, each blood specimen is individually tested, and the blood bank screening is converted to ID-NAT until no further positive results are found [58, 59]. After a period of time where ID-NAT testing remains negative, screening of blood reverts back to MP-NAT. A positive NAT may represent either active infection or a false positive which is less likely during WNV season (June–December in North America). A positive WNV NAT during low-incidence seasons or the absence of human infections is more likely to represent a false-positive result. Unlike deceased organ donors, blood donors can be contacted, counseled, and told to defer donating products for 120 days [58]. Nucleic acid testing of blood products has worked well to preserve the blood bank safety in the United States as viremia corresponds to the majority of the time when blood products are transmissible. Data suggest that once IgM antibody is detected, blood donors no longer transmit WNV [37].

Organ Donor Screening

Unlike blood donation, similar data are not available with respect to WNV transmissibility from tissue or organs, and it may be transmissible after an antibody has developed, even when WNV RNA is no longer detectable. Organ Procurement Transplantation Network (OPTN) policies differ between deceased and live donation and require that individual transplant centers have written plans to screen for specific pathogens based on variable geographic risks including WNV and trypanosomiasis [14, 15]. Laboratory screening should be based on geography and seasonal risk of mosquito bites, although the potential limitations of a family's knowledge of a donor's travel and exposure histories need to also be considered.

Limitations of serologic and NAT screening are highlighted by reports of transmission of WNV in at least two deceased organ donors who were WNV antibody positive but NAT negative [18, 23, 24]. The timing of screening for live donors should be close to the time of transplant. WNV was transmitted from a human stem cell donor who initially tested negative 3 weeks prior to donation but was found to be antibody positive on repeat testing when the pediatric recipient developed the disease [21]. These cases emphasize the importance of considering geographic risks, timing of testing, as well as education for prevention around the time of donation, as highlighted later in this chapter.

Animal models of WNV have demonstrated persistence of the infectious virus in tissues particularly of the kidney for significant periods after clearance of plasma viremia, suggesting that tissue transmissibility in the absence of viremia may be possible [60, 61]. Of concern, a small study found persistent WNV viruria in 5 of 25 (20%) of patients up to 6 years after severe WNV encephalitis [62], although two subsequent larger studies failed to confirm these observations. Gibney et al. found no viruria in 40 patients 6 years after acute WNV infection, and Baty and colleagues observed very low-level viruria in only 1 of 63 patients (1.6%) <5 months after acute WNV infection [63, 64]. Further studies by Murray and colleagues found WNV by electron microscopy in urine sediment in 12 individuals up to 9 years after their initial infection [65]. The infectivity of organs from WNV RNA-positive donors who are also positive for IgM as well as those who are negative for WNV RNA but have either persistent WNV IgM or viruria remains uncertain.

In 2011 an American Society of Transplantation Consensus Conference on donor-derived WNV was held, co-sponsored by the Canadian Society of Transplantation and The Transplantation Society, and results were presented at ATC 2011 (personal communication Marian Michaels). Conclusions and recommendations included:

- WNV appears to carry a risk of more severe disease in transplant recipients compared to healthy hosts.
- There was no evidence for one organ recipient type being at higher risk than others.
- Universal testing was NOT recommended due to the concern for organ wastage due to false-positive results during seasons when WNV is not circulating in a particular geographic area. Rather it was recommended that organ procurement agencies develop communication with their local blood banks so that they can be made aware of circulating WNV in the blood donor population; at that time, consideration for testing organ donors could be put into place.
- The consensus was to not use organs from donors testing positive with the caveat that use could be considered when there was an increased chance of the result being a false positive or a potential recipient had an emergent life-threatening condition without other life-sustaining therapeutic options so that they, their family, and healthcare team might consider the risk: benefit ratio to be in favor of using the organ.

In the United States, individual screening of living organ donors for West Nile virus is performed locally when positive surveillance testing or infection of vectors (mosquitoes, birds) or "innocent bystanders" such as humans is reported. Screening deceased donors when WNV is circulating is also generally followed. In addition, deceased donors with history of unexplained fever, altered mental status, or other symptoms of unknown etiology during WNV season should be evaluated before organ acceptance.

In the case of live donation, WNV NAT screening should be performed within 7–14 days of donation [66]. If positive, confirmatory testing by repeat NAT or serology

may be performed, and if testing remains positive, the donor is considered to be infected with WNV. If repeat NAT or serologies are negative, the donor may have cleared the viremia or there may be a delay in the development of WNV antibodies. Similar to the FDA recommendations for a 120-day deferral period for blood donors, the Organ Procurement and Transplantation Network (OPTN) recommends deferral of donor candidates for 120 days followed by repeat NAT screening prior to organ donation [66, 67]. Serologic testing is not recommended, since WNV IgG is likely to be associated with past infection and WNV IgM can last for variable periods of time. The OPTN recommends that "local expertise should be used in making decisions regarding timing of organ donation and additional testing on initial NAT reactive donors" [67]. If a recipient or donor tests positive for WNV or is suspected to have WNV after transplantation, OPTN safety portal and the OPO should be notified immediately so that all recipients of organs from that donor can be evaluated and managed expeditiously [68, 69].

Environmental Prevention of West Nile Virus Infection

Since transmission of WNV is primarily through mosquito bites, avoidance is key to prevention. Knowledge of the epidemiology and reports of WNV in the locale are helpful to counsel potential live donors, transplant candidates, and recipients during mosquito season in order to prevent infection.

Specific effective insect repellents have been listed by the CDC [6]:

- Picaridin (known as KBR 3023 and icaridin outside the United States).
- N,N-Diethyl-meta-toluamide (DEET).
- Ethyl butylacetylaminopropionate (IR3535).
- Oil of lemon eucalyptus (OLE).
- Para-menthane-diol (PMD).
- 2-Undecanone.

Behavioral and lifestyle adjustments are helpful to prevent bites, with avoidance of outside activities from dusk to dawn when *Culex* spp. mosquito activity is increased. In addition, standing pools of water should be minimized or avoided to decrease mosquito breeding grounds.

Key Points

- Great variability exists (both year-to-year and geographically) in WNV activity.
- Immunocompromised populations may have a higher risk for neuroinvasive disease than immunocompetent populations:
  - The full spectrum of WNV epidemiology in transplant recipients is still emerging information.
- Transplant recipients can acquire West Nile virus at transplantation from donors or transfusions.

- Transplant recipients can also acquire WNV from infected mosquitoes.
- West Nile virus should be considered in transplant patients with fever and neurologic symptoms early after transplant or during mosquito season in their geographic area.
- Treatment of WNV disease at this time is supportive:
  - Decreasing immunosuppression, when possible, is advised; transplant teams may wish to increase immunosuppression again once the infection is cleared so as to avoid rejection.
  - Trials evaluating specific treatment strategies have failed to document a successful intervention to date.
  - Intravenous immunoglobulin may be of benefit early in the disease, but dosing and timing require further study.
- Transplant candidates, recipients, and potential living donors should be counseled on the means for mosquito avoidance.

Conclusion

While rare, WNV can cause severe and fatal disease after transplantation. Accordingly, candidates and recipients of transplantation should be educated about preventive strategies. In addition, screening should be considered for donors during periods of WNV circulation. Evaluation and differential diagnosis of transplant patients with neurological symptoms with fever should include WNV. If infection is found early after transplantation, consideration should be given for a potential donor-derived infection and reporting should be made to the OPTN safety portal to allow for timely evaluation of other recipients from the same donor. The mainstay of treatment is supportive care with some evidence of response to intravenous immunoglobulin.

Introduction

Currently, more than 500 arboviruses (arthropod-borne viruses) have been identified, of which nearly 150 are associated with human infection [1]. Five arboviruses (West Nile, yellow fever, dengue, chikungunya, and Zika) have recently re-emerged in both hemispheres, and outbreaks have been reported mostly in tropical and subtropical countries (Fig. 1).

Diseases caused by arboviruses bring particular challenges to the transplant community whenever donors or immunocompromised recipients travel or live in endemic regions. Although dengue is the most common mosquito-borne disease in tropical and subtropical regions, chikungunya and Zika have been circulating in the Americas for several years now, bringing renewed attention to how these infections behave in immunocompromised hosts.

These three arboviruses have demonstrated the potential for blood and graft transmission, extended viremia, and complicated engraftment, which has affected donor selection or deferrals, among other impacts. In the acute phase, the diseases have a similar clinical presentation and, if contracted in the perioperative window, may be confused with adverse transplant reactions, hindering timely diagnosis and management and occasionally resulting in severe or fatal outcomes. Thus, diseases caused by arboviruses may represent a threat to immunocompromised hosts living in or traveling to endemic regions.

Disease Epidemiology

Dengue

Dengue virus (DENV) is a small single-stranded RNA virus belonging to the genus *Flavivirus* and family *Flaviviridae* and transmitted by mosquitoes of the genus *Aedes (Aedes aegypti* and *Aedes albopictus)* [2]. Dengue occurs both as an endemic and epidemic disease. A recent study estimates that 390 million dengue infections worldwide occur every year, of which 96 million manifest clinically, with variable severity [3]. An estimated 3.9 billion people in 128 countries are at risk of infection with DENV [4].

Dengue virus comprises four main serotypes, DENV-1, DENV-2, DENV-3, and DENV-4. Infection by one serotype provides lifelong immunity against that serotype, but only partial protection against subsequent infections by other serovars. In immunocompetent hosts, the risk of severe disease is greater in secondary infection, due to the mechanism known as antibody-dependent enhancement (ADE). A robust immunologic response seems to be a prerequisite for the development of severe dengue, when elevated circulating levels of IL-8, IL-10, TGF-β, and interferon-γ may be detected [5].

Besides mosquito bite, other routes of dengue transmission may occur and have recently been reviewed [6]. Nonvector transmission of dengue can occur through blood transfusion, solid organ transplant (SOT) and hematopoietic stem cell transplantation (HSCT), perinatal transmission, breast milk, percutaneous (needlestick or laboratory accident), and mucocutaneous (blood splash) [6].

In the last decade, an increasing number of dengue infections have been described in transplant recipients due to the expansion of DENV [7–12]. In endemic areas, this number may be much higher, since most cases are mild and present as a flu-like illness, with some manifestations resembling posttransplant syndromes.

In general, dengue infections in transplant recipients are acquired by vector transmission during travel to endemic areas, or in recipients living in such areas [9, 10, 12]. However, other sources of infection are relevant in the transplant setting, such as the graft itself and blood transfusions. Most transfusion-transmitted (TT) dengue cases are asymptomatic, and viremic donors have been detected during outbreaks [13–15]. Although rare, an increasing number of allograft transmission cases have been reported in transplant recipients.

In HSCT, two cases of dengue transmitted by the graft have been well documented [16, 17]. The first case occurred during the 1994–1995 dengue epidemic in Puerto Rico. The donor developed fever 2 days after marrow harvesting, and DENV-4 serotype was confirmed in donor samples [16]. The recipient died of severe dengue 11 days after HSCT. DENV-4 was detected in blood, ascitic fluid, and tissue samples. The other case of graft transmission occurred in a HSCT recipient whose unrelated donor had returned from Sri Lanka 3 days before donation [17]. In SOT recipients, graft transmission has also been reported [18–23] and has been recently reviewed [21–23]. In one case report, the evidence of graft transmission is

weak, as both donor and recipient were from an endemic area and the living donor had acquired dengue 6 months before donation. Such long persistence has not been demonstrated in the healthy population infected with DENV. Since the genetic identity between donor and recipient viruses was not demonstrated, vector transmission is more likely to have occurred in this setting [18].

In cases of graft transmission, dengue symptoms usually start in the first 10 days after transplantation. A living donor who developed symptoms 2 days after donation transmitted dengue to a liver transplant recipient in Delhi [20]. Mathew and colleagues also reported on a liver transplant recipient who acquired DENV through the organ allograft. Using phylogenetic analysis, they were able to rule out other infections and match the molecular signature to the donor, who presented with fever, thrombocytopenia, and abdominal pain on postoperative day (POD) 6 and had positive RT-PCR for DENV-1. On POD 9, the recipient developed abdominal pain, thrombocytopenia, and encephalopathy that quickly progressed to renal dysfunction and graft failure, leading to death despite aggressive treatment [23].

Chikungunya

Chikungunya virus (CHIKV) belongs to the family *Togaviridae* genus *Alphavirus* and is transmitted by *Aedes* mosquitoes *(Aedes albopictus* and *A. aegypti).* Until now, four lineages distinguished by genotypes have been identified [24].

CHIKV was first isolated in the 1952 outbreak in a southern province of Tanzania [25, 26]. The re-emergence of CHIKV in the twenty-first century involved the dispersal of two endemic genotypes, the African genotype and the Asian genotype. CHIKV quickly spread to the islands along the coast of Africa in the Indian Ocean and caused a massive outbreak on Réunion Island in 2004, affecting approximately 34% of the population [27]. In 2013, cases of CHIKV infection were reported in St. Martin's Island, later spreading throughout the Caribbean, Central America, South America, and North America [28, 29]. In 2006, several cases of CHIKV infection were reported in Europe [30]. In 2017, up to 1,010,724 cases were reported in the region of the Americas, mainly in Mexico, the USA, and Brazil [31]. In 2018, there were 26,840 cases of probable CHIKV infection reported in Brazil, and by March 2019, more than 15,352 cases of probable CHIKV infections have already been registered [32].

Regarding other modes of CHIKV transmission, few articles discuss transmission by blood transfusion or organ transplantation. The maximum viremic period of CHIKV infection is 2 days before and 17 days after symptom onset. The mean and maximal risks of CHIKV viremic blood donation were estimated to be 38–52 per 100,000 donations (0.04–0.06%), respectively [33]. In the 2005 outbreak in La Réunion, CHIKV was detected in 4 of 12 healthy donors of corneal grafts, demonstrating the potential risk of transmission during tissue transplantation [34].

Zika

Zika virus (ZIKV) is a *Flavivirus* in the family *Flaviviridae* and was first identified in 1947 in a sentinel rhesus monkey in the Zika Forest of Uganda [35]. Two species are considered the main competent vectors, *Aedes aegypti* and, less commonly, *A. albopictus*. Before 2007, only sporadic human disease cases were reported from countries in Africa and Southeast Asia [36]. In 2007, an outbreak of ZIKV occurred in the island of Yap, Micronesia, with approximately 5000 cases reported [37]. In 2013, an outbreak began in French Polynesia, and the virus subsequently spread to other Pacific Islands [35]. After reaching Brazil in May 2015, ZIKV was subsequently detected through much of the Americas. Microcephaly, a devastating effect of ZIKV infection during pregnancy, was first observed (and later confirmed) during the ZIKV epidemic in Brazil [38]. From January 2015 through March 2017, a total of 754,460 autochthonous cases of ZIKV disease were reported to the Pan American Health Organization (PAHO) from countries and territories in the Americas, 27% of which were laboratory confirmed. So far, a total of 84 countries or territories globally have reported autochthonous mosquito-borne ZIKV transmission. In the Americas, the only countries that have not reported cases of vector-transmitted ZIKV are Bermuda, Canada, Uruguay, and continental Chile [36].

Alternative ways of ZIKV transmission include sexual, perinatal, and via blood products [39]. A relevant concern related to ZIKV transmission is the capacity of viral persistence in fluids and organs. ZIKV RNA can persist in semen up to 370 days [40], although infectious ZIKV can be detected during a much shorter period, around 40 days [41]. Although never definitively demonstrated, the risk for ZIKV transmission through organ or tissue transplantation is plausible. Chen et al. have demonstrated that ZIKV infects and persists in the human renal proximal tubular epithelium suggesting that these cells are a potential reservoir of ZIKV in the human urinary system, explaining the prolonged persistency of ZIKV in patient urine and highlighting the possibility of organ transmission through kidney transplantation [42].

So far, the majority of ZIKV cases in transplant patients were acquired by mosquito bite. During the ZIKV epidemic in Brazil, some cases were reported in SOT and HSCT recipients. Nogueira and colleagues described four cases in SOT recipients (two for the liver, two for the kidney) who developed symptomatic ZIKV infection diagnosed by RT-PCR [43]. In a nearby region, a heart transplant recipient with fever, malaise, and seizures was diagnosed with ZIKV meningoencephalitis [44]. A prospective study conducted in 2016 in Brazil described the clinical findings and outcomes in four cases of ZIKV in HSCT recipients and hematologic malignancy patients [45]. Transfusion transmission is another possibility. Musso et al. reported a 2.8% incidence of blood donors positive for ZIKV by PCR at the time of donation during the French Polynesian ZIKV outbreak [46]. Similarly, 0.5–1% of donors were found to be ZIKV RNA positive in Puerto Rico and Brazil, respectively, during the recent ZIKV epidemic [47, 48]. The first case of

Zika in a liver transplant recipient was transmitted by the platelet component transfused during surgery. The blood donor was asymptomatic at the time of donation [49]. Two other cases of ZIKV transmission by platelet transfusion have also been documented [50].

Clinical Impact on Transplantation

Dengue

Dengue has a wide clinical spectrum varying from asymptomatic to severe clinical manifestations. Seroprevalence studies suggest that the number of asymptomatic carriers is three times that of dengue fever cases. Since 2016, symptomatic dengue is grouped into three categories: dengue without warning signs (DNWS), dengue with warning signs (DWWS), and severe dengue (SD), as shown in Fig. 2. Severe disease and lethal outcome may occur even in the absence of warning signs [51].

After a 3- to 15-day incubation period, the disease presents abruptly as a flu-like illness in three phases – febrile, critical, and recovery. The three phases are not clearly distinguishable in transplanted patients, in whom symptom duration is longer, thrombocytopenia occurs in more than 80% of cases, and incubation period is shorter in case of graft transmission [22]. Atypical presentations of dengue in SOT and HSCT recipients include acute colitis and encephalitis [52, 53].

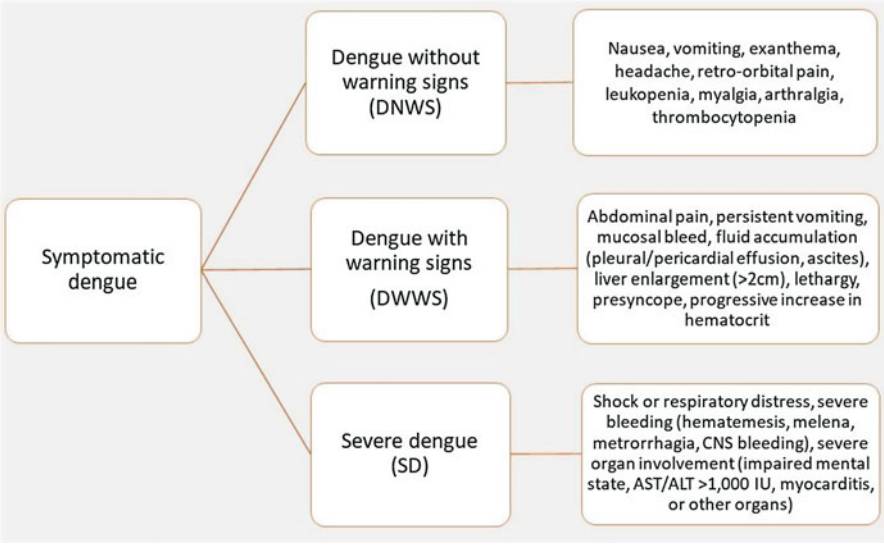

Fig. 2 Clinical classification of dengue

A recent prospective study in HSCT recipients conducted during dengue season in Brazil showed the main clinical findings to be fever (100%), thrombocytopenia (80%), myalgia (80%), and rash (60%), with or without hemorrhagic episodes, similar to immunocompetent individuals. Severe dengue occurred in one patient (20%). An important finding of this study was the observation of prolonged viremia (more than 15 days) in all patients who had blood samples collected serially [12]. In the immunocompetent population, dengue viremia persisted from 4 to 7 days (median 5 days) in 69% of the patients and was uncommon after the fifth day (12.5%) [54, 55].

Among SOT recipients, the largest case series was published in 2013 and reported the clinical findings of 102 DENV cases after renal transplantation [7]. Forty-four patients (43%) had primary dengue infection, and 58 (56.8%) had secondary dengue infection. Most patients presented with fever (80%), which was less frequent in patients receiving high-dose steroids. DWWS or DNWS occurred in 88%, and SD occurred in 11.7%, with graft dysfunction in 66.7% of these. Thrombocytopenia was seen in 95% of cases, with a mean duration of 11 ± 9 days. Interestingly, patients on a cyclosporine (CSA) containing regimen had less severe disease [7]. Some authors have shown that CSA can be a potential drug for the treatment of flavivirus infections [56].

In recent literature reviews, the incidence of SD in transplant vs immunocompetent patients was reported as 16% vs. 3.7% [8], with dengue mortality rates varied from 0.026% in DNWS up to 5% in SD in immunocompetent patients [57], while studies in transplant populations show mortality rates ranging from 0% to 38% [58]. There are some reports of complicated dengue in kidney transplantation presenting early in the postoperative period with or without fever, abdominal pain, and third-spacing, with imaging demonstrating bleeding around the graft requiring blood products and sometimes surgical evacuation to achieve hemostasis. Poor outcomes such as graft failure, protracted hospitalization, and two deaths were reported [59, 60]. Furthermore, an excellent article by Pinsai and colleagues summarizing and comparing recent dengue case series in kidney recipients shows data suggesting that mycophenolate mofetil (MMF) may increase disease severity [58]. Another article by Subbiah and colleagues also reported the need to de-escalate from MMF in 60% of patients due to refractory cytopenias, with the medication resumed later [61]. To clarify these discrepancies, a meta-analysis or prospective trials comparing these different scenarios could have significant impact on future recommendations, especially in hyperendemic countries.

In this uncertain scenario, practitioners should be aware of the increasingly recognized association between hemophagocytic lymphohistiocytosis (HLH) and DENV [58, 62, 63]. HLH is a sporadic or familial disease characterized by loss of immune homeostasis and a dysregulated immune response manifesting as a cytokine storm to exogenous triggers in a genetically predisposed host. It presents with fever, hepatosplenomegaly, rash, neurologic symptoms, cytopenia in two or three lines, and elevated ferritin that quickly progresses to multi-organ system failure and death. Chung and colleagues summarized recent DENV-associated HLH with outcomes and important clinical pearls [64]. In many ways, HLH behaves similarly to severe DENV making it hard to diagnose if a high index of suspicion is not maintained. In

endemic countries, an intervening DENV infection in pediatric HSCT recipients transplanted due to familial forms of HLH may be misdiagnosed as disease relapse or graft-versus-host disease (GVHD) [65].

Chikungunya

After a mosquito bite, CHIKV reaches the bloodstream and spreads through the liver, muscles, joints, spleen, lymph nodes, and brain. Unlike ZIKV and DENV, CHIKV is symptomatic in more than 95% of cases [26]. In immunocompetent patients, the incubation period varies between 2 and 10 days [30]. After this, an abrupt onset of fever is observed, followed in a few days by symmetric polyarthralgia in 90% of patients, with maculopapular rash in about 50%. Myalgia, malaise, nausea, and headache are also typical, and the acute illness lasts 1–2 weeks [66]. Persistent or recurring arthralgia is characteristic, with 20–43% developing incapacitating chronic polyarthralgia that persists for months or years after the acute phase [67, 68]. Chronic CHIKV arthritis often causes severe pain and disability, and pathogenesis is not well understood. It is hypothesized that continued low-level viral replication in the joints, viral RNA persistence in the synovium, and induction of autoimmunity are the possible causes [69]. There are also reports of neurologic, cardiac, renal, and hepatic manifestations with a fatality ratio of 17% in cases of encephalitis [70, 71].

The intensity of joint symptoms and overall course in transplant recipients may not be as severe as is seen in the immunocompetent population. In general, the disease has been reported as mild with favorable outcomes [72–74]. In general, most of the patients presented with arthralgia, 85% had fever, and 46% developed chronic arthritis by 3 months of follow-up, but no graft dysfunction or deaths were reported [72–74]. Rosso and colleagues recently reported similar findings in Colombia during the 2015 outbreak. Ten SOT recipients that acquired CHIKV were followed for 3 months. Diagnosis was confirmed through RT-PCR and graft transmission ruled out by testing donor samples. Initial clinical manifestations were arthralgia in 100%, fever in 90%, headache in 40%, and myalgia. Interestingly, there were no reports of graft dysfunction, severe complications, or death, and only 30% had mild arthralgia lasting >5 days. All patients achieved full recovery in 3 months without protracted joint pain [75].

Another recent publication from Brazil retrospectively describes 32 cases of CHIKV in kidney transplant recipients. All presented with arthralgia, 47% with overt joint inflammation, and 44% evolving to chronic arthralgia. During the acute phase, seven patients (21.9%) showed acute kidney injury (AKI), but kidney function tended to recover, with transitory graft dysfunction resolving after 3 months. Previous corticosteroid use was not associated with AKI or chronic arthralgia [76]. Similarly, CHIKV infections in HSCT recipients have been reported without increased morbidity [45]. The use of immunosuppressive drugs may play a role in the paucity of symptoms.

Zika

It is estimated that around 80% of ZIKV infections are asymptomatic. Immunocompetent hosts infected with ZIKV by mosquito bite may present with mild fever, maculopapular rash, nonpurulent conjunctivitis, headache, retro-orbital pain, arthralgia, myalgia, and, less commonly, vomiting and edema [35]. In pregnant women, ZIKV infection has been associated with severe congenital complications. Microcephaly is the most devastating feature of congenital infection caused by ZIKV. Other neurological disorders include Guillain–Barre syndrome (GBS), acute myelitis and meningoencephalitis, isolated single or multiple cranial nerve palsies, and stroke [35, 77].

There are few interesting reports of ZIKV in transplant recipients from Brazil [43–45]. In the case series reported by Nogueira and colleagues, four SOT recipients (two for the kidney, two for the liver) infected with ZIKV had symptoms such as fever, headache, cough, myalgia, diarrhea, and vomiting, and three developed concomitant severe bacterial sepsis, with complications such as biliary abscess, graft dysfunction, and one hepatic artery thrombosis requiring re-transplantation. All survived despite these critical events [43], and it is unclear which manifestations can be attributed to ZIKV or solely to bacterial sepsis. In 2017, a fatal case of ZIKV meningoencephalitis was reported in a heart transplant recipient; however, the cause of death was determined to be arrhythmia due to acute cardiac allograft rejection in the setting of abrupt interruption of immunosuppressive drugs [44]. Also in Brazil, Machado and colleagues described a total of four cases of ZIKV in malignant hematology and HSCT recipients, with prolonged RNA detection and delayed engraftment (HSCT) being observed with no further complications [45]. As the symptoms of ZIKV, CHIKV, and DENV are similar, these infections should be considered in the differential of neutropenic fever or rash in posttransplant settings, alongside GVHD and graft rejection, in patients living in endemic areas.

Diagnosis of DENV, CHIKV, and ZIKV

Dengue

Fever and rash are good markers of arbovirus infection, especially during mosquito season, and should prompt DENV, ZIKV, and CHIKV investigation [45]. Thrombocytopenia is a hallmark of dengue and helps to differentiate it from other arboviruses [12, 45]. After disease onset, DENV can be detected in serum, plasma, circulating blood cells, and other tissues for 4–5 days. Currently, nucleic acid tests (NAT) and NS1 antigen detection are recommended to diagnose dengue in the acute phase since results are available within a few hours. Due to the occurrence of prolonged RNAemia (over 15 days), frequently observed in transplant patients, NAT can be used to diagnose dengue even after the first week of illness in this population [12, 58].

After the acute phase of infection, serology used to be the method of choice for diagnosis. Previous studies showed that specific IgM antibodies are detectable in 50% of patients by days 3–5 after illness onset, increasing to 80% by day 5 and 99% by day 10. IgM levels peak about 2 weeks after the onset of symptoms and then decline to undetectable levels over 2–3 months. IgG is detectable at low titers at the end of the first weeks, increasing slowly thereafter with serum IgG still detectable after several months, probably persisting for life [2]. In recent years, with the spread of ZIKV and CHIKV in dengue regions, cross-reactivity in serological tests has unfortunately been observed, with some Zika patients testing false-positive for dengue [78, 79]. As a result, both serological diagnosis and seroprevalence estimates are compromised.

Chikungunya

The diagnosis of CHIKV infection requires laboratory corroboration. Lymphopenia is a key finding, though increased AST/ALT, thrombocytopenia, and hypocalcemia are frequently seen [24]. The laboratory diagnosis is based on NAT in blood samples, viral culture, or detection of IgM and IgG antibodies through serological tests. Viral isolation from blood cells is the gold standard, but technical complexity and delay in results hinder its use in clinical practice [30]. IgM is useful in patients presenting after the acute phase, being detectable between 2 and 12 days and persisting for several weeks [66]. Antigenic cross-reactivity between CHIKV and other alphaviruses has been reported [80]. ELISA assays using recombinant envelope protein-2 antigen for diagnosis of CHIKV without cross-reactivity with other alphaviruses were reported by Fumagalli and colleagues. CHIKV detection parameters for IgG were 89.7% sensitivity and 100% specificity while for IgM were 92.5% sensitivity and 79.0% specificity, showing similar results to immunochromatography assays (LumiQuick, USA) for CHIKV IgM and IgG [81].

In the first week of symptoms, NAT is the method of choice. High viral load ($>1 \times 10^6$ copies/mL) in quantitative RT-PCR was observed in 80% of the patients in the series reported by Rosso and colleagues. However, this was not associated with worse outcomes, which are more likely to occur in immunocompetent patients [75]. In transplant recipients, CHIKV viremia seems to be shorter than in DENV infection [45].

Zika

In symptomatic patients, laboratory confirmation of ZIKV infection can be made through NAT and serology, but older generation immunological assays are known to exhibit cross-reactivity with other *Flaviviridae*, particularly DENV [82]. However, a new Zika NS1 blockade-of-binding ELISA was found to be 91.8% sensitive and 88.9% specific in discriminating ZIKV from DENV and can be used >10 days after

disease onset or presumed exposure, which is an advantage [83]. The definitive diagnosis is established by detection of viral nucleic acid in urine or serum, with the former being more reliable since most patients exhibit transient viremia making serum diagnosis elusive. Recent studies have shown that viral shedding in urine lasts 8–15 days in 41.4% of patients and 16–30 days in an additional 11.2% of patients [84]. Thus, detection by RT-PCR in the urine allows for a broader detection window and, per a recent study, performs better when compared to serum [85].

A method using Trioplex RT-PCR was found to detect and discriminate between ZIKV, CHIKV, and DENV, which is a great addition to the diagnostic armamentarium in tropical countries where these arboviruses commonly co-circulate. No cross-reaction or PCR inhibition was observed in the clinical samples tested [86].

In conclusion, transplant recipients with suspected arbovirus infection living in or returning from endemic areas should be tested by NAT during the acute phase of the disease. Recent developments in simultaneous multiplex RT-PCR technology have made fast, specific, and definitive diagnosis possible in geographic regions where the three arboviruses share the same biting arthropods and seasonality, with high specificity and sensitivity [86]. Serological diagnosis has been hindered by the occurrence of cross-reactivity among *Flavivirus.* The commercially available ELISAs to detect dengue IgG and/or IgM have shown low specificity when used for patients infected by ZIKV [79].

Management of DENV, CHIKV, and ZIKV Infections in Transplant Recipients

Dengue

Overall assessment includes history and physical exam, laboratory tests, and evaluation of disease severity [10]. Investigation of previous DENV infection is mandatory as seropositive patients have a greater risk of developing SD if infected with a different serotype. Based on the findings, clinicians are able to determine the phase of the disease, the presence of warning signs, and the patient's need for hospital admission (see Fig. 2) [2].

There is no specific antiviral drug to treat dengue, and generous fluid replacement is the mainstay of therapy. Freeman and colleagues summarize new developments in DENV-targeted therapy [87], including a combination of sunitinib (VEGF receptor tyrosine kinase inhibitor) and TNF-alpha inhibitors to halt the ADE phenomenon and prevent progression to SD [88]. VIS513, a pan-serotype monoclonal antibody targeting domain III of dengue E protein, has been shown to reduce viral load in the acute phase of dengue [89]. Some authors have shown that CSA can be a potential drug for the treatment of flavivirus infections [56]. On the other hand, balapiravir, celgosivir, and chloroquine have proved ineffective in trials [90–92]. Anecdotally, there are reports of successful use of IVIG to reverse capillary leak in a renal

transplant patient [61], though a randomized controlled trial in immunocompetent patients demonstrated that IVIG does not significantly change outcomes but also causes no additional harm [93]. Prospective studies to evaluate the role of IVIG in dengue are warranted in the transplant setting. Currently, there is not enough evidence to recommend decreasing or switching immunosuppression regimens in infected transplanted patients. De-escalating immunosuppressants may trigger graft rejection [7]. As mentioned previously, some authors have transiently held MMF in case of severe cytopenias, and patients on a cyclosporine (CSA) containing regimen appeared to have less severe disease [7, 58]. More studies are needed to clarify the best immunosuppressive strategy in this scenario.

Chikungunya

Treatment of acute CHIKV is mainly supportive and symptomatic. The co-administration of nonsteroidal anti-inflammatory drugs (NSAIDs) with low-dose systemic steroids has been recommended to reduce pain and improve quality of life in treating acute CHIKV with arthralgia. Aspirin should be avoided [94]. Antiviral agents and monoclonal antibodies are in initial stages of testing. Niclosamide, nitazoxanide, and suramin have shown anti-CHIKV activity [95, 96]. A combination of ribavirin and doxycycline has shown antiviral activity in vitro and in an animal model [97]. Giancotti and colleagues identified about 69 small-molecule compounds that were derived using a benzylidene-acrylohydrazide antiviral scaffold with potential direct anti-CHIKV activity in Vero cell lines [98]. A recent review describes the antigenic sites and mechanisms of action of 18 different monoclonal antibodies (mAbs) against CHIKV [99]. Other excellent reviews of potential therapeutic compounds have been recently published [100, 101]. Although promising, these compounds need to be tested in clinical trials.

Zika

So far, there is no specific FDA-licensed therapy for ZIKV infection. Treatment for uncomplicated disease includes rest, hydration, and symptomatic management for fever and arthritis. NSAIDs and aspirin should be avoided until DENV has been ruled out. Freeman and colleagues point recent advances in research toward direct antiviral therapy including specific DENV anti-E dimer epitope antibodies that cross neutralizes ZIKV in rhesus monkeys [87, 102]. Chloroquine administered to ZIKV-infected pregnant mouse models reduced vertical transmission and viral load in fetal brain. There are ongoing studies using small molecules, but there are also ethical barriers to the inclusion of pregnant women in clinical trials without extra safety precautions [103]. Another study showed in vitro therapeutic effects of atovaquone against ZIKV, particularly the Brazilian and Ugandan strains, likely via depletion of nucleotides blocking pyrimidine biosynthesis [104]. The drug is considered FDA category C in pregnancy, which makes it attractive for such vulnerable populations.

Preventive Measures

Transplant donors or recipients living in or traveling to endemic regions should receive information about arbovirus transmission and *Aedes* habits to avoid exposure. Insect bites should be minimized by application of mosquito repellent (N, N-diethyl-m-toluamide DEET, picaridin or IR3535) and protective clothing [2].

Vector Control

The backbone of dengue, zika, and chikungunya prevention is based on vector control and community programs to keep the environment free of potential breeding sources (flower vases, uncovered water storage barrels, discarded tires, etc.). The vector is well adapted to urban and domestic environments, and *Aedes* distribution maps have been shown to help predict the local, regional, and international spread of arboviruses. Local outbreaks of these arboviruses have typically followed within 5–15 years of infestation by *Aedes aegypti* and *Aedes albopictus,* emphasizing the importance of vector density control [105].

Fascinating interdisciplinary work is being done in mathematical forecasting models using climate parameters to predict the next *Aedes aegypti* mosquito season and its associated risk of arbovirus epidemics. Huber and colleagues examined the influences of seasonal temperature mean, variation, and temperature at the start of outbreaks in disease dynamics. The model projects that intermediate temperatures at about 24–25 °C produced the largest epidemics, while warmer temperatures at the start of epidemics promote more rapid outbreaks due to fast burnout of the susceptible population [106].

Another interesting line of research attempts to make mosquitos resistant to arboviruses. One study identified an insect symbiont, *Wolbachia* wStri, that was shown to inhibit by >99.9% of the replication of ZIKV, DENV, and CHIKV in *Aedes albopictus* cells. RNA transfection and metabolic labeling studies demonstrated that the replication defect is at the level of RNA translation [107]. Moretti and colleagues and Xue and colleagues are also working in *Wolbachia*-induced sterility and mathematical modeling of such strategies, respectively. This interdisciplinary work is essential in a future where climate volatility and change will expand the mosquito geographical reach and its associated diseases [108, 109].

Vaccines

The first licensed Sanofi Pasteur CYD-TDV vaccine (Dengvaxia) is a tetravalent, recombinant, live-attenuated vaccine with a yellow fever 17D vaccine virus backbone, administered in a three-dose schedule at 6-month intervals. The vaccine was initially licensed for individuals aged 9–45 years living in areas with dengue seroprevalence >70%. Pooled results from two parallel phase-3 trials showed a clear benefit in DENV-seropositive individuals, with efficacy of 81.9% [110].

However, there was less protection observed for infections caused by DENV-2 and a significant excess of dengue hospitalization in the vaccinated group aged 2–5 years (RR = 7.45; 95% CI 1.15–313.80) [110, 111]. This was also the age group with the lowest pre-vaccination seroprevalence (51%), strongly suggesting that the ADE phenomena are not merely a theoretical concern, but a real issue with live-attenuated dengue vaccines. Safety data of 4-year follow-up from the abovementioned clinical trials showed a relative risk of 1.327 (95% CI 0.56–3.48) for patients seronegative at baseline to have virologically confirmed dengue hospitalizations, irrespective of age [112].

In September 2018, the WHO published a position paper reviewing safety data for Dengvaxia. Due to the excess risk in seronegative subjects, individual pre-vaccination screening is recommended with only seropositive individuals advised to receive CYD-TDV. Alternatively, vaccination without individual screening could be considered in areas with recent documentation of seroprevalence rates of at least >80% by age 9 years. The position paper did not recommend use in immunocompromised patients due to paucity of data and suggested research priorities including highly discriminative rapid diagnostic tests (RDTs) to evaluate serostatus prior to vaccination at the point of care and the development of safe, effective, and affordable DENV vaccines that could be administered irrespective of serostatus [113].

In that regard, there is emerging research on next-generation vaccines that offer the promise of no increased ADE risk. Two candidates, DSV4 and T-mVLP, do not utilize pre-membrane (prM) and envelope domain (ED)-II epitopes, which have been shown to produce serotype cross-reactive immune responses, focusing instead on ED-III which is also serotype-specific and has been shown in mouse AG129 models to produce neutralizing antibodies and not predispose to ADE. These candidate vaccines make use of virus-like particles (VLP) delivery platforms and can be mass-produced using the yeast *Pichia pastoris.* Both candidates require clinical trials to assess their performance and safety profiles before expanding their use to the broader population and specifically to transplant recipients [114].

Vaccines against Zika and chikungunya are in fast-track development and show promise in recent studies. Prow and colleagues report on a single-vector construct SCV vaccine that encodes the structural polyprotein cassettes of both ZIKV and CHIKV. Vaccination in wild-type (WT) and interferon alpha/beta receptor (IFNAR) −/− mice induces neutralizing antibodies to both viruses that halt viremia in CHIKV and ZIKV infected mice, as well as preventing arthritis from CHIKV and placental/fetal infection in female and male testes infection from ZIKV in IFNAR −/− mice [115]. Another group reported an additional new vaccine candidate for both CHIKV and ZIKV. It is a single dose, bivalent recombinant vaccine, based on a chimeric vesicular stomatitis virus (VSV) that expresses the CHIKV envelope polyprotein E3-E2-6K-E1 in place of the VSV glycoprotein and the membrane envelope glycoproteins of ZIKV. This vaccine induced neutralizing antibodies to both CHIKV and ZIKV in WT and A129 mice [116]. No large-scale commercial vaccine is currently available, but its development appears promising. When these vaccines do become available, safety and efficacy studies in immunocompromised animal models followed by clinical trials will be necessary before recommending their use in

transplant recipients. One recently published double-blind, randomized, placebo-controlled phase-2 trial demonstrated immunogenicity, safety, and tolerability for a CHIKV-specific vaccine enrolling healthy volunteers in Austria and Germany [117].

Blood Supply Safety

There are also ongoing efforts to increase blood supply safety and prevent TT of arboviruses. Amotosalen and ultraviolet A light (UVA) have been demonstrated to inactivate ZIKV in platelet and plasma components [118]. TT-ZIKV through platelets has been reported in the past [49, 50]. Another study demonstrated the efficacy of amustaline and glutathione (S-303/GSH) for CHIKV pathogen inactivation in red blood cell concentrates [119].

Screening Recommendations and Donor Deferral

There are several international guidelines on tissue and blood donor screening [120–122]. Most of them focus on epidemiological risk factors and the risk-benefit ratio of each particular case and note the impact that unduly restrictive policies might have in the organ supply especially in tropical and resource-deprived countries. Two recent articles discuss the similar course of ZIKV in immunosuppressed as compared to immunocompetent patients as important factors for decision-makers to consider [123, 124].

Since August 2016 the FDA has a universal ZIKV NAT screening policy for the blood supply in place, initially as NAT for every individual donation that was later revised in July 2018 toward a mini-pool NAT strategy with a trigger for individual screening during local autochthonous transmission or travel-related risk [47, 125]. However, a recently published Monte Carlo simulation questions this strategy by projecting ZIKV transfusion infections and cost-effectiveness per quality-adjusted life-years (QALY) gained, showing screening was cost-effective only in the high mosquito season in Puerto Rico, and no evaluated screening policy was cost-effective in the 50 states of the US mainland. Even without screening, the simulation showed a very low risk of ZIKV complications (one GBS case every 16 years in Puerto Rico and every 84 years in US mainland). The analysis does not account for more subjective aspects of blood safety policies, like public trust in the blood supply [126].

Some guidelines suggest avoiding traveling to endemic areas 30 days prior to donation and avoiding sexual intercourse for 6 months with a male traveler returning from a region with an active outbreak of ZIKV [66].

Although viral RNA can be detected in semen more than 350 days after initial symptoms, a recent study showed that infectious ZIKV is detected up to 38 days after symptoms onset [41]. Some authors suggest ruling out acute infection in donors traveling or living in regions with active outbreaks, with organs still utilized and follow-up monitoring of recipients after transplantation [124]. Donor screening for

Action		DENV	CHIKV	ZIKV
Blood screening		No	No	According to country recommendation
Donor screening	Endemic regions	Yes, in symptomatic donors	Yes, in symptomatic donors and corneal donors (during outbreaks)	Yes, in symptomatic donors
	Non-endemic regions	No. Check recent travel and consider screen specially if symptoms suggestive of arbovirus in the last 30 days.		
Donor deferral		Discard organs from donors with documented DENV within 30 days.	Discard organs from donors with documented CHIKV within 30 days. Defer corneal donors during local CHIKV outbreaks	Defer donors with documented ZIKV for a period longer than 1 month
Diagnosis during acute phase		NAT, NS1	NAT	NAT

Fig. 3 Screening and deferral recommendations

arboviruses is not routinely recommended. However, in areas of arbovirus endemicity, screening for DENV, ZIKV, and CHIKV should be considered, particularly in symptomatic donors [127]. If screening is not feasible, donors from endemic regions should be deferred if they have a recent history of febrile illness suggestive of arbovirus in the last 30 days [121, 122]. Due to the high frequency of silent eye infection, some authors recommend screening of corneal donors for CHIKV during outbreaks [34].

The FDA has recommended a 4-week deferral for donor candidates with a recent travel history arriving from ZIKV endemic countries [125]. However, a risk analysis performed in Canada using the Monte Carlo simulation showed that a 21-day travel deferral would provide an extremely safe margin [128]. Current screening and deferral recommendations are depicted in Fig. 3.

Conclusions

Clinical manifestations of DENV, CHIKV, and ZIKV are similar in transplant recipients. Therefore, in case of suspected arbovirus infection, transplant recipients living in or returning from endemic areas should be tested by NAT during the acute phase of the disease. Recent developments in simultaneous multiplex RT-PCR technology have made fast, specific, and definitive diagnosis possible in geographic regions where the three arboviruses share the same biting arthropods and seasonality, with high specificity and sensitivity.

Serological diagnosis is currently a challenge, as recent data showed cross-reactivity of dengue tests in patients with proven ZIKV. So far, NAT is preferred in

blood bank and pretransplant donor selection, as well as in symptomatic or suspect cases after transplantation.

Among the three discussed arbovirus infections, DENV showed greater morbidity with a protracted course, prolonged viremia, and more associated complications. No specific FDA-approved treatment is available, and current vaccines can elicit ADE in previously exposed individuals, while safe vaccine alternatives are still in development. Management of arboviruses is mainly supportive, with attention to warning signs of decompensation. Reduction of immunosuppression is not recommended as it may trigger rejection or GVHD.

Key Points

- Clinical manifestations of DENV, CHIKV, and ZIKV are similar in transplant recipients, and laboratory corroboration is necessary.
- NAT is preferred in the acute phase of the disease. DENV and ZIKV serology may cross-react.
- DENV has a more aggressive course than ZIKV and CHIKV with more complications and prolonged viremia. Management of DENV is mainly supportive, with attention to warning signs of decompensation.
- Wise management of immunosuppression is paramount. Avoid abrupt reduction.
- No specific treatment is currently available. DENV vaccine is not recommended in transplant recipients. CHIKV and ZIKV vaccines are in development.
- Screening and deferral recommendations are still controversial and vary among endemic and non-endemic regions.

Introduction

Epidemiology

Yellow fever (YF) is caused by a single-strand RNA virus of the genus *Flavivirus* and is transmitted to humans by blood-feeding mosquitoes mainly belonging to the genera *Haemagogus* and *Sabethes* (in the Americas) and the genera *Aedes* (in Africa and the Americas), respectively [1]. YF is often called the "original" hemorrhagic fever. The sylvatic cycle consists of transmission through the bite of

a mosquito that has previously fed on a viremic primate, and urban YF occurs through interhuman transmission. In the Americas, YF is transmitted by *Haemagogus* mosquitoes in the jungle environment (sylvatic cycle) and *Aedes aegypti* in urban settings (urban cycle), whereas in Africa, transmission to humans occurs via *Aedes* spp.

There is an estimated occurrence of 200,000 cases of YF cases worldwide annually with 30,000 deaths [2], with 90% of cases occurring in Africa. Thirty-four countries in Africa and 13 countries in Central and South America have regions that are endemic for YF. In South America, the most affected countries are Peru, Bolivia, Brazil, and Colombia.

There are three conditions that must be present in order to result in a YF epidemic: the introduction of the virus in a susceptible population, the presence of competent mosquito vectors, and inadequate prevention strategies (vector control and immunization of human populations) [3].

In Africa, the epidemiology is commonly mixed due to a high density of vector mosquito populations in close proximity to large unvaccinated populations, thus provoking far greater epidemics than in South America [1, 4]. A large urban outbreak occurred in 2015 in Angola and subsequently spread to the Democratic Republic of Congo, with 961 confirmed cases and 137 deaths [5]. In Asia, the only reported cases were of 11 Chinese workers who had been infected in Angola and were therefore imported cases [6]. The potential international spread to countries with susceptible populations and presence of mosquito vectors is of great concern. It has been recently reported that the YF virus has also been detected in *Aedes albopictus* [7].

In South America, the possible explanations for the recent resurgence in YF include low vaccine coverage, migration of susceptible individuals to forested endemic regions, and increasing urbanization [4]. In Brazil, after the major epidemic of urban yellow fever in the late 1930s, cases were limited to endemic areas such as the Amazonian states, with a few outbreaks in the southeast (Minas Gerais and São Paulo in 2002 and 2008, respectively) and the south (Paraná and Rio Grande do Sul in 2008) [8]. Since 2014, there have been epizootics in monkeys, and between December 2016 and May 2018, there have been 2050 confirmed YF cases with 681 deaths (case fatality rate of 33.2%) [9]. It was demonstrated through phylogenetic and phylodynamic tools that the outbreak originated in Northeastern Brazil, moving southward to areas of unvaccinated populations, at a rapid rate of 4.25 km per day [10].

During the Angola and the Democratic Republic of Congo outbreak, the novel strategy EYE (Eliminating Yellow fever Epidemics) began, as an initiative of the World Health Organization, and aims to eliminate yellow fever by 2026.

Clinical Manifestations

The incubation period following mosquito bite ranges from 3 to 9 days. The clinical presentation of YF ranges from a subclinical infection to severe systemic disease. The majority of patients are asymptomatic.

In symptomatic patients, there are typically three phases of disease. The majority of patients present only the first phase, in which viremia is present. This phase may be subclinical or characterized by fever, malaise, generalized myalgia, nausea, vomiting, irritability, insomnia, and prostration [4]. Laboratory abnormalities include thrombocytopenia, leukopenia, and elevated serum transaminase levels. The second phase is not always present and is characterized by up to 48 h of remission of symptoms. The third phase occurs in approximately 15% of cases – using a Bayesian model, one study estimated that for every severe YF case identified, there may be up to 70 infections that are either asymptomatic or oligosymptomatic [11]. The severe cases are characterized by nausea, vomiting, mild jaundice, and coagulopathy, with involvement of various organs and systems, notably severe liver damage with encephalopathy and/or seizures, cardiovascular dysfunction with bradycardia or arrhythmias, circulatory shock, and varying degrees of acute kidney injury [4, 12]. Hemorrhagic manifestations include epistaxis, mucosal bleeding, hematemesis, and catheter-site bleeding. In convalescent individuals, the elevation of bilirubin is delayed and is seen approximately 2–3 weeks after onset of symptoms.

Case fatality rates in severe forms range from 20 to 60%. The few studies on prognostic factors demonstrated that serum aminotransferase and bilirubin levels were independently associated with higher mortality [13]. Also renal failure, notably blood urea nitrogen levels above 100 mg/mL, was associated with a higher risk of death [13]. Overall, case fatality rates are lower in Africa (approximately 20%) compared to South America (30–60%), suggesting that there may be genetic factors that determine prognosis [1].

Diagnosis

YF diagnosis may be confirmed by virologic or serologic tests [14], as clinical symptoms generally overlap with a wide range of diseases, including dengue, leptospirosis, viral hepatitis, and malaria [15].

Virologic tests include detection of viral RNA in serum samples via molecular methods such as conventional or real-time reverse transcription polymerase chain reaction (RT-PCR), with confirmation of YF infection given by a positive result [14], viral isolation (rarely used because of its complexity), and immunohistochemistry in tissues, commonly performed in necropsy samples, although molecular diagnostics can also be performed in tissue samples. In the past, it was believed that YF viremia only lasted for the first 5 days of the illness [16], but more recent studies using molecular tools have shown that the virus can still be detected in blood up to 20 days after symptom onset in more severe cases [17–19]. It has also been demonstrated that viral RNA was still present in urine and semen samples up to 21 days after symptom onset [20].

Serologic tests may be performed by ELISA or plaque reduction neutralization test (PRNT) [21]. Both techniques may present cross-reactivity with other flavivirus diseases, such as dengue and Zika, especially in areas of high co-circulation with these viruses. Prior immunity to dengue virus is the most frequent confounder [22]. Moreover, serology is unable to differentiate between vaccine-induced

immunity and post-disease immunity. There are no validated ELISA commercial kits for detection of YF IgM. The confirmation requires seroconversion in samples of an interval of at least 1 week or a fourfold increase in IgG testing in acute and convalescent samples [21, 22].

In fatal cases, diagnosis can be confirmed by molecular diagnostics of tissue or immunohistochemistry [14]. YF virus has been isolated from the liver, spleen, kidneys, lungs, heart, and brain of symptomatic patients [23, 24].

Prevention

Vector control and immunization are the mainstay of prevention strategies for YF control. As has previously been seen with dengue, chikungunya, and Zika, *Aedes aegypti*-mediated epidemics can spread rapidly in unvaccinated populations. A recent study estimated that between 393.7 million and 472.9 million people still require YF vaccination in areas at risk of disease transmission in order to achieve the 80% coverage threshold recommended by the World Health Organization (WHO), representing between only 43% and 52% of the population in these risk zones [25].

The Asibi strain of YF virus was successfully attenuated, resulting in the first vaccine developed in the 1930s [26]. There were two vaccines – the 17D vaccine and the French neurotropic vaccine. Production of the latter was interrupted in 1982 due to high rates of adverse neurological events. Nowadays, there are the 17DD (manufactured in Brazil) and the 17D-204 strain vaccine (YF-VAX, manufactured by Sanofi Pasteur, Swiftwater, Pennsylvania), with similar immune responses [27]. In clinical trials, 80–100% of vaccinated individuals develop protective immunity within 10 days [28] and 99% within 30 days [29].

YF vaccine is recommended for persons aged $\geq$9 months who are traveling to or living in areas at risk for YF transmission [26]. In April 2013, the WHO Strategic Advisory Group of Experts on Immunization concluded that a single primary dose of YF vaccine is sufficient to confer sustained immunity and lifelong protection, with no need for a booster dose every 10 years, as previously recommended [30]. In 2015, a committee of experts issued recommendations for certain populations who would benefit from YF vaccine booster doses [31]: women who were pregnant at receipt of first dose; HSCT recipients when sufficiently immunocompetent to be revaccinated; people infected with human immunodeficiency virus; travelers in high-risk settings, including those planning on spending a prolonged period in highly endemic areas; and laboratory workers of wild-type YF virus laboratories.

After YF vaccine administration, recipients usually develop low-level viremia within 3–7 days, which persists for 1–3 days, followed by the development of YF virus IgM antibodies [32]. Although the viremia is low, it is high enough to be transmitted through blood products [33], as reported in 2010, when five patients received six blood products from individuals who had been vaccinated for YF 4 days prior to donation. One patient died without further information regarding viremia or serologic testing, and of the 4 other blood product recipients, all were asymptomatic with no laboratory abnormalities compatible with YF infection. Three of these

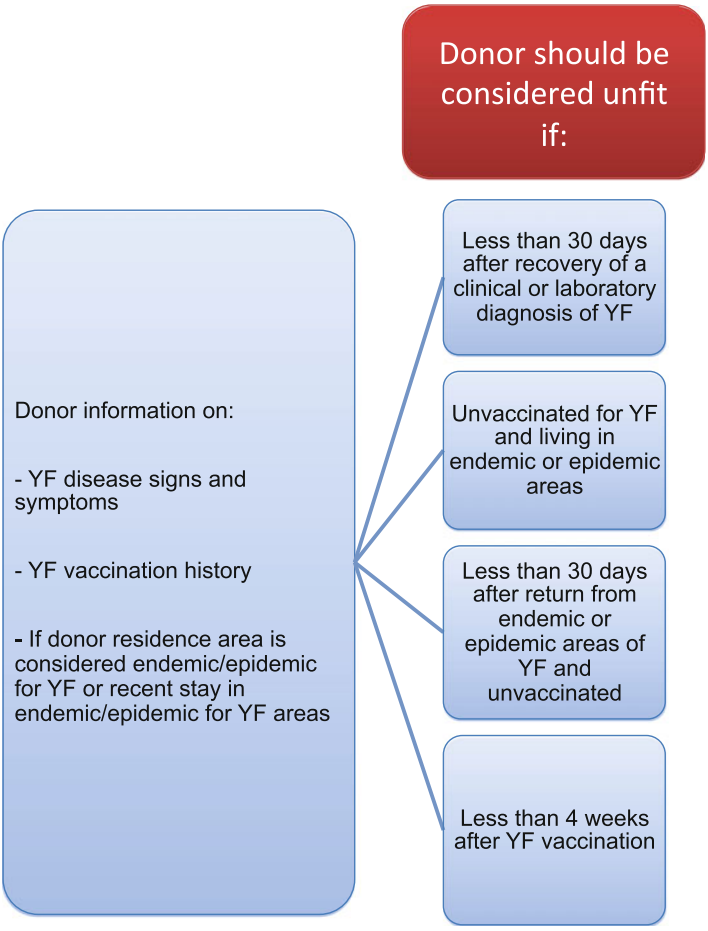

Fig. 1 Recommendations for the acceptance of solid organ donors with previous infection, living or with a recent stay in endemic or epidemic areas, or a recent history of YF vaccination. (Adapted from Brazilian Ministry of Health [35])

patients presented positive IgM and PRNT titers approximately 30 days after transfusion. The American Red Cross recommends deferral from blood donation for 2 weeks after receipt of YF vaccine [34].

In 2017, the Brazilian Ministry of Health issued recommendations for the acceptance of tissue and SOT donors with past infection or a recent history of YF vaccination (Fig. 1) [35].

Adverse events due to YF vaccination are usually mild: fever, myalgia, prostration, malaise, and headache may occur for 5–10 days after vaccination, in 10–30% of vaccine recipients [29]. Serious adverse events include vaccine-associated neurological disease, viscerotropic disease, and egg allergy-associated hypersensitivity reactions such as anaphylaxis [36].

The rate of adverse reactions following YF vaccine depends on the population studied. Data on US and European travelers report a rate of viscerotropic disease ranging from 0.25 to 0.4 per 100,000 doses, while in Peru, the rate was 7.9 per 100,000 doses [37]. The rate is also higher in elderly persons (over 60 years), reaching 2.3–12.6 per 100,000 doses [38, 39]. In the same elderly population, nonserious adverse events were considerably higher in first-dose vaccines (17.5%) compared to those receiving booster doses (9.5%) in a Brazilian study of over 700 vaccinated travelers [40]. In Brazil, a study based on the passive National Surveillance System following immunizations estimated overall rates of serious YF vaccine-related adverse events as hypersensitivity, 0.9 per 100,000 doses; anaphylactic shock, 0.023 per 100,000 doses; neurotropic disease, 0.084 per 100,000 doses; and viscerotropic disease, 0.019 per 100,000 doses [41].

Due to the increased risk of developing adverse events, current contraindications for YF vaccination as issued by the WHO are [42] children below 9 months, pregnant or breastfeeding women, people with severe hypersensitivity to egg antigens, severe immunodeficiency, and age over 60 years.

Recently vaccinated individuals (less than 30 days) that present with YF infection should undergo molecular testing in order to differentiate infection by wild-type YF virus or vaccine strain [14].

Prevention in Transplant Candidates

Clinical manifestations in transplant recipients have been previously described in other arboviruses. In renal transplant recipients, dengue manifestations appear to be similar to the general population, with some degree of graft dysfunction [43], with similar findings with Chikungunya infection [44]. Dengue virus shedding has been demonstrated to be more prolonged in immunocompromised persons (up to 80 days) compared to immunocompetent patients (up to 7 days) [45]. Literature is scarce regarding YF clinical manifestations in SOT patients, with only one fatal case in a kidney recipient [46] (Fig. 2).

In real life, the compliance with vaccine administration in transplant candidates may be suboptimal, as observed in a single-center study where patients were poorly informed by transplant physicians or general practitioners regarding pretransplantation vaccination [47]. Another single-center study involving 105 kidney transplant candidates showed YF vaccine coverage of only 3.8% [48]. However, efforts should be focused on this strategy especially where live vaccines are concerned, as they are contraindicated after transplantation. A French recommendation endorses the YF vaccine prior to transplantation whenever immunologic conditions allow. If the transplant recipient is traveling, then a contraindication medical certificate may be issued, though this increases the risk of wild-type disease if the individual enters a YF risk zone [49].

Most studies on live vaccine posttransplant are limited to observational and case series or reports. One of them, including 19 SOT recipients vaccinated for YF [50], showed no serious adverse events. A meta-analysis of live attenuated

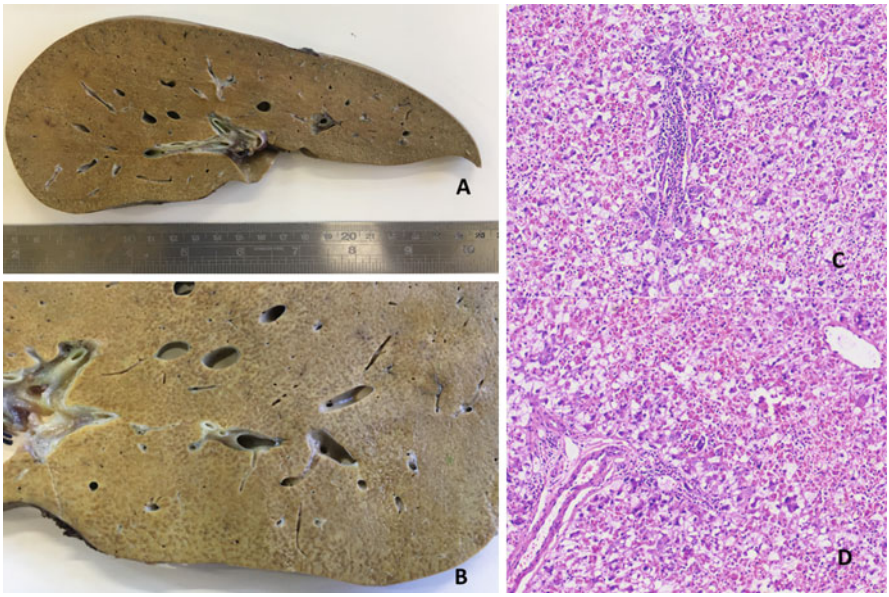

Fig. 2 (**a** and **b**) Explant of a liver transplant recipient with the severe form of yellow fever showing the liver with a yellowish to tan, homogeneous, and soft cut surface. (**c** and **d**) Characteristic midzonal necrosis with numerous Councilman-Rocha Lima bodies, sparing hepatocytes in periportal and perivenular zones

vaccination in immunocompromised individuals observed 1 fatal case of vaccine-related YF disease in a patient with rheumatoid arthritis and systemic erythematous lupus receiving treatment with methotrexate and corticosteroids, while 20 SOT recipients did not report serious adverse events or infection related to vaccination [51]. Nonetheless, the numbers are small, and therefore recommendations cannot be made for the administration of live vaccines in this population, thus limiting use of these vaccines to the pretransplant period.

The persistence of YF antibodies in SOT recipients has been demonstrated in those vaccinated prior to transplantation. Of 53 individuals (29 kidney recipients and 18 liver recipients), all but one had protective titers of antibodies after a median period of 3 years (0.8–21), and of 46 patients with a known estimated date of vaccination, the antibodies were still detectable after a median time of 13 years [2–32] after YF vaccination [52].

In the following sections, the literature on YF vaccination in hematologic malignancies and HSCT, kidney, and liver transplant recipients will be reviewed. Heart and lung recipients will not be discussed due to scarcity of data.

Hematological Malignancies and HSCT Candidates

Data on YF vaccination in this population is scarce, as the vaccine is contraindicated in this population. YF vaccination is possible after a HSCT and a 2-year period

without graft-versus-host disease or immunosuppressive treatment, with a case series of 21 recipients immunized with no adverse events at a median of 39 months after transplantation and a median of 33 months after withdrawal of immunosuppression [53]. Among those individuals vaccinated prior to transplantation, one third had persistent protective immunity after the procedure [53].

One single case report presents the case of a patient with acute myeloid leukemia who started chemotherapy 7 days after receiving a first dose of YF vaccine, resulting in prolonged viremia (15 days) with no other complications, while surprisingly maintaining antibody titers for more than 30 months after transplantation [54].

Kidney Transplant Candidates

In renal failure, an impairment of cell-mediated immunity is observed [55]. There is a reduced absolute number of peripheral blood T lymphocytes as a result of depressed activation and proliferation of T lymphocytes [56]. Regarding humoral response, chronic renal failure individuals are known to show poor protective efficacy from vaccines [57]. Early studies indicate defective macrophage function as a result of a uremic environment and impaired generation of activated antigen-specific T helper cells without adequate B cell antibody synthesis as a result of diminished interleukin 1 and 2 production [58].

Despite these findings in early literature, there have been safety studies on live, attenuated varicella-zoster vaccine in end-stage renal disease recipients that demonstrated that the vaccine was safe and antibody responses were protective [59]. In a larger safety study of the herpes zoster vaccine, 300 individuals, including 61 with chronic renal disease, had similar rates of adverse events compared to immunocompetent patients [60].

Literature is scarce concerning YF vaccine efficacy in hemodialysis patients. One study analyzed the YF vaccine status of 130 hemodialysis patients, and unvaccinated individuals were referred for immunization. Of the 86 referred patients, 45 were actually vaccinated, and there were no serious adverse events attributable to the YF vaccine, including anaphylaxis and neurologic or viscerotropic disease [61].

In a French study on YF vaccination in 84 elderly individuals after a median of 14 years after vaccine, there was one case of renal insufficiency among the studied population, with persistence of neutralizing antibodies [62].

Liver Transplant Candidates

In view of the morbidity of infection in cirrhotic patients, prevention through immunization is crucial in the management of this population, particularly those who are candidates for liver transplantation, as posttransplantation vaccine response is less efficient [63]. The literature mostly addresses influenza, hepatitis A and B, and pneumococcal vaccines in cirrhotic patients [64].

In inactivated influenza vaccine studies, although the percentage of cirrhotic patients who develop seroprotection is lower overall than healthy controls, the indication still stands, due to the high morbidity and mortality in this population [63]. Specific humoral immunity in cirrhotic patients against influenza was demonstrated to be comparable to age-matched controls, while cell-mediated response was only worse in Child C cirrhotic patients [65].

There are some studies on other live vaccines, such as the herpes zoster vaccine. One cohort study demonstrated clinical efficacy in patients with chronic conditions, including liver diseases [66].

There are no studies in the current literature concerning YF vaccine and cirrhotic patients. However, in light of the recent epidemic, the Brazilian Ministry of Health issued YF vaccine recommendations for liver transplant candidates [35]: indicated for all candidates below 60 years of age; if over 60 years, the patient is evaluated for comorbidities and requires authorization from the attending physician and consultation with the transplantation team, with a recommendation of transplantation deferral for 4 weeks after vaccination.

Liver Transplantation as an Emerging Treatment Option

Some drugs have been evaluated for YF treatment, such as interferon-alfa and antivirals such as high-dose ribavirin in experimental models though, to date, none has proven effective, and management of severe YF consists of supportive treatment [67–69]. YF virus has recently been demonstrated to be susceptible in vitro and in vivo to the antiviral sofosbuvir [70, 71], and randomized clinical trials are currently ongoing in Brazil.

It was believed that the clinical outcome was correlated with the severity of liver damage, leading to coagulopathy-related disorders and consequently multiorgan failure [1]. Until 2018, epidemics of YF had occurred in areas lacking high-complexity medical care facilities. In the epidemic that struck the southeast of Brazil from December 2017 to April 2018, cases occurred in close proximity to the city of São Paulo, and patients were therefore referred to quaternary hospitals. In this context, the first liver transplantation in a case of severe YF was performed in December 2017 in Brazil, with a successful outcome [72], and subsequently another six cases were performed at the same center, in the context of high mortality rate among severe cases of YF. Of seven transplanted patients, three survived, and four died at a median of 5.5 days after transplant [4–16]. One of the surviving patients progressed to severe pancreatitis and required several debridements (surgical and interventional radiology-guided) with secondary bacterial infections. The other two liver recipients presented with neurologic impairment after transplant, mainly apraxia, with gradual improvement. The outcome of the liver graft was unremarkable in all three cases, and none underwent liver biopsies after transplantation. The four patients who did not survive had signs of YF reinfection

of the liver graft, and two patients had severe necrotizing pancreatitis at necropsy. A key feature that could define prognosis is acute pancreatitis, which has not previously been described in YF. Management of these cases includes abdominal imaging, and the presence of signs of necrotizing pancreatitis should constitute a contraindication for liver transplantation.

Owing to the limited experience, precise recommendations cannot be made. However, in an analysis of other cases of the same epidemic in which patients receiving vasopressors and/or mechanical ventilation did not survive except for the three cases in which liver transplantation was performed, it is safe to say that the procedure was life-saving for these patients.

Liver transplantation in YF has also been performed in other transplant centers in São Paulo, Minas Gerais, and Rio de Janeiro, adding an additional 16 liver transplantations in Brazil. Overall, of 23 transplanted patients in Brazil, six (26%) survived. As a consequence of the high lethality in severe cases, many underwent the procedure in extremely severe clinical conditions and succumbed shortly after transplantation.

As a consequence of travelers returning from endemic or epidemic regions in Brazil or Africa, liver transplantation for severe YF has also been successfully performed in Argentina (G. A. Soteras, personal communication) and Holland (S. Darwish Murad, personal communication). In France, it has also been performed, but the patient succumbed due to posttransplantation necrotizing pancreatitis (O. Soubrane, personal communication).

The precise indications for liver transplantation in the context of YF are unknown, as the classical indications of Clichy [73] and King's College [74] criteria were not defined for systemic diseases like YF. The clinical picture of liver failure in YF patients is distinct from that of fulminant hepatitis due to other classical causes such as hepatotropic viruses or drug hepatoxicity, because YF is a systemic disease. Other successful cases of liver transplantation due to acute liver failure related to infectious systemic diseases have been performed, such as in herpes simplex virus (HSV) [75], Epstein-Barr virus (EBV) [76], parvovirus B19 [77], and dengue [78]. Similarly, there is the risk of a posttransplant viral recurrence following immunosuppression, and in the context of HSV and EBV, acyclovir may be administered as an attempt to prevent recurrence. However, in YF, there are to date no antivirals proven to be efficacious.

More recently, in the epidemic that began in January 2019 in Brazil, data from the State of São Paulo showed that there were fewer cases, with 65 autochthonous confirmed cases [79] as opposed to 504 cases in 2018, and a different management strategy was undertaken in our center. Plasma exchange was performed in patients considered at high risk of death, yielding good results (unpublished data), based initially on previous experiences of plasma exchange in acute liver failure [80]. Current management therefore includes plasma exchange with replacement with fresh frozen plasma, and liver transplantation may be indicated in severe YF cases where there is suspicion of baseline chronic hepatopathy. Supportive management also includes anticonvulsive prophylactic drugs and antimicrobial prophylaxis, as for acute liver failure [81].

Conclusions

Adequate vaccine coverage should be the focus of YF control in countries in which there are epidemics or endemic regions for YF. Because YF vaccine is composed of live, attenuated virus, it is contraindicated in SOT and HSCT recipients, and vaccine should be preferably administered prior to transplantation. Despite the scarcity of data, SOT candidates living in or traveling to endemic or epidemic areas should be vaccinated, and transplantation should preferably be deferred for a period of 4 weeks after vaccination.

Management of severe YF is based on emerging data on liver transplantation and plasma exchange and should include a multidisciplinary approach to this serious disease with high rates of lethality.

Key Points

- The resurgence of yellow fever epidemics continues to occur in non-endemic areas of Africa and Latin America.
- Although the majority of cases are oligosymptomatic, case fatality rates in severe forms may reach up to 60%.
- The diagnosis can be made by virological or serological tests, as clinical manifestations may overlap with a wide range of diseases.
- Vector control and immunization are the mainstay of prevention strategies for the control of yellow fever, and adverse event rates vary according to existing literature.
- As it is a live attenuated virus vaccine, contraindications for the yellow fever vaccine includes immunocompromised populations, thus limiting the use of these vaccines to the pretransplant period, with albeit scarce data in transplant candidates as well.
- Liver transplantation has been recently performed as a form of treatment with some successful cases, although precise indications and contraindications are difficult to establish. Plasma exchange, along with supportive intensive care management, has also been successfully performed in severe cases.

Introduction

The rarely seen viral encephalitides, lymphocytic choriomeningitis virus (LCMV) and rabies virus encephalitis, are some of the most feared infections, especially in the immunosuppressed host. Luckily, although mortality is high from these viruses when seen after transplant, they remain a rare occurrence. There are no published reports of LCMV or rabies in hematopoietic stem cell recipients, not to say they are

not microbiologically plausible, but this chapter will focus on solid organ transplant recipients.

Both LCMV and Rabies virus are zoonoses and therefore can be acquired through primary infection of the recipient via animal exposure. However, the published reports of these infections all focus on donor-derived transmissions [1].

Screening of organ donors and organ recipients for these infections is challenging and requires a high level of suspicion. The symptoms vary depending on the region of the brain affected and can present as global cerebral dysfunction or focal neurological deficits. Cardinal signs of encephalitis such as altered mentation carry a wide differential in transplant recipients, and clinical presentations may vary owing to the inoculum of infection and level of immunosuppression.

Since 2002, several clusters of infectious encephalitides have been reported in groups of transplant recipients. These donor-derived transmissions have been investigated in depth by the US Centers for Disease Control and Prevention (CDC) and other major healthcare bodies. Some of these emerging pathogens include rabies virus, LCMV, and Eastern equine encephalitis virus (EEEV), among several others. We will review these pathogens and their clinical impact on organ transplantation [2]. Of note, West Nile virus will be discussed in a separate chapter.

For a more detailed discussion on West Nile Virus in transplant patients, please refer to ► Chap. 40, "West Nile Virus and Transplantation."

Rabies Virus

Infection from rabies virus dates back to the twenty-third century BC and continues to be one of the most dreaded diseases [3]. The major way rabies is transmitted to humans is through animal saliva, specifically from bats or small mammals like raccoons, skunks, foxes, and dogs, but any mammal can become infected. Globally, 55,000 people die annually from rabies, mostly secondary to dog bites. The raccoon is known to be the most rabid animal in the United States, but disease in humans is mostly attributed to bat exposure [4]. The virus is neurotropic and can also be acquired through contact with infected nervous tissue. The virus typically causes disease 2–8 weeks after infection but has been reported to remain latent for many years [3], increasing the risk for asymptomatic infection that could be transmitted by transplantation.

The first case of transplant acquired rabies virus infection was in 1978 from a corneal transplant [5]. Infection transmitted from donor to recipients in solid organ transplantation (SOT) was first reported in 2004 [2]. Humans are usually dead-end hosts for the virus, but organ transplantation serves as a route for human-to-human transmission [6].

When the disease manifests in humans, it is virtually 100% fatal – in 2007, only five known cases existed that survived – four were immunized, while one survived apparently through natural immunity [7]. Developing countries serve as major reservoirs for the virus with dogs as the infected source in most nations [7]. Infection

of solid organ transplant recipients goes against previous dogma that retrograde axonal migration is the only mode of spread. It raises evidence for hematogenous spread – probably through infecting macrophages [8, 9].

Based upon our underlying knowledge of rabies in general, coupled with the information obtained from the cluster analyses of organ donor-derived rabies transmissions between 2003 and 2018, we shall review some of the important features of this disease.

Signs and Symptoms

Rabies can present in various forms – encephalitic (furious) form and paralytic (dumb) form. It also differs in presentation based upon the animal variant and mode of acquisition. The classic (encephalitic) form may include the cardinal signs of fluctuating consciousness, phobic spasms, and autonomic dysfunction, while the bat variant usually includes localized symptoms or neuropathic pain described as burning, itching, tingling, or numbness [3].

Donors often present with vague symptoms that overlap with several more common possible diagnoses. In the 1996 corneal donor, presenting symptoms included fever, abdominal pain, and diarrhea with no known exposure to a rabid animal [5]. In the 2003 rabies transmission, the donor presented with nausea, vomiting, and abdominal pain followed by intermittent episodes of confusion, agitation, and ballistic movements of the trunk. He also had a subarachnoid hemorrhage that was thought to be the cause of his symptoms [3]. The donor in the 2011 transmission case had nausea, vomiting, upper extremity paresthesias that progressed to seizures, worsening mental status, dysphagia, autonomic dysfunction, and respiratory failure, presumed at that time to have been secondary to ciguatera poisoning [4].

Transplant recipients have also presented with variable symptoms. The corneal recipients presented with confusion, agitation, photophobia, hydrophobia, hypersalivation, and finally cerebral encephalitis. Ocular symptoms were not seen in those cases, but prior reports have suggested some patients having redness and pain in the eyes for about 2 days prior to being diagnosed with rabies [5].

The lung transplant recipient in the 2003 cohort died of surgical complications. The other four recipients, including the one with vascular allograft transplant, presented back to the hospital around 27 days posttransplantation and died by 42 days with symptoms consisting of rapid neurological deterioration, agitation, restlessness, delirium, and hallucinations. Tremors and myoclonus were present in some of the patients. All cases were complicated by respiratory failure, increased secretions, cardiac rhythm disturbances, paralysis, coma, and absence of brain stem reflexes leading to death within 7–23 days after onset of neurological symptoms [3].

The incubation period was very prolonged, 17 months, in the 2011 kidney transplant recipient and, therefore, initially not expected to be donor-derived. This patient presented to the hospital with sciatica-like pain radiating down from his hip along with tenderness over his transplanted kidney. These symptoms then

progressed to bilateral lower extremity weakness with paresthesias, encephalopathy, excessive salivation, and hemodynamic instability, and the patient died within 22 days of hospitalization [4]. The effect of immunosuppression on rabies virus infection is not clearly understood [2]. The very long incubation period in the recipient in the 2011 case was possibly due to the donor being infected with a raccoon variant of rabies, as opposed to the much more common bat variant. Only one other case of raccoon rabies infection in a human is in the literature, and the incubation period of that infection was unknown [10].

Diagnosis

The differential diagnosis of symptoms in the case of rabies infection is very broad and includes CNS infection from herpes and varicella viruses, cryptococcal infection, noninfectious etiologies such as posterior reversible encephalopathy syndrome, and many others. CNS imaging with MRI and lumbar puncture with CSF analysis is necessary to investigate a diagnosis in patients presenting with neurologic symptoms.

In cases of rabies transmitted through corneal transplants, diagnosis was made by clinical signs and a brain biopsy. Donor corneal impressions can be helpful – since specificity is 100% but sensitivity is slated at 46% [5].

Apart from clinical signs and symptoms, the diagnosis of rabies may be aided by CSF analysis, serological markers, and the gold standard of brain biopsy histopathological analysis coupled with immunofluorescence (IF) testing.

Historically, rabies has been a postmortem diagnosis. Antibodies are slow to appear in serum and CSF. Corneal smears are not reliable, and MRI findings are not pathognomonic. Nucleic acid sequence-based amplification testing on saliva, urine, CSF, or hair follicles will be positive early in the course of infection; this testing should be coordinated with state department of public health laboratories in the United States. If initially negative, serial testing may be recommended given the intermittent nature of viral shedding. IF testing on nuchal skin in combination with RT-PCR has high sensitivity, but brain tissue exam remains the gold standard. False negatives by this method could be due to the predilection of the virus in affecting the brain stem, thalamus, and the cord in earlier stages of the disease, areas that are not usually biopsied [7].

In the 2003 cohort of SOT-associated rabies infection in recipients, CSF exam revealed increased cells, increased protein, and normal glucose. Initial CT scans were normal in all four patients, and some of the subsequent scans showed subtle changes. MRI showed increased fluid-attenuated inversion recovery signal in varying regions of the brain in different patients. EEG showed moderate to severe generalized slowing in delta to theta range. Postmortem macroscopic exam of the brains showed different changes in different patients such as congestion, brain stem flattening, hemorrhages, etc. Histopathological findings were consistent with global hypoxic ischemic injury with the demonstration of Negri bodies [3].

Treatment

A review in 2018 noted that in the 13 cases of rabies virus transmission through solid organs or tissue allotransplantation, there were 30 recipients afflicted, 20 of whom died. The remaining patients received postexposure prophylaxis (PEP) and survived, except a heart recipient who died of an unrelated pulmonary infection. PEP with rabies immunoglobulin administration and vaccination series has shown to be an effective measure in controlling this infection [6]. Some patients died despite administering PEP, likely due to an aggressive virus variant [6, 11]. The penetrance of donor-derived rabies infection appears to be very high. Therefore, all recipients of a suspected donor should be tested and receive PEP.

In immunocompromised hosts, it is advised to give rabies immunoglobulin coupled with five doses of vaccine and to test for rabies virus-neutralizing antibody (RVNA) titers in the serum $\geq$7 days after the vaccine. A concentration of $\geq$0.1 IU/ml is considered adequate in the United States, but the World Health Organization (WHO) considers $\geq$0.5 IU/ml instead. It is unclear if routine serological testing needs to be done given that the recipients still technically harbor the virus by way of infected organs. Also, we need further data on how to manage those patients who never reach either of these targets despite PEP. Some experts advise repeating the whole regimen, while others say administer double-dose vaccines, akin to hepatitis B vaccine nonresponders, but there are no robust data to support this [12–14]. Challenges include differences in serologic responses depending on the host, level of immunosuppression, and monitoring of serial titers as immunity has persisted in some while waned in others. Data regarding postexposure management are available in HIV patients, but there are no prospective trials in transplant recipients [15].

Lymphocytic Choriomeningitis Virus (LCMV)

LCMV is a rodent-borne virus of the *Arenaviridae* family that was first discovered in 1933 as a cause of encephalitis. It can cause a broad spectrum of illness ranging from a mild, self-limiting "flu-like" illness in immunocompetent hosts to an aggressive variant leading to multisystem end-organ dysfunction and death, especially in immunocompromised hosts [12, 16, 17].

Serological surveys in the United States found that up to 5% of individuals have been infected with LCMV [12]. The main and natural reservoir of infection is the domestic mouse. Infections usually occur through contact with lab mice or infected hamsters [17]. Contact with mouse excreta/urine/other secretions via household dust or infected food and drink is a common mode of acquisition in humans [17]. Other than vertical transmission, human-to-human transmission was not reported prior to December 2003 and April 2005 when eight organ transplant recipients from two donors were diagnosed with donor-derived LCMV infection [12].

Since 2003, 5 such clusters have been reported worldwide, and only 5 out of 17 recipients have survived the infection. In some of these cases, the donor was not proven to be infected with the virus and did not demonstrate symptoms of active

infection but could have had contact with a vector sharing the same strain of virus as the recipients [16]. This phenomenon makes it a challenging infection to consider and diagnose in a potential donor prior to transplant. One such case cluster is shown in Figure 1, demonstrating the pace of illness. Fig. 1 Clinical timelines for LCMV infection in a donor-derived cluster. (Reproduced with permission, first published in: Mathur G, Yadav K, Ford B, Schafer IJ, Basavaraju SV, Knust B, Shieh WJ, Hill S, Locke GD, Quinlisk P, Brown S, Gibbons A, Cannon D, Kuehnert M, Nichol ST, Rollin PE, Ströher U, Miller R. High clinical suspicion of donor-derived disease leads to timely recognition and early intervention to treat solid organ transplant-transmitted lymphocytic choriomeningitis virus. Transpl Infect Dis. 2017 Aug;19(4). https://doi.org/10.1111/tid.12707. Epub 2017 May 24)

Signs and Symptoms

LCMV infection in immunocompetent humans is usually sporadic, benign, and usually asymptomatic extrapolating from the seroprevalence. It usually presents in one of three major clinical forms – influenza-like syndrome, aseptic meningitis, or meningoencephalitis. Each of these phases may present individually as self-limited illnesses or in sequence – usually each lasting 1–2 weeks [17].

The incubation period ranges from 5 to 13 days followed by fever, headache, myalgias, and occasionally abdominal pain, diarrhea, and rash. A period of convalescence may be followed by meningitis or, rarely, meningoencephalitis, parotitis, pneumonitis, arthritis, myocarditis, orchitis, or alopecia. Mortality from this infection, as previously stated, is usually less than 1% [12]. The lungs seem to be the primary organ involved, causing pulmonary infiltrates, interstitial edema, and eventual viremia allowing the virus to migrate to other organs including the meninges, choroid plexus, and ventricular ependymal linings. The subsequent high-level viral replication and resulting inflammatory response cause the symptoms of meningitis [18]. This may play out differently in organ transplant recipients given direct inoculation via infected organs.

Deceased organ donors involved in the reported clusters presented for medical care with symptoms unrelated to LCMV infection. On a retrospective analysis, some of them had positive serologies showing exposure to the virus, some only had exposure to infected rodents without any evidence of active or past infection, while some had neither obvious exposure nor evidence of infection. Out of the 17 organ transplant recipients from these 5 clusters, 12 (71%) died. All the recipients presented with a subacute onset of illness 2–3 weeks after transplant with symptoms including fever, abdominal pain, diarrhea, peri-incisional erythema and tenderness, rash, altered mental status, and eventually progression to multisystem organ failure [16].

The marked severity of illness and fatal outcomes in transplant recipients is likely secondary to the extent of immunosuppression, especially affecting T-cell population, coupled with the direct implantation via transplanting infected organs [12].

Diagnosis

Leukopenia, thrombocytopenia, and transaminitis were seen in most of the donor-derived cases [12, 16]. CSF analysis may show lymphocytic pleocytosis with WBCs ranging from 300 to 3000 cells/cc. CSF glucose might be slightly low with an elevated protein [16].

In the United States, the CDC typically runs more specific tests for LCMV. The virus can be isolated in blood or CSF with the use of in vitro cell culture. Serological testing using IF assays, enzyme-linked immunosorbent assay (ELISA), or Western blot may be done [17]. As per the reports on the clusters from 2003 and 2005, histopathological findings included necrotic and occasionally hemorrhagic foci in all infected tissues with a notable absence of inflammatory infiltrates and viral inclusions. LCMV antigens were present in affected tissues. In one case, even though the donor had no evidence of prior infection, he had known exposure to a hamster that harbored LCMV with the same sequence thereby proving causality [12]. This was replicated in one of the outbreaks in Australia in 2008 where there was a strong suspicion for donor-derived disease as all recipients of the donor fell ill [19]. These reports and those from several subsequent cluster analyses included organ donors with no evidence of LCMV infection, neither serologies nor tissue positive for LCMV presence, thus making diagnosis a challenge in deceased organ donors [16]. A high index of suspicion and a close look at all recipients of a donor are required to make these diagnoses.

Treatment

One of the kidney recipients in the 2005 cluster was treated with ribavirin for 37 days and survived. Immunosuppression was also reduced. Therapy was stopped once RT-PCR studies on kidney biopsy samples were negative, and the development of IgM antibodies was noted [12]. However, no trials have been done that prove ribavirin efficacy in treating LCMV. In the SOT-associated LCMV outbreak in 2011, two out of the four afflicted survived without ribavirin [20]. Ribavirin has been used to treat Lassa fever and has in vitro activity against LCMV, but it is unclear if the survival of the transplant recipient was due to ribavirin or was due to a reduction in immunosuppression [12]. The utility of ribavirin and immunoglobulin administration remains unclear.

Favipiravir, currently approved as an anti-influenza drug in Japan, has in vitro activity against several RNA viruses including arenaviruses. A study was conducted in mice that were inoculated with lower-dose LCMV virus to produce a protracted illness and mortality rate of 70–80%, mirroring the target population of organ transplant recipients. Results showed 300 mg/kg/day of favipiravir had superior efficacy if started within 2 days of symptom onset when compared to a 100 mg/kg/day ribavirin group and a placebo group. Survival was not improved if favipiravir was started 6 days after symptom onset. The equivalent dosing in humans would be approximately 24 mg/kg/day, and studies have shown good tolerance with doses as high as 40 mg/kg/day [21].

Emerging Viruses

There have been several instances of other infectious encephalitides transmitted through organ transplants, such as Eastern equine encephalitis and borna disease virus.

Eastern equine encephalitis virus (EEEV) is an arbovirus that cycles between the *Culiseta* mosquito and birds residing in freshwater hardwood swamps with sporadic infections in other vertebrates through bridging vectors like the *Aedes* mosquito. The average incubation period in EEEV infection is 4–10 days. Between 2003 and 2016, a median of 8 cases has been reported in the United States annually, typically in the 20 states along the Atlantic and Gulf Coasts. Although rare, it is one of the most severe arboviral illnesses with a fatality rate close to 30%. Most persons infected are either asymptomatic or suffer from a mild, nonspecific illness. Symptoms may include fever, and <5% progress to have symptoms like headaches, confusion, neurologic deficits, seizures, or coma. Survivors may have lasting neurological sequelae like hemiparesis, seizure disorder, or cognitive dysfunction. The risk of neuroinvasive disease may depend on the route of infection or immunosuppressed state.

The first instance of transplant-associated EEEV encephalitis transmission was reported in the fall of 2017 where one donor transmitted the infection to three recipients. All three presented with signs and symptoms of neuroinvasive infection within a week of transplantation; two of them died, while one survived with neurologic deficits. Similar to other viral encephalitides, the diagnosis of these cases required a high index of suspicion by the infectious diseases physicians involved. It is essential to investigate the recipients of the donor for unusual symptoms to diagnose [22].

Diagnostic testing may reveal peripheral leukocytosis and CSF neutrophilic pleocytosis and hypoglycorrhachia. Brain MRI may be revealing of T2/FLAIR sequence showing enhancement of the basal ganglia, thalami, and brain stem. Serum EEEV IgM usually turns positive within the first week of infection. At times, convalescent testing may have to be performed to confirm serologies. Viremia usually resolves by the time neurological symptoms occur thereby limiting the utility of PCR testing on serum and CSF. Cluster analysis showed that PCR testing on whole blood might be of greater yield when compared to that performed on serum and CSF. EEEV antigens and RNA may also be detected in transplanted tissue by IHC and RT-PCR. Pathological evaluation may demonstrate cytopathic effects with resulting necrosis.

No human vaccine or antiviral therapy exists against EEEV infection. IVIG was used in all three recipients, but no controlled trials have proven efficacy with this therapeutic modality.

A risk of transfusion-associated of infection also exists as blood is not routinely screened for EEEV. Given that most infections are asymptomatic, a high index of suspicion is required to evaluate potential donors for this infection. The lack of an ideal screening test or rapid diagnostic test to detect the virus during the incubation period limits our ability to prevent transmission to organ recipients. Knowledge of

local surveillance data, especially with respect to equine disease prevalence and mosquito pools in the organ donor's region, may be helpful in strengthening screening criteria [22].

As per a report in NEJM in 2018 [23], borna disease virus-1 (BoDV) transmission through solid organ transplantation occurred in Germany, and three recipients were infected from the same donor, of which two died. This virus is known to cause progressive meningoencephalitis in horses and sheep. However, zoonotic transmission to humans through pet squirrels has been reported. The donor had no signs or symptoms of neurological illness on presentation (Table 1). The recipients presented with varied neurological symptoms including facial palsy, anosmia, and acute, flaccid tetraparesis between 80 and 112 days posttransplantation. Neuroimaging revealed encephalitis and cerebral atrophy. Diagnostic metagenomic sequencing performed on a brain biopsy specimen of one of the recipients confirmed the diagnosis. It was further confirmed by the detection of viral antigens in the tissue using RT-PCR and IHC techniques. Identical BoDV-1 sequence was obtained from a brain biopsy specimen of the second recipient. The third recipient's infection was confirmed by antibody testing on serum and CSF. The source and state of infection in the donor could not be ascertained [23]. BoDV is a lethal disease and should be considered as a potential cause of viral encephalitis in recipients when the donor could have had potential direct or indirect contact with BoDV reservoirs.

Prevention of Donor Association Transmission

Screening all organ donors for these rare viruses is resource consuming and impractical given the time constraints required for donor evaluation and the difficulties with next-of-kin medical histories. However, having a standardized case definition coupled with a uniform screening procedure for infectious encephalitis by organ procurement organizations may help in the early detection of potentially lethal transmissible infections. Rapid screening test panels in such targeted cases might be helpful [4].

In the United States, the Organ Procurement and Transplantation Network (OPTN) Disease Transmission Advisory Committee (DTAC) developed guidelines to help OPOs and transplant clinicians decide if a donor could be at increased risk of an undiagnosed central nervous system infection [24]. A recent paper developed a risk calculation to predict donors with nonbacterial central nervous system infections and report the following features in the donor are concerning: male gender, fever, immunocompromised donor, CSF protein >45 mg/dl, altered mental status within 48 h of presentation, psychiatric features during hospitalization, cranial nerve abnormalities, meningeal signs, focal motor weakness, sensory disorders, movement disorders, and Babinski's reflex [25–27].

Caution is recommended when deciding to use organs from such donors. If diagnostic tests are sent on the donor, results will likely not return prior to transplant. Therefore, expedited notification of results must be sent to all receiving transplant

Table 1 Summary of rare viral encephalitides in organ transplantation

Infection	Donor symptoms	Recipient symptoms	Time of presentation posttransplant	Mortality rate	Treatment options
Rabies	Vague symptoms with significant overlap. Including but not limited to fever, nausea, vomiting, abdominal pain, confusion, agitation, autonomic dysfunction, and respiratory failure	Predominant neurological symptoms, signs and symptoms of autonomic dysfunction complicated by respiratory failure, cardia arrhythmias, coma, and death	Majority of the cases presented within 27–42 days posttransplantation. One case who presented 17 months later	20/30 (67%)	Postexposure prophylaxis with Ig and vaccine
	One donor had raccoon exposure. Donor from another cluster did have history of a bat bite. Canine exposure in donors has also been reported				
LCMV	Fever and other vague symptoms eventually progressing to neurological deterioration. Symptoms unrelated to LCMV infection	Fever, abdominal pain, diarrhea, peri-incisional erythema and tenderness, rash, altered mental status, and eventually progressing to multisystem organ failure	2–3 weeks	12/17 (71%)	Ribavirin, favipiravir, IVIG (unclear efficacy of these therapies)
	Some had rodent exposure				
EEEV	No signs or symptoms of neurological disease	Signs and symptoms of neuroinvasive disease including headaches, altered mentation, seizures, coma, etc.	Within 1 week	2/3 (67%)	IVIG
BoDV-1	No signs or symptoms of neurological disease	Varied neurological symptoms including facial palsy, anosmia, and acute, flaccid tetraparesis	80–112 days posttransplantation	2/3 (67%)	Unknown

centers along with national and local governing bodies once results are available [4, 27, 28].

The key to the prevention of rabies virus transmission globally is to address the baseline disease prevalence and improve disease reporting in developing countries of Asia and Africa [6] coupled with effective vaccination strategies for those potentially exposed or at high risk of exposure through animal contact. There are no vaccines that target LCMV, EEEV, or BoDV infection.

Zoonotic transmission of these viruses is a risk posttransplant with possible drastic outcomes in the setting of immunosuppression. Therefore, it is essential for recipients to be aware of the specific preventive measures and limit exposure to exotic animals [12, 29]. Patients should be sure to vaccinate pets for rabies as recommended and avoid handling wild animals such as bats or raccoons. Patients should also be educated about mosquito protection posttransplant.

Prevention of Recipient-Acquired Infection

Quite separate to infection that may be transmitted from donors, transplant recipients are at risk of routine community-acquired viral encephalitis at similar rates to the general community. Under these circumstances precise data on the clinical outcomes is lacking, but high mortality might be expected. Prevention is the best path forward; therefore understanding the natural transmission cycles of the viruses involved is key.

For rabies there are a number of animal hosts in the United States and across the world. Bats, domestic and wild dogs, foxes, coyotes, and raccoons all carry rabies to varying degrees in North America. Bites from any of these animals, or in fact even finding roosting bats inside houses of transplant recipients, should prompt a rapid discussion about rabies postexposure vaccination. For West Nile and Eastern equine encephalitis, mosquitos are the nature vector, as is the case with dengue, Zika, chikungunya, and a number of other infections relevant to transplant. During the summer months, a careful discussion of mosquito avoidance with transplant recipients can help attenuate the risk of illness, especially those traveling. Finally, LCMV is typically associated with rodents, and while complete avoidance is often challenging, patients should be discouraged from keeping such animals as pets in their posttransplant phase.

Challenges and Next Steps

The rare but dangerous possibility of donor-derived transmission of rabies, LCMV, EEEV, and BoDV is fraught with many challenges. The overall risk of transmission of these infections is low given low prevalence, especially in the developed nations [3]. However, the incidence may increase as resource-limited countries perform more transplants [6].

Underreporting is a possibility as many of these infections are difficult to diagnose and require specialized tests that are not commercially available [6]. Overlapping symptoms, difficulty in obtaining and processing samples from donors and recipients along with limited testing ability for rare infections, and geographical spread of transplant centers that might receive organs from one potentially infected donor limit the ability to diagnose rare transplant-related infections [4]. Variable presentations in diseases like rabies, e.g., bat variant, differing from classic bites, vague symptoms in prodromal phase, and rapidity of deterioration once in fulminant neurological phase makes it a difficult diagnosis to make, especially if exposure is not suspected or known. Donors often present with symptoms that could fit with a wide variety of diagnoses, making definitive diagnosis problematic [3].

Screening all donors for these infections is not practical [4]. Antemortem testing exists for most of these infections but requires a high index of clinical suspicion and often involves use of send-out tests or testing by the CDC [3]. Imaging findings are typically vague. Paucity of rapid diagnostics leads to delay in diagnosis and usually is confirmed after the transplant has occurred.

A standardized case definition and targeted screening of donors that are high risk may help in early detection of potentially lethal transmissible infections [4, 25]. In the era of globalization, worldwide travel increases risk for exposures to unusual and rare infections in patients – hence it is of utmost importance to get a good travel, social, and occupational history during donor screening [7]. There is a need for developing risk scores and calculators to identify infectious versus noninfectious causes of encephalitis. Obviously, while doing so, it is important to balance the risk of declining uninfected organs [27].

Rapid diagnostics are changing the overall scene in medicine, especially in the field of infectious diseases. They can help assess for the presence of infection in donors prior to transplantation or soon after transplant and therefore allow early initiation of appropriate management [12]. They can help identify potentially infectious donor organs so that such organs may only be used in extreme or dire cases with prior consent from the patient along with instituting appropriate posttransplant management protocols, thereby trying to reduce mortality [4]. In spite of high fatality rates from these infections, it is essential to diagnose them early to institute appropriate infection control measures and reduce spread [3].

As per a report in 2008 [19], unbiased high-throughput sequencing was used to identify a new variant of arenavirus that was potentially implicated as a cause of encephalitis in organ transplant recipients. Deep sequencing assays and other forms of metagenomic testing can be helpful in identifying rare organisms causing encephalitis especially when conventional tests fail to do so. Over the upcoming years, new and unusual infections are bound to appear in even more atypical fashions especially in the immunocompromised host. Availability, validation, and interpretation of these next-generation testing protocols should be considered high priority if we wish to tackle these complex clinical conundrums [30, 31].

The clusters of transplant-related infectious encephalitides underscore the importance of maintaining a high index of suspicion in potential donors for such infections that could have fatal consequences. Essential data on screening, diagnosis, and

treatment remain limited [32]. In cases of rabies and LCMV, a global registry to document experience with PEP in infected organ recipients would allow a better understanding of these clinical entities [15].

Efficient communication between the OPTN (or similar bodies outside the United States), local organ procurement organizations, hospitals dealing with all recipients, local health officials, and caregiver teams with ancillary staff including lab personnel is key to a swift diagnosis and implementation of management plans [25]. It requires added efforts on behalf of everyone in the organ transplant community including the Department of Health and Human Services, the CDC, hospital networks, physicians, and support staff to maintain the organ supply chain and avoid adverse events [32]. These efforts would go a long way in mitigating, if not eradicating, the risk of transmitting lethal infections via organ transplantation.

Conclusions

Clusters of these infections, though rare, have led to increased awareness about the severity of these illnesses, their high mortality rates, and of the transplant community being somewhat underprepared to deal with them. It is key to maintain a high index of suspicion for these infections in organ donors presenting with unexplained neurological illnesses, apt exposure history, and appropriate epidemiological correlation. Regulating organ transplants from such donors is a possible way of preventing transmission to organ recipients and could help in avoiding further complications. However, as we all know, this is easier said than done given the paucity of vital organs all over the world. Rigorous screening with new-age diagnostics and therapies may help protect these immunocompromised hosts from dire consequences in the future.

Key Points

- A number of highly pathogenic viral infections can lead to clinical encephalitis in transplant recipients. Although each remains rare, the high mortality mandates concern and mitigation.
- Careful donor evaluation can help mitigate the risk of donor-derived viral encephalitis for solid organ recipients, which has a high penetrance among all recipients.
- Few treatments exist once viral infection is established. Ribavirin and favipiravir have been studies in small case series for LCMV, and postexposure prophylaxis should certainly be given to anyone exposed to rabies, irrespective of the route of exposure.
- Teaching transplant recipients safe living techniques, especially vector avoidance, can go a long way to help reducing the risk of many significant viral infections.
- Clinicians should continue to remain vigilant that new viral infections emerge with some frequency, and often transplanted immunosuppressed patients have the

gravest and most severe clinical outcomes. Having an open mind for viral discovery can help identify infections, particularly clusters, more rapidly, especially in an era of expanded microbiologic testing.

Introduction

Recipients of solid organ transplantation (SOT) are at increased risk of fungal infections. Among these pathogens, invasive candidiasis (IC) remains the most common fungal infection in patients with solid organ transplantation except for lung transplant recipients, where invasive *Aspergillus* is the dominant organism [1]. IC is defined as a *Candida* infection from an otherwise sterile space and should be distinguished from oral thrush, esophagitis, and vaginitis.

While IC rates are among the highest in small bowel transplant (SBT) accounting for 85% of all invasive fungal infections (IFI), the rates for other organ transplants vary; IC represents IFI in 68–80% of orthotopic liver transplant (OLT), 23–47% in lung transplant (LT), 38–68% in orthotopic heart transplant (OHT), 49–60% in kidney transplant (KT), and 76% in pancreatic transplant (PT) [1–3]. Unlike hematopoietic stem cell transplants where *Candida glabrata* is the most common species (likely due to widespread fluconazole prophylaxis), *C. albicans* is the most common species in SOT (30–74%) followed by *C. glabrata* (30–38%), *C. parapsilosis* (9–12%), *C. tropicalis* (5–6%), and *C. krusei* (2–5%) [3–7]. However, the incidence of species varies according to transplanted organ and use of prophylaxis [5]. In addition, the prevalence of infections due to different *Candida* species has significant geographical variations [8–11] (see Table 1).

Clinically, of all forms of IC, bloodstream infection with *Candida* or candidemia is the most common presentation across all SOT. In the Transplant-Associated Infection Surveillance Network (TRANSNET) study, candidemia was found in 64% OHT, 54% LT, 32% PT, 44% KT, and 41% OLT [2]. Deep intra-abdominal infections are the second most common presentation, accounting for approximately 14% of all IC [2]. However, intra-abdominal infections are more common following abdominal transplants compared to thoracic, found in about a quarter of abdominal transplants but less than 5% of thoracic transplants [2, 3]. In lung transplant, intrathoracic infections are the second most common presentation of candidiasis (i.e., empyema, tracheobronchitis, and pulmonary abscesses) [2]. Urinary tract infections represent the third most common form of IC accounting for approximately 11% [7].

The median time to occurrence varies between different cohorts, which may be related to epidemiological changes, transplantation technique, prophylaxis protocols, and the expanded types of transplanted organs and tissues. In general, candidemia was diagnosed early between 2 and 6 months following SOT. In a large cohort from the United States consisting of 16,808 patients between 2001 and 2006, the median time to occurrence was 80 days [1]. A multicenter prospective Australian cohort of 1068 patients between 2001 and 2004 showed that 52% of the cases of IC occurred after 6 months [2, 12], although they only analyzed cases of candidemia and most of the patients were renal transplant recipients, which may explain the late onset of IC presentation. All IC cases in LT recipients in that cohort occurred within the first 30 days which may be secondary to prior airway colonization, complexity of transplant, and the increased net state of immunosuppression. In support of early IC presentation in LT, another study by Scheanman et al. confirms that the median time to presentation in LT was indeed early at 25 days [13].

The all-cause mortality range related to IC is between 21% and 34%, although significant variation exists depending on the species, transplanted organ, and comorbidities (e.g., diabetes, COPD, renal insufficiency, CHF) [7, 12, 14]. The mortality is higher for non-*albicans* species (*C. glabrata* 27%, *C. krusei* 31–52%, *C. parapsilosis* 23–35%, and *C. tropicalis* 44%) as compared to *C. albicans* at 22%. In regard to mortality related to organ type, the highest proportion is noted in LT (36%) followed by OLT (30%), OHT (25%), kidney (22%), kidney-pancreas (15%), and pancreas (13%) [2].

Epidemiology, Risk Factors, and Prophylaxis

Lung Transplant

Mortality in lung transplant recipients strongly correlates with allograft rejection and infections. To prevent rejection and improve allograft survival, lung transplant recipients are often managed with high levels of immunosuppression, which increases the risk for invasive fungal pathogens and other opportunistic infections.

Candida infections were historically the most common type of IFI following lung transplantation ranging from 43% to 80% [15–17]. However, the incidence of IC has decreased from 20% in 1980–1986 to 1.8% in 2001–2004 [13]. Despite this decrease in incidence, a cohort of 16 centers in the United States from 2001 to 2006 investigating 1195 lung transplant recipients (TRANSNET) found that the 12-month incidence of IC in lung transplant is the highest at 8.6% in contrast to non-lung SOT where incidences are lower (OLT 4.7%, OHT 4%, pancreas 3.4%, and KT 1.3%). Although *Candida* infections are common in lung transplant, *Aspergillus* remains the most common IFI representing nearly double the *Candida* rate at 44% of all IFI cases in lung transplant recipients [1].

In contrast to the TRANSNET registry, subsequent single-center studies spanning from 2003 until 2014 have demonstrated a higher prevalence of IC ranging from 11.4% to 23%. The authors suggested that their high incidence of IC may have been the result of the lack of prophylaxis and breakthrough infections with nebulized amphotericin B [18, 19]. The median time to occurrence is also highly variable ranging from 6 days to 52 days [7, 19]. However, most results suggest that IC is an early post-lung transplantation event and usually occurs within 30 days [13, 18, 19].

Recently, a prospective study nested within the Swiss Transplant Cohort Study reported all clinically relevant infections in 3541 solid organ transplant recipients. Among 286 lung transplant recipients, 45% developed IC, of which 65% were due to *C. albicans* [3]. In all studies, *C. albicans* represents the most common species isolated (60–70%), followed by *C. glabrata* (13–16%), *C. parapsilosis* (16%), and *C. tropicalis* (11–14%) [2, 18]. However, there are significant regional and center-to-center variations, specifically in the non-*albicans* composition.

In a cohort that spanned almost three decades, Schaenman et al. showed that tracheobronchitis (38%) was the most common *Candida* infection followed by candidemia (28%) [13]. Subsequent studies have shown that candidemia is the most common presentation followed by intrathoracic infections (pleural space and surgical site) which may reflect more modern prophylactic interventions [1, 2, 4, 18, 19]. Multiple infection sites (e.g., candidemia plus intrathoracic infections or intra-abdominal) remain common ranging from 25% to 40% [12, 18]. Pneumonia secondary to *Candida* species is a rare entity and is seen in less than 5% of all IC [13].

The overall mortality for IC in LT recipients is 36.4% [2]. However, there is significant variation within the 90-day mortality according to species (mortality by species, *C. albicans* 22.6%, *C. glabrata* 27.7%, *C. krusei* 31.5%, *C. parapsilosis* 35.2%, and *C. tropicalis* 44%). Organ dysfunction, disseminated infection, and allograft rejection were independently associated with poor outcomes [2]. Although the overall mortality for IC is high, it may represent a marker of overall poor clinical status in addition to potential *Candida* virulence factors. In fact, the *Candida* attributable mortality was estimated to be lower at 15% in one study [13].

Multiple studies to correlate risk factors for *Candida* infection, including pre-transplant diagnosis of cystic fibrosis, pre-transplant *Candida* colonization (presence of fungus in the respiratory secretions in the absence of symptoms, radiologic and endobronchial changes), acute and chronic allograft rejection, cytomegalovirus infection, and hypogammaglobulinemia, found that the only significant risk factors

for IC included the type of lung transplant (single vs. double lung allograft), primary graft dysfunction (PGF), use of airway stents, and allograft rejection [2, 20, 21]. Interestingly, all these variables suggest a more complicated post-transplant clinical course and are likely associated with intensified anti-rejection regimens.

Koo et al. assessed a targeted strategy of adding intravenous echinocandin (micafungin in this study) to nebulized amphotericin B during the first 7–10 days for patients with bilateral lung transplant followed by 3–6 months of further oral antifungal therapy only in individuals with positive microbiologic presence of yeast or mold in their day-of-transplant cultures. Those recipients with positive fungal growth received oral antifungal therapy tailored to their fungal isolate [19]. When comparing their pre- and post-intervention analysis, the authors note a reduction in *Candida* infections of 90% suggesting that a targeted strategy can be effective for those with positive cultures at the time of transplant. The 2015 International Society of Heart and Lung Transplant (ISHLT) guidelines recommend that, depending on local epidemiology, universal prophylaxis *Candida*-active agents should be considered such that nebulized amphotericin B +/− fluconazole or echinocandin should be used in the first 2–4 weeks post-transplant to target *Candida* species [20] (Table 2).

Heart Transplant

The epidemiology of invasive candidiasis in OHT has shifted over recent decades. The incidence of IC has decreased from 6.1% in the 1980s to 2.1% in the early

Table 2 Indications for post-transplant prophylaxis. Recommended prophylaxis by organ. (Adapted from Practice ASTIDCoP [28])

Transplanted organ	Recommended prophylaxis
Lung	Universal prophylaxis with agents that have systemic activity against *Candida* species should be considered in the immediate post-Tx period (i.e., first 2–4 weeks)
	Following this period, universal or preemptive prophylaxis are suitable options depending on the transplant center and should be considered for up to 6 months
Heart	Routine *Candida* prophylaxis is not recommended
Kidney	Routine *Candida* prophylaxis is not recommended
Pancreas	Prophylaxis should be considered if the patient has one or more risk factors including enteric drainage, vascular thrombosis, and post-perfusion pancreatitis. Duration should be individualized according to persistence of risk factors
Small intestine	Universal prophylaxis is recommended for at least 4 weeks or until the anastomosis has healed, and rejection is not present
Liver	Prophylaxis is recommended in recipients with $\geq$2 of the following risk factors: prolonged or repeat operation; re-transplantation; renal failure; high transfusion requirement (transfusion of $\geq$40 units of cellular blood products including platelets, packed red blood cells, and auto transfusion); choledocojejunostomy; and *Candida* colonization in the perioperative period

2000s [22]. In the TRANSNET cohort (2001–2006), Pappas et al. showed that the cumulative incidence at 12 months of an invasive fungal infection in OHT patients was 3.4%. Invasive candidiasis was the most frequent invasive fungal disease and represented half of the infections [1]. Similarly, in a large Italian cohort from the 1985 until 1997, Grossi et al. demonstrate that the incidence was 2.2% [23]. Unlike the TRANSNET study, invasive aspergillosis was the most common IFI, and IC represented only 19% of all invasive fungal infections. It is uncertain if the discrepancy is due to regional variations or due to differences in the surveyed time period. Interestingly, over 50% of the IFI occurred within 30 days of an episode of acute rejection.

A recent report from the Swiss transplant cohort study showed that IC represented 38% of all IFI, of which 86% were secondary to *C. albicans* [3]. A subsequent analysis of the TRANSNET study revealed that candidemia remains the dominant IC clinical presentation at 65%, followed by intrathoracic infections (i.e., deep surgical site infections, empyema) at 8.3% and disseminated disease representing 6.2% of all cases. In the TRANSNET update, *C. albicans* represented 53% of all isolated species, followed by *C. glabrata* (19%), *C. parapsilosis* (8.5%), and *C. krusei* (4.3%).

In a retrospective analysis investigating the development of IFI, Tissot and colleagues showed that renal replacement therapy, extra-corporeal membrane oxygenation, and prior airway colonization with *Aspergillus* species were independent risk factors for the development of IFI [24]. Subsequently, they provided targeted prophylaxis to a high-risk group, which included caspofungin, and showed a significant reduction of IFI as well as improved 30-day mortality. In addition, no cases of IC were identified in patients with targeted prophylaxis as compared to 9% in the control, non-prophylaxis group [24]. Another cohort has shown that increased induction immunosuppression or delayed chest closure are independent risk factors for the development of invasive fungal disease. However, these patients received OKT3 (anti-CD3) and daclizumab (anti-CD25) as induction immunosuppression, which are no longer used for induction rendering this data difficult to extrapolate to contemporary cohorts [25].

Other induction agents have been investigated for increased risk of IFI. Echenique et al. showed that the use of anti-thymocyte globulin, antibody-mediated rejection, and renal replacement therapy were independent risk factors associated with IFI [26]. None of the studies provided risk factors specific for the development of IC.

The use of IFI chemoprophylaxis has been studied in OHT with some success. Muñoz et al. identified the protective effects of itraconazole given as universal prophylaxis for invasive aspergillosis in OHT. Although they showed a significant prolonged 1-year survival, this study compared all heart transplant recipients from 1988 through 1995 (without prophylaxis) to 1995 until 2002 (with prophylaxis). The authors conclude that the use of itraconazole in OHT recipients decreased IFI from 11% to 3%. That said, during the study periods, significant improvements in perioperative management and immunosuppressive medications were made in parallel rendering the individual impact of itraconazole on survival difficult to ascertain. Interestingly, no cases of invasive candidiasis were noted in patients with prophylaxis [27].

Currently, neither the 2015 guidelines from the international society of heart and lung transplantation nor the 2019 guidelines from the American Society of Transplantation Infectious Diseases Community of Practice have specific recommendations for either targeted or universal prophylaxis against invasive candidiasis following heart transplantation [20, 28].

Liver Transplant

The advances in surgical technique, medical management, and more modern immunosuppressive strategies have led to a decrease in the incidence of invasive fungal infections over the past three decades in OLT. Before the advent of prophylactic strategies, the risk for invasive fungal infections in liver transplant recipients ranged from 7% to 42% [29, 30]. While a wide range of fungal pathogens were found post-liver transplant, the vast majority of IFI in liver transplant recipients are secondary to invasive candidiasis (80%), possibly due to *Candida* as a normal commensal in the gastrointestinal tract coupled with the technical necessity to surgically manipulate the bowel. During the first 6 months following liver transplant, IC represents 85% of all IFI but then drops to 40% in the subsequent 6 months following transplant. *C. albicans* remains the dominant species isolated in patients with invasive candidiasis ranging from 45% to 65% [31–33]. There are regional variations on prevalence of non-*albicans* species. In some reports, *C. parapsilosis* is responsible for 19–28% of IC [31, 32, 34].

Most of the cases occur within the first month with a median time to occurrence of 10–21 days, though older reports described later times to infection [31, 35, 36]. The mortality related to IC remains high, ranging from 25% to 70% compared to liver transplant recipients without *Candida* infection (2.8–6.4%) [32, 37–39].

A wide array of risk factors have been described for IC in OLT, including hospitalization prior to liver transplantation, renal failure with or without requirement for dialysis (creatinine >2), split liver grafts, living donation, transplant due to acute fulminant hepatic failure, high blood product transfusions, abdominal reoperation including re-transplantation, bile leaks, thymoglobulin, colonization with *Candida* species, and choledocojejunostomy anastomosis [31, 32, 34–36, 38, 40–43].

Several studies have correlated severity of pre-transplant liver disease status with *Candida* infection following OLT. In a study by Bassetti et al., 83% of patients with candidemia had a pre-transplant MELD score >15 [33]. In addition, Saliba et al. showed that pre-transplant MELD score of 20–30 or ≥30 was associated with a 2.1-fold or 3.1-fold increase in relative risk of invasive candidiasis, respectively [41].

A simple predictive model for risk stratification showed that the risk of invasive fungal infection ranged from 1% in patients with no predictors to 67% in patients with two or more predictors (creatinine of >3.0 mg/dL, operative time of > or = 11 h, re-transplantation, and early colonization) [44]. Based on these observations, the American Society of Transplantation Infectious Diseases Community of Practice has recognized patients as high risk for development of invasive fungal disease if they

have ≥2 risk factors including prolonged or repeat operation, re-transplantation, renal failure, high transfusion requirement (≥40 units of cellular blood products including platelets, packed red blood cells, and autotransfusion), choledocojejunostomy, and *Candida* colonization in the perioperative period (isolation of *Candida* in at least two non-sterile sites (e.g., urine, sputum) in the absence of signs or symptoms of invasive disease in the 4 weeks preceding transplantation) [28].

Due to the high incidence of invasive candidiasis following liver transplant, multiple trials have addressed the use of prophylactic antifungal therapy during the immediate post-transplant period. Earlier trials of universal prophylaxis with liposomal amphotericin B showed that it was more effective than placebo with IC rates close to 0% versus 16%, respectively. In addition, this intervention was cost-effective [45]. A recent study of a simplified targeted prophylaxis with amphotericin B lipid complex or liposomal amphotericin B on high-risk individuals was safe and applicable and was associated with low IFI incidence in both the high-risk group (5.4%) and low-risk group (0%) [38].

Given their safety profile, multiple triazoles (e.g., fluconazole, itraconazole) have been studied for prophylaxis. In a double-blind randomized control trial of universal prophylaxis with itraconazole vs. placebo, Sharpe et al. showed that itraconazole was well tolerated and reduced the rate of IFIs in patients undergoing OLT (4% with itraconazole vs. 24% with placebo) [46]. In another study, the use of fluconazole led to a significant decrease of the risk of IC. However, the incidence remained higher than expected, which was attributed to using lower doses of fluconazole (100–200 mg once daily) [31]. Compounding this lower dosage may have led to the surge of fluconazole-resistant organisms including *C. glabrata* [34, 47]. Although fewer data on prophylactic itraconazole is available, several studies suggested similar efficacy when compared to fluconazole [46, 48, 49].

While prophylaxis in high-risk individuals has been shown to be effective in reducing the risk of invasive candidiasis, the use of universal prophylaxis with fluconazole on a large cohort of liver transplant recipients did not show a reduction in the risk of invasive candidiasis, suggesting that prophylaxis may need to be rationally applied in a risk-stratified manner separating those with high- and low-risk profiles [39].

Echinocandins (e.g., anidulafungin, micafungin) are effective in the reduction of IFI incidence when used as targeted prophylaxis in high-risk individuals [38]. In addition, echinocandins have similar efficacy in reducing the risk of invasive candidiasis in high-risk individuals when compared to amphotericin B (liposomal amphotericin B and amphotericin B lipid complex) and triazoles [40].

There has been controversy about the use of antifungal prophylaxis and the potential to produce selective pressure, leading to antifungal resistance or selective population pressure. Raghuram et al. found that only 43% of their *C. albicans* and 33% of *C. glabrata* isolates were fluconazole sensitive. However, a low dose of fluconazole was prescribed in that trial (100 and 200 mg once daily) which may have been a factor for resistance selection [31]. In fact, a meta-analysis by Playford et al. found that fluconazole prophylaxis did not increase invasive fungal infections or

colonization with fluconazole-resistant fungi [49]. Echinocandin prophylaxis has also been associated with an increased risk of IC due to *C. parapsilosis* and echinocandin resistance [53].

Based on all these studies, the American Society of Transplantation Infectious Diseases Community of Practice recommends that antifungal prophylaxis should be given to all adult liver transplant recipients at high risk for development of IC ($\geq$2 of the following risk factors: prolonged or repeat operation, re-transplantation, renal failure, high transfusion requirement [transfusion of $\geq$40 units of cellular blood products including platelets, packed red blood cells, and autotransfusion], choledocojejunostomy, and *Candida* colonization in the perioperative period) [28] (Table 2).

The duration of prophylaxis is poorly defined with significant duration variability among the studies. Reported durations extend from 5 days up to 8 weeks. Most studies have used a variety of endpoints including empiric durations of 4 weeks and use of prophylaxis until discharged or when identified risk factors have resolved [38, 40, 42, 45–47, 52, 54, 55].

Patients on the wait list are at increased risk of fungal infections which in turn can negatively affect the outcomes of liver transplant candidates and recipients, causing disease progression and increased mortality [56]. Patients with severe alcoholic hepatitis admitted to the intensive care unit (ICU) have an increased susceptibility to invasive mycoses associated with high mortality. Lahmer et al. showed that 25% of patients admitted to the ICU due to alcoholic hepatitis developed invasive candidiasis with two thirds succumbing prior to transplant [57]. In a sub-analysis report of the Fungal Infection Risk Evaluation (FIRE) study, Theocharidou et al. showed that the incidence of IFI in cirrhotic patient is higher compared to other critically ill patients in a medical ICU (1% vs. 0.4%) but in-hospital mortality was similar in the two groups [58]. Risk factors for development of IFI in patients with cirrhosis include the use of prophylactic antibiotics, high MELD score, and hepatorenal syndrome. Fungal infections are an emerging problem in cirrhosis. In addition, there is a shift toward increased prevalence of *C. glabrata* and *C. parapsilosis*. This trend in turn may affect the success of antifungal prophylaxis and empiric therapy following transplant. Delayed diagnosis due to a low index of suspicion is common which may contribute to a high mortality rate [59, 60]. Despite these studies, there are no current guidelines on how to risk stratify patients, and most authors do not recommend antifungal prophylaxis in the pre-transplant setting [59].

Kidney

Kidney transplant remains the most common type of transplant performed in the United States and worldwide (organ procurement and transplantation network, 2019) [61]. Fortunately, the incidence of candidiasis and invasive fungal infections remains low. A large cohort of 8672 patients from March 2001 through March 2006 in 15 different transplant centers in the United States showed that the incidence of IFI

in renal transplant recipients was 1.3% and half (49%) of those cases were secondary to IC [1]. More contemporary cohorts have shown similar incidences of IFI ranging from 1.3% up to 5% with IC representing 29–55% of all fungal infections [3, 62–68].

However, there are significant regional variations as described by Santos et al. In Iran the incidence of IFI was reported at 0.87%, while in Turkey, Kuwait, and India, it was 4%, 3.5%, and 14%, respectively [63]. In North America, the incidence of IFI is 1.3% while in Spain is 1.7% [1, 69]. Specifically, IC represents about 49% of all IFI [1]. Over the past two decades, *C. albicans* had been the most common isolated species, and more contemporary cohorts suggest that *C. glabrata* is rapidly rising and may soon represent the most common invasive *Candida* species in KT [2, 67, 70–72].

The most common presentation of invasive candidiasis are bloodstream infections followed by intra-abdominal infections (44% and 11%, respectively). Candiduria is common following KT but is rarely of clinical significance with a median time to occurrence of 25 days, likely to be diabetic, female patients who have experienced significant prior antimicrobial exposure. Antifungal therapy in patients with asymptomatic candiduria has been shown to have no impact on the risk of recurrence, urinary clearance, or the development of severe complications [2, 71–73]. Given the low incidence of infection, and the lack of impact of treatment of asymptomatic candiduria, both the Infectious Diseases Society of America (IDSA) and the American Society of Transplantation Infectious Diseases Community of Practice do not recommend antifungal therapy for asymptomatic candiduria [28, 74] (Table 2).

Pancreas

The incidence of IC following pancreas transplantation ranges from 2.7% to 20% [1, 75–79]. There are no differences in the incidence of invasive candidiasis between different types of pancreas transplants (simultaneous pancreas-kidney, pancreas transplant alone, pancreas after kidney) [80]. Up to two thirds of the cases occur during the first 6 months [78].

Based on a single-center study by Benedetti et al., both the IDSA guidelines and the American Society of Transplantation Infectious Diseases Community of Practice recommend systemic perioperative antifungal prophylaxis for enteric-drained pancreas transplant recipients, vascular thrombosis, and post-perfusion pancreatitis [28, 74] (Table 2). However, this study presented multiple limitations, including large differences in the study populations and a lack of multivariate analysis. In addition, the group that received fluconazole continued to have a high incidence of fungal infections compared to other studies [79]. In subsequent studies of universal antifungal prophylaxis, no difference in intra-abdominal fungal infections has been found between bladder and enteric-drained pancreas allografts [81, 82].

In a study of 154 enteric-drained pancreas transplants, Bartoletti et al. showed that 1.9% of the patients developed invasive *Candida* infections [76]. While all the

patients were scheduled to receive antifungal prophylaxis, more than 10% failed to follow the protocol and did not receive prophylaxis. The lack of antifungal prophylaxis did not affect the incidence of IC [76]. Similar to Bartoletti, in a recent single-center study, Shaik et al. showed that enteric-drained pancreas transplant recipients who did not receive systemic antifungal prophylaxis had similar infectious complications, including an incidence of invasive candidiasis of 3.6%, which is similar to previously reported rates [75].

Small Intestine

Recipients of small bowel are at extremely high risk for the development of invasive candidiasis. The rate of invasive fungal infections ranges from 25% up to 59%, of which 80–100% represent invasive candidiasis. Recipients of small bowel alone are at higher risk, when compared to small bowel and liver and multivisceral transplants [83, 84].

The Prospective Antifungal Therapy (PATH) Alliance is a comprehensive multicenter, prospective, observational registry that collects detailed clinical data on patients with IFIs, with special emphasis on fungal epidemiology, diagnosis, treatment, and associated patient outcomes [6]. While both the TRANSNET and the PATH Alliance registries showed that *C. albicans* represented almost half of all *Candida* isolates, studies including only small bowel transplant recipients show that *C. albicans* infection can range from 22% to 53% [83–85]. In the largest cohort, a mix of non-*albicans* species represented two thirds of all isolates [84]. This observation may be secondary to the use of azoles as prophylaxis. Candidemia is the most common presentation (14–66%), followed by intra-abdominal infections (28–37.5%) and *Candida* isolated from the urinary tract (2.5–40%) [83, 85–87]. Patients at high risk are those with graft rejection or dysfunction, enhanced immunosuppression, anastomotic disruption, abdominal re-operation, or multivisceral transplantation. Despite the lack of clinical trials, most experts recommend continuing prophylaxis with fluconazole as the preferred agent for at least 4 weeks and until the anastomosis has completely healed and there are no signs of rejection [28] (Table 2). Studies investigating use of selective oral decontamination of the gastrointestinal tract with antimicrobial agents show that this strategy has no impact on the rate of bloodstream infections or abdominal fungal infections [88].

Donor-Derived *Candida* Infections

Candida species are one of the most common fungal pathogens transmitted from donors to recipients and are associated with frequent graft dysfunction, as well as significant morbidity and mortality [89]. In kidney transplants, it is estimated that 1 case of donor-derived invasive candidiasis will occur per 1000 grafts with a median time to occurrence of 25 days [90].

Many of these infections are presumed to be secondary to preservation fluid contamination, which can occur prior to or at the time of organ procurement. The rates of preservation fluid contamination range from 9.5% up to 37%, although of those specifically due to *Candida* species range from 0.6% up to 4.1% [91–96]. *C. albicans* remains the most common species identified ranging from 25% up to 64% of all cases [93, 95, 96].

The risk factors for contamination of the preservation fluid include intestinal perforation at time of procurement, multiorgan procurement, and en bloc transplantation [91]. While the contamination of preservation solution in kidney transplants does not increase the risk of allograft pyelonephritis, multiple reports of both kidney and liver transplant indicate an increased risk for vascular complications including arteritis and aneurysms, graft site abscess, surgical site infections, and graft loss [90, 95, 97–99].

Despite the high rates of preservation fluid contamination, there are few studies on how to manage these infections. A study by Levesque et al. showed that treatment of liver transplant recipients in whom *Candida* sp. was isolated from the preservation fluid only reduced the rate of complications from 33% to 27% [95]. However, a study by Oriol et al. showed that pre-emptive therapy with high-risk preservation fluid contamination (defined as isolation of *Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa*, and *Enterobacte*r spp. and/or *Candida* species) led to a decrease in the rate of infections [96]. In the cohort with contaminated high-risk preservation fluid with pre-emptive therapy, no complications were found versus a rate of 8.5% complications in the contaminated high-risk group without pre-emptive therapy. This suggests that pre-emptive therapy in solid organ recipients with high-risk culture-positive preservation fluid may lead to a decrease in subsequent preservation fluid-related infections. Donor candidemia has also been implicated in donor-derived infections [68]. In addition, a recent study has shown the transmission of *C. auris* in a lung transplant recipient whose donors' bronchial tree was colonized with *C. auris* [100]. Hence, the presence of *Candida* in donor cultures should prompt consideration for treatment.

Candida Diagnostics

The gold standard for diagnosis of invasive candidiasis relies on the isolation of *Candida* species using a culture-based method. This goal can be achieved by either blood cultures or collecting deep tissue specimens. Other techniques include the detection of components of the *Candida* cell wall including mannan/anti-mannan or 1-3-β-D-glucan. In addition, new molecular strategies allow for the detection of *Candida* nucleic acid using direct from blood PCR. The sensitivity and specificity of these tests vary depending on the pathogen load (e.g., transient candidemia vs. persistent candidemia vs. no candidemia) and prior exposure to therapy and most importantly the net state of immunosuppression [74, 101] (Table 3).

Table 3 Diagnostic test performance for invasive candidiasis. Performance of diagnostic tests for invasive candidiasis in blood samples. Mn, *Candida* mannan antigen; Anti-Mn Ab, Anti-*Candida* mannan antibody; PCR, Polymerase chain reaction; T2MR, T2 magnetic resonance. (References in parenthesis)

Test	Sensitivity (%)	Specificity (%)	Comments
Culture [104]	21–71	NA	In the presence of candidemia, the sensitivity is higher than in patients with invasive candidiasis without candidemia
l-3-β-D-glucan [109–113]	58–85	80–98	Performance depends on cutoff value. Has a low positive predictive value
Mannan [114–118]			
per sample	17–61	92–99	
per patient	53–62	91–94	
Anti-Mn Ab [114–118]			
per sample	23–39	87–100	
per patient	54–65	79–87	
Mn/Anti-Mn Ab [114–118]			
per sample	55–68	94–98	
per patient	79–87	82–90	
PCR [119]	88–98	88–95	
T2MR [121–123]	86–94	99	Sensitivity and specificity vary by species

Culture-Based Diagnostic Methods

The sensitivity of blood cultures in invasive candidiasis ranges between 21% and 71% with an overall sensitivity of about 50% [101]. Blood cultures are sensitive for the detection of viable *Candida*, and the limit of detection is $\leq$1 colony-forming unit/mL [102]. Although the sensitivity of blood cultures for *Candida* bloodstream infections with or without deep-seated infections is about 75%, the sensitivity is much lower in cases of low-level candidemia, intermittent candidemia, deep-seated candidiasis that persists after sterilization of the bloodstream, or deep-seated candidiasis without candidemia [101, 103]. Furthermore, the sensitivity of tissue cultures from deep-seated infections is approximately 50% which may be related to sampling error, small sample volumes, or low burden of infection [104]. While most of the studies include immunocompromised populations, there are no specific results for the performance of blood and tissue cultures for the diagnosis of invasive candidiasis in the solid organ transplant population.

Blood and tissue cultures have slow turnaround time (median time to positivity of 2–3 days) with 98% of positive cultures detected by the first week and 99% by the second week [105]. Given that the time to initiation of antifungal therapy impacts the morbidity and mortality in patients with candidemia, more rapid diagnostic tools are in need [106–108]. However, cultures have the advantage of providing identification to a species level as well as providing antifungal susceptibility testing.

Non-culture Diagnostic Methods

1-3-β-D-Glucan, Mannan, and Anti-mannan Antibodies

The lack of sensitivity of blood cultures in the diagnosis of invasive candidiasis, especially deep-seated infections without candidemia, has led to the development of multiple tests to detect components of the fungal cell wall. 1-3-β-D-Glucan, *Candida* mannan, and circulating IgG anti-*Candida* mannan antibodies have been tested during the past decades with variable results.

1-3-β-D-Glucan can be detected by multiple commercial platforms as a surrogate marker of invasive candidiasis with or without candidemia. 1-3-β-D-Glucan is a cell wall component of multiple pathogenic fungi, including as *Aspergillus* species, *Pneumocystis jirovecii*, and many others with few exceptions including *Cryptococcus* and species from the *Mucorales* group. False positive tests are associated with infusion of albumin, intravenous immunoglobulins, hemodialysis with cellulose membranes, gauze packing of serosal surfaces, and infections with gram-negative bacteria, including *Pseudomonas aeruginosa* [109, 110].

There have been ample reports on the performance of 1-3-β-D-glucan for invasive fungal infections [109, 111, 112]. In two recent meta-analyses, the sensitivity of a positive result was 75–80%, and the specificity was ~80% [113, 114]. Studies of active surveillance for invasive candidiasis in high-risk surgical patients in the intensive care unit showed that the sensitivity 1-3-β-D-glucan increased when the test was repeated twice weekly [112, 115]. Furthermore, two consecutive positive results within the same week increased the specificity of the test [116].

Koo et al. showed that higher values of 1-3-β-D-glucan are associated with higher positive likelihood ratios. Furthermore, sensitivity and specificity of the test were not affected by the prior use of antifungal therapy [109].

The use of circulating *Candida* antigens, including mannan antigen (Mn), and anti-mannan antibodies (A-Mn-Ab) has been reported in several studies. Prior studies have shown that positive Mn was preferentially observed in the absence of A-Mn antibodies, while high levels of A-Mn antibodies are usually not seen with circulating Mn [117]. Mikulska et al. showed that the pooled sensitivity for Mn, A-Mn-Ab, and Mn/A-Mn-Ab was 58%, 59%, and 83%, respectively, and had a pooled specificity of 93%, 83%, and 86%, respectively [118]. Interestingly, 75% of the patients with candidemia had a positive Mn and A-Mn-Ab test prior to the positive fungal blood culture which increased up to 86% on the day of positive blood cultures. Furthermore, 86% of patients with hepatosplenic candidiasis had positive Mn or A-Mn-Ab prior to the development of characteristic radiological features [118].

The presence of circulating Mn varies depending on the type of IC presentation. Previous studies show that Mn was detected in only 7% of patients with transient or catheter-associated candidemia compared with 76% with persistent candidemia or IC [119, 120]. In addition, the test is more sensitive with *C. albicans, C. glabrata*, and *C. tropicalis* (sensitivity of 80–100%) compared to *C. krusei* and *C. parapsilosis* (sensitivity of 40–50%) [121].

Polymerase Chain Reaction

PCR-based methods to detect *Candida* spp. from positive blood cultures are now commercially available. Avni et al. reported a meta-analysis of 54 studies, where they show that the pool sensitivity for proven/probable IC is 95% (88–98%) and specificity of 92% (88–95%), with a positive likelihood ratio of 14 and a negative likelihood ratio of 0.05 [122]. However, there is a remarkable heterogeneity in these studies. The sensitivity of PCR varies according to the type of IC syndrome. While the sensitivity in candidemia is only 50–62%, the sensitivity for deep-seated infections is 83–95%. A possible explanation is related to the intermittent release of circulating DNA with line-related infections versus more constant circulating DNA as a result of deep-seated infections [103]. The inoculum of *Candida* CFU per mL affects the sensitivity of PCR as it can reliably detect 1 CFU per mL in 5% of the cases versus 83% for 10 CFU per mL and 100% for 100 CFU per mL [123]. Given that it does not rely on the detection of live organisms, the test is not affected by the use of antifungal therapy. When paired with blood cultures, the sensitivity of PCR (PCR plus blood culture) rose to 98% suggesting that this test may be an important complementary tool for the relatively insensitive blood cultures [103].

T2 Magnetic Resonance (T2MR)

T2MR combines the nuclear magnetic resonance and PCR molecular assay to directly detect and identify the species of *Candida* spp. directly from whole blood. The T2MR system can detect *C. albicans*, *C. glabrata*, *C. parapsilosis*, *C tropicalis*, and *C. krusei* [124].

In the Direct study, the pooled sensitivity of a positive T2MR was 91.1 (86–94.2%) and a specificity of 99.4% (99.1–99.6%) [125]. Both the sensitivity and specificity varied by species such that *C. albicans/C. tropicalis* has a sensitivity of 92.3% and specificity of 98.9%; *C. parapsilosis*, sensitivity 94.2% and specificity 99.3%; and *C. krusei/C. glabrata*, sensitivity 88.1% and specificity 99.9%. In a population with a prevalence of IC of 5–10%, the positive predictive value ranged from 71.6% to 84.2%, and the negative predictive value ranges from 99.5% to 99.0% [125]. In contrast, in the general hospital setting, the prevalence of candidemia is significantly lower, which would limit the positive and negative predictive values.

In a recent study in the ICU, the use of negative T2MR test allowed for the early discontinuation of antifungal agents. In patients with negative T2MR tests, only 2%

developed proven candidemia with a median time of 21 days (range, 9–30 days) which raises the possibility of a de novo infection rather than a false negative. The short turnaround time and the high negative predictive value suggest that T2MR may be a valuable adjunctive test for antifungal stewardship [126]. There is limited data on the performance of T2MR in the diagnosis of deep-seated infections without candidemia.

Treatment

Empiric therapy for invasive candidiasis should be initiated as soon as the diagnosis is suspected, as early treatment initiation decreases mortality [106–108, 127, 128]. The choice of therapeutic agent should take into consideration the epidemiology of *Candida* species in the local medical center, prior exposure to antifungal agents, and the tissue penetration of the drug. In addition, removal of central line catheters and drainage of the potential source have direct impact on survival [74, 129, 130].

There are four major classes of antifungal medications available for the treatment of invasive candidiasis, with several new classes in development. These include triazoles, polyenes, echinocandins, and flucytosine. It is important to note that the recommendations on the treatment of IC are largely derived from studies on patients with candidemia and other common forms of IC [131].

Early studies showed that fluconazole was not inferior to amphotericin B in the management of candidemia in non-neutropenic patient [132]. Although there was a trend toward more rapid clearance from bloodstream, the combination of fluconazole plus amphotericin B deoxycholate was not superior to fluconazole alone [133]. Subsequently, Kullberg et al. showed that voriconazole was as effective as a regimen of amphotericin B in the treatment of candidemia [134]. Other studies have shown that echinocandins, including caspofungin, anidulafungin, and micafungin, are as effective as amphotericin B deoxycholate and were associated with significantly lower adverse effects [135, 136]. There are no significant differences between echinocandins, and higher doses have not been shown to be superior to standard dosing, except in the management of *Candida* esophagitis and infective endocarditis [137, 138].

In patients with IC due to *C. albicans*, anidulafungin was more effective than fluconazole, with more rapid clearance of positive blood cultures [138]. A meta-analysis by Andes et al. showed that therapy with an echinocandin (e.g., micafungin, anidulafungin, caspofungin) had significantly better survival rates than either a polyene (e.g., amphotericin B) or a triazole (e.g., fluconazole, voriconazole) [139].

Given these data, echinocandins are recommended as the first line of therapy for candidemia by the Infectious Diseases Society of America except for tissue with low penetration, including eyes, central nervous system, and urinary tract. Initial echinocandin treatment can then be followed by step-down to oral triazole therapy depending on *Candida* isolated and susceptibility to complete the therapy [28, 74]. Recommendations for the agent of choice, dosing, and length of therapy are detailed in Table 4.

Table 4 Treatment of invasive candidiasis. (Adapted from Clinical Practice Guideline for the Management of Candidiasis: 2016 Update by the Infectious Diseases Society of America and Practice ASTIDCo. Candida infections in solid organ transplantation: Guidelines from the American Society of Transplantation Infectious Disease Community of Practice)

Type of infection	Primary	Alternative	Duration	Comments
Candidemia and invasive candidiasis	Echinocandin: Micafungin 100 mg/day Caspofungin 70 mg loading then 50 mg/day Anidulafungin 200 mg loading then 100 mg/day	Azole: Fluconazole 12 mg/kg loading dose and then 6 mg/kg IV/PO daily if the patient is not critically ill and fluconazole-resistance is unlikely Lipid formulation amphotericin B (AmB) (3–5 mg/kg daily) is a reasonable alternative if other antifungals are not an option (availability or resistance)	If there is no obvious metastatic complication, therapy should be continued for 2 weeks from documented clearance of bloodstream infection Transition to an azole is recommended after 5–7 days if the patient is stable and the isolates are susceptible to the selected azole	Central venous catheters (CVCs) should be removed as early as possible Dilated ophthalmological examination should be performed in all patients within the first week, except in neutropenic patients in whom the exam should be delayed until recovery from neutropenia For invasive candidiasis, duration of therapy may be at least 2 weeks and resolution of symptoms attributable to invasive candidiasis Source control, with drainage and/or debridement should be included in intra-abdominal candidiasis or abscess/ collections.
Chronic disseminated candidiasis	Lipid formulation amphotericin B (AmB) (3–5 mg/kg daily) Echinocandin: Micafungin 100 mg/day Caspofungin 70 mg loading then 50 mg/day Anidulafungin 200 mg loading then 100 mg/day	Azole: Fluconazole 12 mg/kg loading dose and then 6 mg/kg IV/PO daily if fluconazole-resistance is unlikely	3–6 months and resolution or calcification of radiologic lesions	Transition to an azole can be considered if the patient is stable and the isolate is susceptible or resistance to selected azole is unlikely

(continued)

Table 4 (continued)

Type of infection	Primary	Alternative	Duration	Comments
Endocarditis and implantable cardiac devices	Lipid formulation amphotericin B (AmB) (3–5 mg/kg daily) with or without Flucytosine 25 mg/kg PO 4 times daily High dose echinocandin: Micafungin 150 mg/day Caspofungin 150 mg/day Anidulafungin 200 mg/day			Transition to an azole can be considered if the patient is stable and the isolate is susceptible to selected azole Valve replacement is recommended If valve is not replaced or patient has prosthetic valve endocarditis, chronic suppressive antifungal therapy with a susceptible azole is recommended For pacemakers and implantable cardiac defibrillators, the entire device should be removed and therapy extended for 4–6 weeks after removal
Osteoarticular and septic arthritis	Lipid formulation amphotericin B (AmB) (3–5 mg/kg daily) Echinocandin: Micafungin 100 mg/day Caspofungin 70 mg loading then 50 mg/day Anidulafungin 200 mg loading then 100 mg/day	Azole: Fluconazole 12 mg/kg loading dose and then 6 mg/kg IV/PO daily if fluconazole-resistance is unlikely	6–12 months for osteoarticular infections. At least 4 weeks for septic arthritis	In osteoarticular infections, transition to an azole can be considered after 2 weeks of IV therapy with either a AmB or echinocandins if the isolate is susceptible to selected azole In septic arthritis, surgical drainage is indicated Device removal is recommended in prosthetic joint infections. If device is not removed, chronic suppressive antifungal therapy with a susceptible azole is recommended

Endophthalmitis	Azole: Fluconazole 12 mg/kg loading dose and then 6 mg/kg IV/PO daily Voriconazole 6 mg/kg loading dose and then 4 mg/kg IV/PO twice daily Lipid formulation amphotericin B (AmB) (3–5 mg/kg daily)	Intravitreal lipid formulation amphotericin B 5–10 mcg Voriconazole 100 mcg	At least 4–6 weeks after surgery	Vitrectomy is usually performed when vitreitis is present
Pyelonephritis	Azole: Fluconazole 3–6 mg/kg IV/PO daily Amphotericin B deoxycholate 0.3–0.6 mg/kg IV D with or without flucytosine 25 mg/kg PO 4 times	Flucytosine 25 mg/kg PO 4 times daily	7–14 days	Nephrostomy tubes or stents in place should be removed or replaced if feasible Elimination of urinary tract obstructions is indicated
Esophageal	Azole: Fluconazole 3–6 mg/kg IV/PO daily Itraconazole solution 200 mg PO D Voriconazole 3 mg/kg PO twice daily	Echinocandin: Micafungin 100 mg/day Caspofungin 70 mg loading then 50 mg/day Anidulafungin 200 mg loading then 100 mg/day	14–21 days	Mild – moderate oropharyngeal infection can be treated with Clotrimazole troche or Nystatin

Special Considerations: Emergence of *Candida auris*

C. auris is an emerging pathogenic fungus that has been reported from at least 32 countries on 6 continents during 2009–2019 [140]. *C. auris* was isolated in 2009 from the outer ear of a Japanese patient [141]. Since that time, there has been a simultaneous appearance around the world that segregates in four major clades [142]. As of now, it is unclear how these clades of *C. auris* appeared in synchronized fashion and the significance of this phenomenon. This yeast is found predominantly on the skin, and there is good evidence that it does not live as part of the gastrointestinal tract and healthy microbiome. *C. auris* is able to persist in the environment for extended periods of time and poses a challenge in the decontamination with conventional cleaners resulting in persistence and multiple reported hospital and ICU outbreaks [143, 144]. *C. auris* presents with reduced susceptibility to fluconazole in over 90% of cases and with reduced susceptibility to voriconazole, itraconazole, posaconazole, and isavuconazole. Varying susceptibility to amphotericin B (35–43% resistance) and resistance to echinocandins (7%) have been reported. Furthermore, 41% of the isolates were resistant to two classes of antifungals, and 4% were resistant to all three classes of antifungal agents (triazoles, echinocandins, and polyenes). Flucytosine has broad antifungal activity but has to be given in combination due to rapid emergence of resistance [74]. The combination of flucytosine with either amphotericin B or echinocandins (i.e., micafungin, caspofungin, and anidulafungin) resulted in in vitro inhibition of most *C. auris* isolates [145]. There are no concrete therapeutic guidelines for the management of *C. auris* infections. The consequences of an active *C. auris* infection are high, with some studies reporting up to a 50% mortality rate [146]. Hence, case-by-case options should be followed in consultation with infectious diseases specialists [147].

Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) is indicated when the standard dosing of any given drug results in marked variability in drug blood concentrations and when relationships between drug exposure (plasma drug level) and either efficacy or toxicity have been established. The plasma drug levels of certain medications may vary due to inconsistent absorption, metabolism, elimination, or interaction with concomitant medications [148–150].

Fluconazole has a predictable pharmacokinetics (PK) with a direct correlation between dosing and blood levels. Although a recent report of 27 liver transplant recipients showed increased treatment success in patients with trough plasma levels >11 mcg/mL, most studies have not measured clinical impact with fluconazole TDM [151–154]. For that reason, current guidelines do not support the use of TDM for fluconazole [28, 74].

Itraconazole has intrinsic suboptimal absorption. In addition, the drug-drug interactions lead to significant PK variability despite the recommended therapeutic

dosing ranges. The suboptimal absorption is particularly poor under circumstances of impaired GI integrity, reduced acidic environment which is required for capsules, and oral intolerance leading to poor compliance, although improved with newer formulations. For itraconazole, when measured by high-pressure liquid chromatography (HPLC), both itraconazole and its bioactive hydroxy-itraconazole metabolite are reported, the sum of which should be considered in assessing drug levels [74, 149]. TDM is recommended for long-term use of itraconazole.

While the absorption of voriconazole is usually reliable, there are large variabilities in PK between individuals. There is ample evidence that TDM is associated with better treatment success and less drug discontinuation due to adverse events [155, 156].

Like the triazoles voriconazole and itraconazole, the PK of posaconazole has marked interpatient variability, and there is increased efficacy when TDM is applied [157]. Isavuconazole is the newest triazole available for management of invasive fungal infections. The utility of TDM of isavuconazole has been unclear, and currently there is insufficient data to support TDM for this agent.

Circulating levels of flucytosine have a strong relationship with both toxicity and efficacy. The strongest of these associations has been bone marrow toxicity with levels grated than 100 mcg/mL [148–150]. For these reasons, there is strong evidence to support TDM when using flucytosine.

Altogether, TDM for itraconazole, voriconazole, posaconazole, and flucytosine are recommended for optimizing the therapy of mucosal and invasive candidiasis [28, 74]. Given reliable pharmacokinetics, neither echinocandins nor amphotericin B nor fluconazole require TDM (see Table 5).

Table 5 Therapeutic drug monitoring parameters based on high performance liquid chromatography. [a] Itraconazole levels are a result of adding both itraconazole and hydroxy-itraconazole (active metabolite). Echinocandins and polyenes do not require therapeutic drug monitoring. (References [28, 77])

	Efficacy		Safety	Levels obtained	
Triazole	Prophylaxis	Treatment	Toxicity	Related to dose	Day
Fluconazole	Not indicated				
Itraconazole[a]	≥0.5 mcg/mL	1.0–2.0 mcg/mL	No data	30 min pre-dose	7–14 days
Voriconazole	≥0.5 mcg/mL	1.5–5.5 mcg/mL	<6 mcg/mL	30 min pre-dose	5–7 days
Posaconazole	≥0.7 mcg/mL	>1.0 mcg/mL	No data	30 min pre-dose	5–7 days
Isavuconazole	Optimal drug concentrations not established				
Antimetabolite					
5-Flucytosine		30–80 mcg/mL	<100 mcg/mL	2 h post-dose	3–5 days

Conclusion

Invasive candidiasis (IC) remains the most common invasive fungal infection (IFI) in patients with solid organ transplant with an unacceptable high morbidity and mortality. *C. albicans* is the most common isolated species though non-*albicans* species are increasing.

While isolation of the *Candida* species in a culture media remains as the goal standard, newer techniques including the detection of cell wall components and PCR are now available with higher sensitivities and more acceptable turnaround times. However, these newer techniques have varying sensitivity and specificity depending on the pathogen load and prior exposure to therapy.

Early initiation of therapy significantly improves survival, but given the limitations of the diagnostic tests, a high degree of clinical suspicion is required. Initial therapy usually involves an echinocandin, though in selected scenarios either amphotericin B or azoles are other options.

Finally, future research efforts in personalized microbiome analysis and host immune susceptibility profiling would allow for pre-emptive prophylactic strategies in selected, risk-stratified patients. Given the emergence of multidrug-resistant *Candida* species such as *Candida auris*, newer medications are in dire need to ensure safe outcomes for future transplant patients.

Future Directions

Invasive candidiasis continues to have a high morbidity and mortality. Early initiation of therapy has been demonstrated to have a positive impact in survival. Due to low sensitivity and long turnaround time of current diagnostic tests, clinicians are forced to have a high index of clinical suspicion. Future research should focus on better diagnostics tests with short turnaround times. In addition, microbiome dysbiosis analysis and host susceptibility profiling may be useful in risk stratification of patients and could potentially aid in defining pre-emptive prophylactic strategies for high-risk SOT recipients. Finally, the emergence of multidrug-resistant *Candida* species, including *Candida auris*, poses new threats to SOT patients and calls for research into newer therapeutic options.

KeyPoints

1. *Candida* species remain a common infectious complication following solid organ transplantation.
2. *Candida albicans* is the most common species isolated.
3. Non-albicans *Candida* species, including *C. glabrata*, are on the rise and demonstrate multidrug resistance.
4. A fungal pandemic caused by drug-resistant *C. auris* requires careful consideration in transplant programs.

5. Culture remains the gold standard for diagnosis, although nucleic acid-based tests are more efficient.
6. Therapeutic drug monitoring of specific antifungal agents permits a safer and more effective outcome.

Introduction

Aspergillus is an ubiquitous mold and found worldwide in soil, food, water, and compost. Contamination of the hospital air supply can occur when construction or renovation is conducted. *Aspergillus fumigatus* is by far the most common species, isolated in 73% of cases [1].

The annual burden of invasive aspergillosis (IA) is estimated to be more than 300,000 cases worldwide [2]. Immunocompromised patients are at highest risk of acquiring the disease.

The usual route of infection for IA is through inhalation of the conidia into the lung or paranasal sinuses. Posttransplant patients have reduced pulmonary host defenses, which inhibits the activity of pulmonary macrophages. If the conidia are not eradicated, they may enlarge and germinate to form hyphae causing disseminated infection by invading blood vessels and parenchymal tissue.

The Transplant-Associated Infection Surveillance Network (TRANSNET) performed a prospective surveillance of invasive fungal infections (IFIs) and identified an overall incidence of 3.4% (range by site, 0.9%–13.2%) among hematopoietic stem cell transplant (HSCT) recipients [3], and a 12-month cumulative incidence of 3.1% (1.2%–6.1%) among solid organ transplant (SOT) recipients [1].

The incidence of IA in HSCT recipients increased during the 1990s, as a multitude of factors such as the receipt of T cell-depleted or CD34-selected stem cell products, corticosteroids, neutropenia, lymphopenia, graft versus host disease (GVHD), cytomegalovirus (CMV) disease, and respiratory virus infections increased this incidence after HSCT [4]. The most important risk factor is prolonged neutropenia, as presented in Table 1.

The incidence of IA in HSCT recipients is bimodal, with the first peak in incidence occurring early after transplantation (<40 days). Several groups have identified a second risk period late after engraftment (40–180 days post-transplant) associated with GVHD and CMV infection [5]. The mean time until diagnosis is 180 days in some case series [1, 4, 5]. The mortality rate in HSCT recipients with IA ranges from 66.6% to 80% and does not differ for those with early onset versus late onset of infection [3, 9]. IA is one of the causes of non-relapse-related mortality in non-myeloablative HSCT recipients, with 9% of overall mortality and 39% of non-relapse mortality in this patient population being due to invasive mold infections [9]. In the PATH alliance analysis, 90-day survival in the allogeneic stem cell

Table 1 Risk factors for invasive aspergillosis in SOT and HSCT recipients [1, 4–7]

SOT patients	HSCT patients
Liver transplant Re-transplantation or reoperation Rejection or change immunosuppression Acute kidney injury -Renal replacement therapy Fulminant hepatic failure MELD >30 CMV infection	**Early IA (<40 days after transplant)** Aplastic anemia, myelodysplastic syndrome, and multiple myeloma [4] Transplantation with T cell-depleted or CD34-selected stem cell products Delayed neutrophil engraftment or prolonged neutropenia CMV disease
Lung transplant Single lung transplant Early airway ischemia Rejection or change immunosuppression Pre-transplant colonization Positive intraoperative *Aspergillus* culture in CF patient Hypogammaglobulinemia CMV infection	**Late IA (days 41–180 after transplant)** Delay engraftment of T lymphocytes Neutropenia Respiratory viruses (influenza and parainfluenza) [7] Graft-versus-host disease Corticosteroids
Heart transplant *Aspergillus* colonization Reoperation Posttransplant hemodialysis Rejection or change immunosuppression Existence of an episode of IA in any patient within the heart transplant program, 2 months before or after transplant Pretransplant diagnosis of COPD High duration of steroids CMV infection	
Kidney transplant Previous pulmonary disease Cardiovascular diseases [8] Delayed graft function Rejection or change immunosuppression CMV infection	

transplant recipient with IA was 59.7% [5]. The most common species of this fungus is *Aspergillus fumigatus*. Figure 1 shows the distribution of *Aspergillus* species in HSCT recipients reported in different cohorts.

In SOT recipients, the overall incidence of IA is slightly lower than in HSCT [6]. Lung transplant recipients report higher incidence compared to other solid organ transplants and are comparable to allogenic hematopoietic stem cell transplant recipients (Fig. 2). Some of the risk factors for developing early IA (<3 months) in SOT include complications in the postoperative period such as the use of vasopressors >24 h after surgery, intensive care readmission, development of renal failure, hemodialysis, and infections due to bacteria and CMV. The risk factors for developing late IA were age >50 years, chronic transplant rejection, and changes in immunosuppression [6]. Risk factors differ, depending on the transplanted organ, and are presented in (Table 1).

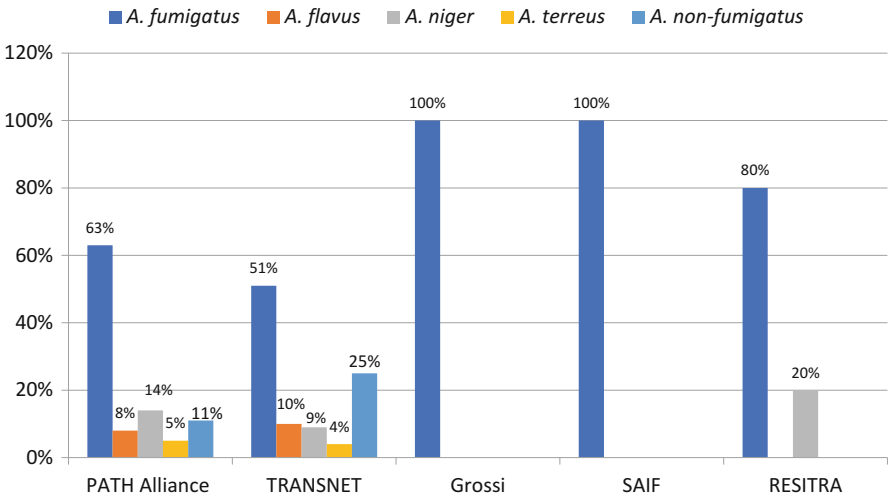

Fig. 1 Distribution of *Aspergillus* infections in lung transplant [1, 3, 5, 10–12]

The median time of presentation in HSCT recipient case series was 184 days after transplant [1]. In the SOT population, IA in liver transplant recipients occurred earlier ranging up to 17 days after transplant [14]. In lung transplant recipients, IA occurred at a median of 7.7 months posttransplantation [15].

Cryptic Emergence of Resistant *Aspergillus* Species and Azole-Resistant Strains

Antifungal resistance in *Aspergillus* spp. is increasingly being recognized and poses additional therapeutic challenges. *A. fumigatus* is eukaryotic with a complex cellular composition, and unlike bacterial pathogens, it does not develop rapid resistance in response to antifungal exposure. Mutations in the *Cyp51A* gene which encodes the Cyp51 enzyme responsible for the last step in ergosterol biosynthesis have been the resistance mechanisms documented in clinical isolates [16]. These resistance mechanisms, which include TR_{46}/Y121F/T289A, TR_{53}, and TR_{34}/L98H, have been implicated in isavuconazole, voriconazole, posaconazole, and itraconazole resistance [17]. G54 and M220 have been associated with resistance to itraconazole and posaconazole [17], while Y121F has been associated with resistance to voriconazole alone [18].

Azole resistance can also be an intrinsic phenotype, as is known to occur in some cryptic *Aspergillus* species related to *A. fumigatus*, specifically *A. lentulus* and *A. pseudofischeri.* On the other hand, wild-type *A. fumigatus* and *A. flavus* are sensitive to azoles [16]. Resistance can be acquired by two major routes, either through long-term azole therapy or via the utilization of azole compounds in the environment, particularly in agriculture [19].

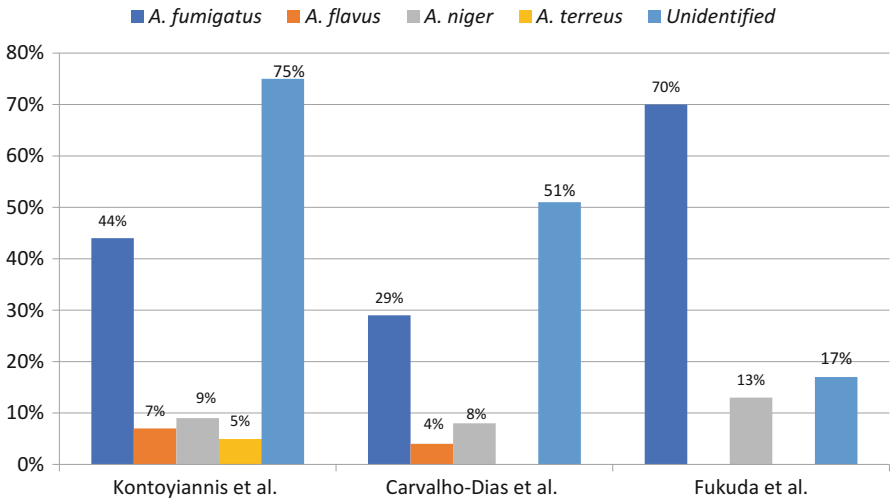

Fig. 2 Distribution of *Aspergillus* species in HSCT [3, 9, 13]

Acquired resistance to azoles in *A. fumigatus* has become a public health concern. A prospective multicenter international survey that included 3,788 *Aspergillus* isolates in 22 centers from 19 countries showed 3.2% of clinical *A. fumigatus* isolates to be azole resistant [20]. However, in a prospective surveillance study in the Netherlands, the prevalence of itraconazole resistance in *A. fumigatus* was 5.3% (range 0.8%–9.5%); 64% were azole naive, and the case fatality rate of patients with azole-resistant invasive aspergillosis was 88% [21]. A recent surveillance study of fungal infection in SOT recipients in the USA showed a low rate of triazole resistance (1/181) in *A. fumigatus* isolates [22]. Additionally, in a cohort of 22 lung transplant recipients with *A. fumigatus*, targeted antifungal prophylaxis did not lead to *Cyp51A* resistance mutations [23]. A retrospective study of breakthrough invasive mold infections that occurred during posaconazole and voriconazole prophylaxis in hematologic malignancy and SOT patients reported 24 breakthrough infections; IA accounted for 21% of cases, and *A. ustus* emerged as the predominant *Aspergillus* pathogen (43% of the cases) [24].

Diagnosis of Aspergillosis

The diagnosis of IA relies on a combination of host, imaging, microbiology, and pathology findings. The standard definitions for IFIs, published by the European Organization for the Research and Treatment of Cancer/Mycoses Study Group (EORTC/MSG) Consensus Group [25], were developed to maintain consistency in clinical and epidemiological studies. Based on these definitions, the diagnosis of IA is often referred to within a scale of certainty: possible, probable, and proven. For the diagnosis of *Proven IA*, there must be histopathologic, cytopathologic, or direct

microscopic examination of a biopsy in which hyphae are seen, accompanied by evidence of associated tissue damage and growth of *Aspergillus* species from culture of a normally sterile and clinically or radiologically abnormal site. A diagnosis of *Probable IA* requires an immunocompromised host with clinical disease and non-definitive microbiological testing (cytology, direct microscopy, and/or culture indicating presence of *Aspergillus* species in a lower respiratory tract specimen or galactomannan antigen index >0.5 in plasma, serum, or bronchoalveolar lavage (BAL) fluid or a serum 1,3 beta D-glucan level of >80 pg/mL). A *Possible IA* diagnosis indicates presence of a compatible clinical disease and an immunocompromised host.

In lung transplant recipients, it is preferred to use the International Society for Heart and Lung Transplantation (ISHLT) guidelines. For the diagnosis of *Proven IA*, there must be a biopsy showing histologic evidence of parenchymal invasion by fungal hyphae, or pseudo-hyphae, or positive culture from sterile tissue alone or sign/symptoms and radiological criteria and laboratory criteria (single positive culture for mold BAL/blood or single positive PCR for mold BAL/blood or positive galactomannan in the BAL or at least two positive sputum cultures/PCRs of fungal organisms). For *Probable IA* the criteria are the same as for proven, except there is negative or absent histology [26]. No category of *Possible IFI* is entertained in the ISHLT definitions, due to a multitude of infectious etiologies that can mimic the radiological patterns of IFI in lung transplant recipients.

Clinical Manifestations

The spectrum of infection caused by *Aspergillus* species is diverse, ranging from allergic responses, asymptomatic colonization, superficial or localized infection, and acute or subacute invasive disease. The clinical presentation and severity depend on the underlying immune defects and risk factors associated with each patient group. In HSCT and SOT recipients, prolonged neutropenia and immunosuppressive therapy cause an increased risk for invasive disease. Table 2 shows the most common presentations of *Aspergillus* infection in different transplant modalities.

Bronchoscopy

Bronchoscopy with bronchoalveolar lavage (BAL) fluid remains the diagnostic procedure of choice for patients with pulmonary aspergillosis. Bronchoscopy should be performed in patients with a suspicion of IA. However, there is no uniform agreement on the best timing for bronchoscopy, and this population of patients commonly present with significant comorbidities that may preclude BAL. The yield of BAL is low in peripheral nodular lesions; in such cases percutaneous or endobronchial lung biopsy should be considered [19].

Table 2 Clinical presentations of infection caused by *Aspergillus* spp.

Type of transplant	Site of infection
HSCT recipients [3, 4]	Common: invasive pulmonary aspergillosis and disseminated infection
Liver transplant recipients [14]	Uniquely predisposed to dissemination of infection beyond the lungs (50–60% cases) Isolation of *Aspergillus* spp. from the respiratory tract of LT recipients is infrequent
Lung transplant recipients [27, 28]	Invasive aspergillosis occurs in 3–15% of lung transplant recipients 58% tracheobronchitis or bronchial anastomotic infections 32% invasive pulmonary aspergillosis 22% disseminated infections with extra-pulmonary involvement *Aspergillus* spp. can be detected in airway sample cultures from 25 to 30% of lung transplant recipients
Heart transplant recipients [10, 28]	Invasive aspergillosis occurs in 6% of heart transplant recipients Common: invasive aspergillosis, disseminated infections Rare: central nervous system infections *Aspergillus* spp. can be detected in 10% of the heart transplant recipients
Kidney transplant recipients [28]	Invasive aspergillosis occurs in 0.7 to 4% of patients Common: invasive aspergillosis, disseminated infections

Microbiology

In the past decade, there has been significant progress in molecular and immunological diagnostic tests for IA. Unfortunately, most of these tests are not widely available, and some are not standardized in the transplant population. Microscopy and culture continue to provide the most certain evidence of IA, and therefore, they should be attempted on appropriate specimens from patients at risk of IA [29]. To detect the presence of fungal elements in biological samples, the most commonly used stain is calcofluor white with 10% potassium hydroxide. While this stain is not specific for *Aspergillus* spp., it nevertheless has the advantage of increased sensitivity and a rapid turnaround time [29]. Other useful stains are Gomori's methenamine silver (GMS) stain and periodic acid-Schiff (PAS). In direct microscopy, *Aspergillus* typically appears as uniform septate hyphae with dichotomous (two-way) acute (45°) angle branching. The hyphae have parallel walls without constrictions and are uniform in width, measuring 3–6 μm in diameter.

Microscopic examination has important limitations that contribute to its low sensitivity. Of note is that the disease is usually required to be at an advanced stage, in order to ensure an abundance of fungal structures for analysis. Furthermore, microscopic examination is also dependent on the number of fields examined and the expertise of the examiner, as the identification of the genus of even the most common pathogenic species of *Aspergillus* can be difficult [30]. Colonies of *Aspergillus* spp. grow rapidly (24–72 h) on a variety of media, growing better in temperatures above 37 °C [30]. Culture of the organism from a sterile site and evidence of tissue

invasion on histopathology are findings that provide the most certain diagnosis of IA. Even though positive culture is the definitive diagnosis of *Aspergill*us infection, we must remember that *Aspergillus* spp. can be a laboratory contaminant or a colonizer of the respiratory tract. Therefore, a positive culture requires careful interpretation, while a negative culture likewise does not rule out a diagnosis of IA.

Immunohistochemistry for *Aspergillus*

Immunohistochemistry (IHC) is a method that selectively identifies specific antigens in tissue cells, based on antigen-antibody recognition. The antibody used in IHC is a polyclonal rabbit anti-*Aspergillus* antibody [31] that conjugates to an enzyme which catalyzes a color-producing reaction. The specificity of the test is determined by the union and binding of an antibody with its counterpart antigen at a light microscopic level. This method has the advantage of being able to identify several fungi, allowing pathological identification of unusual filamentous and yeast-like infections. For the identification of *Aspergillus* spp., polyclonal and monoclonal antibodies have been produced. However, most of these antibodies cross-react with other fungi, thus limiting the use of these tests. Currently none of these tests have received FDA approval.

Serological and Molecular Tests

Due to the limitations of the conventional methods mentioned above, in the last few years, new diagnostic tools have been developed. These new tests attempt to detect antigens and molecular compounds in fungal cell components and thus do not rely on fungal culture.

Galactomannan Antigen Detection

Galactomannan (GM) is a polysaccharide which consists of a mannose backbone and a variable number of galactofuran side chains. GM makes up a major part of the cell wall of *Aspergillus* spp. [32]. Currently, the most common method to determine GM in serum and BAL fluid is a double sandwich enzyme-linked immune assay "Platelia" (Bio-Rad). While the manufacturer recommends an optical index cutoff value of 0.5 in both serum and BAL, due to the large number of false positives in BAL at this cutoff value, the upcoming revision of the EORTC-MSG criteria has instead proposed a cutoff of 1.0 [33, 34].

The *Aspergillus* galactomannan antigen test has important limitations. The GM concentration in vivo is determined not only by the amount of production and secretion from the fungus but also by the degree of angio-invasion that is required to reach the circulation through the alveolar-capillary membrane. Due to the large size of the GM molecule, it cannot freely diffuse from the alveoli through the

endothelial lining of the pulmonary capillaries. As such, angio-invasion is always required [32]. Additionally, GM production is influenced by antifungal therapy, meaning that there is a significant decrease in the sensitivity of this test in patients who are receiving antifungals [35].

Cross-reactivity can occur with this test in cases of histoplasmosis, fusariosis, and talaromycosis (formerly penicilliosis). This is due to the fact that other filamentous fungi may have GM present in their cell wall (although in lower amounts than in *Aspergillus* spp.). False-positive GM has been documented in 13% of cases in liver transplant patients [36] and in 20% of lung transplant patients [37].

The sensitivity of GM can vary depending on the state of immunosuppression of the host. Neutrophils are believed to be involved in the uptake and elimination of GM [32]. This potentially explains the higher sensitivities seen in the context of neutropenia (~70%) such as in the HSCT populations and the decreased sensitivity seen in SOT recipients (~20%) [38].

Testing for BAL GM can improve the diagnosis of IA. The sensitivity of BAL GM has been assessed in a limited number of studies in the transplant population, and it has been seen that by increasing the cutoff value to 1.0, there is an increase in specificity, as outlined in Table 3. In lung transplant recipients, serum GM had a specificity of 95% but a low sensitivity (30%) for the diagnosis of IA [23]. A meta-analysis showed that the serum GM assay may have a greater utility in hematopoietic stem cell transplant recipients than in SOT recipients, in whom the sensitivity and specificity of the test were 22% and 84%, respectively [24]. Therefore, serum GM should not be used to diagnose IA in SOT recipients; BAL GM is preferred for the diagnosis of IPA in SOT recipients. Moreover, screening with GM and β-D-Glucan in liver transplant recipients has been reported to have limited utility [48].

(1-3)-β-D-Glucan

β-D-glucan can be detected by the Tachypleus or Limulus assay. While the presence of β-D-glucan in serum signifies the presence of fungal invasion, unfortunately this test is nonspecific for *Aspergillus* spp. Cross-reactivity with other fungi (including *Candida* and *Pneumocystis*) can lead to false-positive results. A higher sensitivity and specificity have been reported in HSCT recipients. The specificity can be improved in general with multiple positive tests and when combined with a positive culture (Table 3). Currently serum or BAL β-D-glucan is not recommended for early screening and diagnosis of IA in SOT recipients [49].

Aspergillus Polymerase Chain Reaction (PCR)

Multiple investigational DNA detection assays including polymerase chain reaction (PCR) have been developed for the diagnosis of IA in the past few years, with mixed results. Currently the use of PCR is not included in the EORTC/MSG definition of invasive fungal disease due to limited standardization and validation.

Table 3 Diagnostic tests for IA in HSCT and SOT recipients

Diagnostic test	HSCT	SOT
Serum galactomannan	Cutoff value >0.5 Sensitivity 82% Specificity 86% [38]	**Lung transplant** Cutoff value >0.5 Sensitivity 30% Specificity 93% [37] **Liver transplant** Cutoff value >0.5 Specificity 87% [36] **Kidney transplant** Cutoff value >0.5 Specificity 58% [38] **All types of sot recipients** [38] Cutoff value >0.5 Sensibility 22% Specificity 84%
BAL galactomannan	**High-risk HM patients** [39] Cutoff value 1.0 Sensitivity 91.3% Specificity 93%	**Lung transplant** [33] Cutoff value 1.0 Sensitivity 60% Specificity 98% **All types of sot recipients** [34] Cutoff 1.0 Sensibility 100% Specificity 90.8%
β-D-glucan	Sensitivity 50% [31] Specificity 91–99%	**Liver transplant** [40] Cutoff 80 pg/mL Sensitivity 58–75% Specificity 65–83% **Lung transplant** [41] Sensitivity 71–80% Specificity 59–70%
PCR	**HM, HSCT, and mixed populations** **Whole-blood** Sensitivity 84% [42] Specificity 76% **Serum** Sensitivity 64% [42] Specificity 95%	**BAL lung transplant** [43] **pan-*Aspergillus* PCR** Sensitivity 100% Specificity 88% ***A. fumigatus*-specific PCR** Sensitivity 85% Specificity 96%
Radiological findings	235 patients with proven or probable IPA. Presence of halo sign: 35% in HCST recipients and 52% in HM [44] 30 patients with probable and proven IPA with HM and prolonged neutropenia, 63% had halo sign [19]	**Lung transplant** [45] 64 proven or probable IPA: 53% nodular lesions, 47% non-nodular lesions, halo sign 3% **Liver transplant** [46] 25 patients proven IPA: 64% pulmonary nodules, 36% masses, 20% consolidations, 80% halo sign **All types of sot recipients** [47] 46 proven or probable IPA: consolidation or mass 72%, large nodules 59%, ground-glass opacity 50%

The sensitivity and specificity reported in PCR can vary depending on the type of sample, the method for DNA extraction, and the primer used in the PCR for detection of DNA. Other notable issues are that PCR is unable to differentiate between colonization and invasive infection, and it can yield false-positive results due to cross-reactivity with other mold species. Additionally, as most of the existing studies of *Aspergillus* PCR are on patients with hematological malignancies, data is very limited in the SOT population [42]. In a meta-analysis including 25 studies, the sensitivity and specificity of PCR for detection of IA were 84% and 76%, respectively. Diverse patient populations were included, including hematological malignancies, HSCT recipients, and other immunocompromised patients [42]. While experience is limited in the SOT population, the few available studies have been encouraging. A study on the performance of a pan-*Aspergillus* PCR (Viracor-IBT Laboratories) and GM in 150 BAL samples of double lung transplant recipients with a diagnosis of IA showed a sensitivity and specificity of 100% and 88%, respectively. In addition, the sensitivity and specificity of *A. fumigatus*-specific PCR were 85% and 96%, respectively [43]. The performance of the PCR increases when used in combination with another diagnostic test. Positive results for both BAL, PCR, and GM testing improved the specificity to 97%, with minimal detriment to sensitivity (93%) [43]. Likewise, the test showed improved performance with a sensitivity of 64% and specificity of 95%, when at least two PCR results returned positive [42].

The *Aspergillus* PCR is a very promising tool, with a noteworthy advantage in its ability to identify mutations associated with treatment resistance, a potentially useful function in SOT patients that have had previous fungal colonization. There are multiple commercially available PCRs that can identify azole resistance phenotypes such as AsperGenius (PathoNostics BV, Maastricht, the Netherlands) which is a multiplex real-time PCR and melting curve analysis that analyzes *A. fumigatus Cryp51A* with the targets of TR_{34}, L98Hm Y121F, and T289A substitutions [41]. For the analyses of *A. fumigatus* genes other than Cyp51A, there are PCR TaqMan probes that target *Cyp51B* S35 and P294 expression and PCR plus sequencing and real-time RT-PCR that target *Cyp51A*, *mdr1-4*, *atrF*, *cdr1B (abcG1)*, and *mfs56.* Additionally, for the analyses of *A. flavus Cyp51* genes, there is PCR plus sequencing, TaqMan probes that target *Cyp51A*, *Cyp51B*, and *Cyp51*C genes plus 5′ and 3′ regulatory sequences [50]. Furthermore, as the use of PCR in combination with other diagnostic tests was associated with improved diagnostic accuracy, it has the potential to provide an earlier diagnosis.

Newer Tests

Monoclonal Antibodies

The lateral flow device (LFD) is an immuno-chromatographic assay that detects a mannoprotein produced by actively growing *Aspergillus* species, using a monoclonal JF5 antibody. Although initially developed for the detection of the

Aspergillus antigen in human serum, it is now also used for detection in BAL fluid. It is a rapid test (15 min) and can be easily done. In a meta-analysis conducted in 2015 [51], the LFD seemed to display a better performance in BAL. Pooled sensitivity and specificity for proven/ probable IA versus no IA cases were 86% and 93%, respectively [52, 53].

Point-of-care lateral flow devices that test for the detection of *Aspergillus* antigens are currently in development. The most promising is based on the JF5 antibody and has shown good performance in clinical studies done in BAL fluid in cases of probable/proven IPA versus no evidence of IA in SOT recipients. It showed a sensitivity of 94% and specificity of 92% and in hematological malignancies a sensitivity of 67% and specificity of 91%, with an overall sensitivity of 73%, specificity of 90%, positive predictive value of 61%, and negative predictive value of 94% [52]. This test is not commercially available currently.

Urinary Antigen Detection

This assay uses a lateral flow dipstick using the galactofuranose-specific monoclonal antibody (mAb476), which recognizes urine antigens after *Aspergillus fumigatus* pulmonary infection. The per-patient sensitivity and specificity for the diagnosis of proven or probable IA was 80% and 92%, respectively [54]. This assay had a better performance in hematologic malignancy patients, where the sensitivity was 89.5% and specificity was 90.9%. False-positive results were noted in patients with *Histoplasma* infections.

This test could provide considerable clinical utility in high-risk populations, particularly in hematological malignancies, though more data is needed for utilization in clinical practice.

Volatile Organic Compounds

Filamentous fungi can produce a vast array of volatile secondary metabolites. Distinctive volatile metabolites of *A. fumigatus* in vitro include camphene, α- and β-pirene, limonene, and the sesquiterpene compounds α- and β-bergamotene. The volatile metabolite profile of *A. fumigatus* in the breath samples from patients with probable and proven IA can be characterized in vitro using thermal desorption-gas chromatography/mass spectrometry. The detection of α-trans-bergamotene, β-trans-bergamotene, β-vatirene-like sesquiterpene, or trans-geranylacetone using this method identified IA patients with 94% sensitivity and 93% specificity [55]. All these studies were done in heterogeneous cohorts of immunocompromised patients, including patients with hematological malignancies, SOT, and HSCT recipients. While these assays all appear promising, they nevertheless require more study to define performance parameters.

MicroRNA

MicroRNA are a new set of biomarkers currently under examination as potential indicators for the evaluation of fungal exposure, particularly following sub-chronic inhalation exposure to *A. fumigatus*. A 2016 study on mice highlighted the influence of conidia germination on gene expression and the subsequent control it exerted on the ensuing pulmonary immune response. Mice exposed to viable *A. fumigatus* conidia showed increased *Clec*7a, IL-13, and IL-33 expression [56].

Radiological Diagnosis

Radiologic imaging in IA is critical, as it is used to identify the type of lesion, along with the number, the size, and the site of infections. A chest CT scan should be performed in any patient with clinical suspicion of invasive pulmonary aspergillosis (IPA) [19].

The typical findings associated with IA include nodules, consolidative lesions, and wedge-shaped infarcts. In HSCT recipients, a "halo sign" can be observed in the pretransplant period, when the patient is neutropenic. Defined as a pulmonary nodule (>1 cm in diameter) surrounded by a perimeter of ground-glass opacity reflecting hemorrhage, the "halo sign" is transient and is seen only in the first 10 days of angio-invasion before disappearing. The initiation of antifungal treatment in patients with "halo sign" has been associated with improved patient outcomes for early stages, compared to later stages of disease [44].

After engraftment and neutrophil recovery, it is possible to appreciate the appearance of an "air crescent sign" which is representative of nodular opacity, with retraction of infarcted lung tissue, along with crescentic and circular cavitation. A nodule or consolidation, and apparent aspergillomas, may develop at previous sites of pulmonary infiltrates [57]. SOT recipients are more likely than neutropenic patients to show peribronchial consolidation (31% vs. 7%) and ground-glass opacity (38% vs. 7%) and less likely to show halo sign (8% vs. 56%) and air-crescent signs (0% vs. 22%) [58].

Positron Emission Tomography (PET)

For in vivo detection of *Aspergillus* lung infections in humans, radiolabeled *Aspergillus*-specific monoclonal antibodies and iron siderophores hold enormous potential for clinical diagnosis. Positron emission tomography (PET) with [^{18}F] fluorodeoxyglucose ([^{18}F]FDG) has also been studied for the diagnosis of invasive fungal disease. However, a 2018 study demonstrated a lack of specificity with this

method, as the uptake of [^{18}F]FDG during *Aspergillus* lung infection could not be distinguished from that seen during sterile inflammation, lung cancer, or bacterial lung infections [59].

Recent studies have demonstrated the enormous potential of antibody-guided PET/MRI (immunoPET/MRI) using the humanized antibody hJF5. This antibody binds to the antigenic determinant β1,5-galactofuranose, which is present in a diagnostic antigen released by the pathogen during invasive growth in the lung. This humanized antibody is currently undergoing toxicity testing prior to clinical trials, which we will use this *Aspergillus*-specific PET tracer to allow immunoPET/MR imaging of IPA in humans [59].

Diagnostic Algorithm

A proposed algorithm for the diagnosis of IA in HSCT is included in Fig. 3, which includes newer tests, such as *Aspergillus* PCR BAL, and the lateral flow device. The use of the proposed algorithm for diagnosis in SOT recipients is shown in Fig. 4.

Treatment of Invasive Aspergillosis

Early treatment with the right agent appears critical for HSCT and SOT patients with IA. There are three classes of antifungal agents available for the treatment of IA: azoles, echinocandins, and polyenes (Table 4). Currently, voriconazole is the drug of choice for the treatment of IA [19, 25].

Voriconazole

A triazole antifungal that inhibits fungal ergosterol biosynthesis, voriconazole is formulated in both oral and intravenous preparations and is metabolized by CYP2C19>>CYP2C9>CYP3A4 to an inactive metabolite (*N*-oxide voriconazole). Voriconazole is hepatically metabolized, with only 5% of the drug appearing unchanged in the urine. There are many factors that can affect the pharmacokinetics of voriconazole, including age of the patient, patients with single-nucleotide polymorphisms contributing to slow metabolism (high frequency in non-Indian Asian population), liver function, CYP2C19- and CYP3A-interacting medications, diet, antacids, proton pump inhibitors, patient weight, as well as the drug dose and formulation itself [19].

The most common adverse event seen with this medication is visual disturbances, principally photopsia that is self-limited, reversible, and not associated with the drug levels. The presentation of this abnormality typically begins within 30 min of administration of the medication and lasts no longer than 30 min [60]. Hepatotoxicity is common in all the azole drugs, but severe hepatotoxicity is uncommon, and this is often related to the serum voriconazole level.

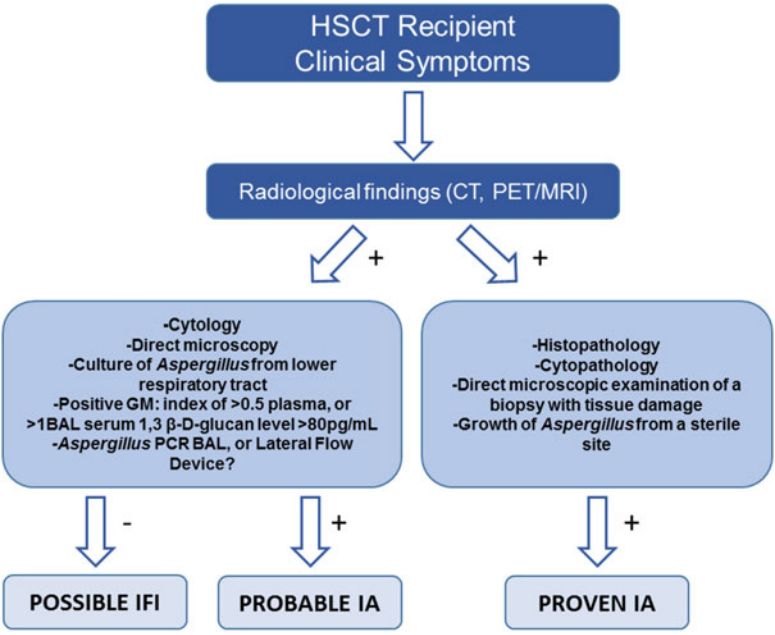

Fig. 3 Diagnostic algorithm of possible invasive fungal infection in HSCT recipients

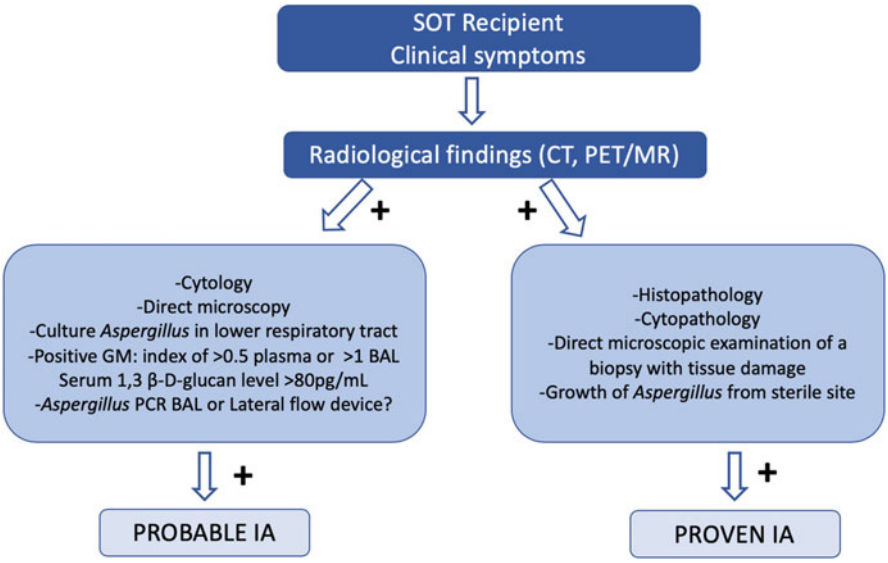

Fig. 4 Diagnostic algorithm for IA in SOT recipients

Table 4 Comparison of the different antifungal therapies for invasive aspergillosis in SOT and HSCT recipients

Drug	Evidence of efficacy	Adverse events	Monitoring
Voriconazole [60–63]	Improved survival compared to amphotericin B (70.8% vs. 57%, respectively) (HR 0.59; 95% CI, 0.40–0.88) [64]	Transient visual disturbances (blurriness, color changes, enhanced vision) seen in 20.6% of patients, <1% require discontinuation. Hepatotoxicity: increased transaminases 13%, 4–8% require discontinuation Rash 6% Hallucination (4.3%) QT prolongation Encephalopathy (levels >5.5mcg/mL) requires discontinuation Enhanced risk of squamous cell carcinoma	Monitor serum level trough concentrations 5–7 days into therapy Target voriconazole troughs >1mcg/mL to <5.5 mcg/mL Once therapeutic, recheck troughs every 1–2 weeks In unstable patients, and when there is uncertainty about concentrations, repeat every 3–5 days. Monitor hepatic function, CNI, and mTOR inhibitor agent levels Monitor cyclosporine levels
Isavuconazole [65, 66]	Non-inferior to voriconazole in invasive mold infections in HSCT and hematologic malignancy. All-cause mortality through day 42 as the primary endpoint (19% vs. 20%, respectively) [67]	Shorten QTc interval Headache 17% Nausea, vomiting, diarrhea (22–26%) LFTs elevations 16% Dyspnea and cough Infusion-related: hypotension, dyspnea, chills (6%)	Evaluate hepatic function prior and during therapy CNI and mTOR inhibitor agent levels Monitor cyclosporine levels Currently, there are no recommendations to monitor drug levels
Posaconazole [19, 68]	Studied in IA and other mycoses refractory or intolerant to conventional antifungal therapy. Overall success 42% for posaconazole and 26% for external control cases collected retrospectively	Generally, well tolerated Nausea, vomiting, diarrhea, abdominal pain Increased liver enzymes Hyperbilirubinemia Adrenal insufficiency	Evaluate hepatic function prior and during therapy CNI and mTOR inhibitor agent levels Monitor cyclosporine levels Currently, there are no recommendations to monitor drug levels
Caspofungin [69, 70]	Previously received amphotericin B, and a favorable response to caspofungin therapy was observed in 45% of	Generally, well tolerated LFT/bilirubin elevations Elevated ALP	Evaluate hepatic function at baseline and every 1–2 weeks during therapy

(continued)

Table 4 (continued)

Drug	Evidence of efficacy	Adverse events	Monitoring
	patients compared to 16% among historical controls, included patients that were HSCT recipients (25%) and SOT recipients (11%)	Histamine-mediated symptoms: rash, facial swelling, and pruritus that are infusion related	Monitor CNI inhibitor agent levels
Anidulafungin [71]	Studied as combination therapy with voriconazole vs. voriconazole monotherapy patients with HM and HSCT recipients. Trend toward decreased mortality at 6 weeks 19.3% vs. 27.5%, respectively (−8.2 percentage points [95% CI, −19.0 to 1.5]; $p = 0.087$)	Generally, well tolerated Histamine-mediated symptoms: rash, facial swelling, and pruritus that are infusion related Phlebitis Fever Diarrhea	Not a substrate, inducer, or inhibitor of CYP450 isoenzymes No significant drug-drug interactions with voriconazole, tacrolimus, ambisome, and cyclosporine No significant increase in LFTs observed
Micafungin [72]	Used as monotherapy for primary treatment, micafungin had a response rate of 50% and 40.9% as salvage therapy	Generally, well tolerated Histamine-mediated symptoms: rash, facial swelling, pruritus, and vasodilation Local phlebitis Fever and chills LFTs elevation	Monitor liver function Monitor sirolimus levels
Amphotericin [19, 64, 73]	**D-AmB**: Voriconazole showed improved survival compared to D-AmB (70.8% vs. 57%, respectively) HR 0.59; 95% CI, 0.40–0.88) [64] **L-AmB**: L-AmB was given to patients with lack of response to prior antifungal therapy; 25% patients were HSCT and 27% SOT; overall, 65% had a favorable clinical response, 44% cured or improved, and 21% stabilized [64]	**D-AmB**: Nephrotoxicity Electrolyte abnormalities Fever, chills and hypotension Anemia Phlebitis **L-AmB**: Infusion reactions Creatinine elevation Anemia Electrolyte abnormalities Transaminase elevations Increased bilirubin	Monitor renal and liver function Monitor serum electrolytes Avoid its use with other nephrotoxic agents

Intravenous voriconazole is administered within a vehicle called cyclodextrin; the accumulation of this substance has been associated with renal toxicity in animal models although this has not been proven in humans [61]. Therefore, oral voriconazole is recommended by the manufacturer in patients with CrCl <50 mL/min. However, in a clinical study, the IV formulation was used with renal dysfunction without any untoward effects [74]. In cases where voriconazole has to be used intravenously, kidney function should be monitored. Administration of voriconazole through an NG tube may require stopping the feed 2 h prior and 2 h after the administration of voriconazole to maximize absorption.

Voriconazole remains the drug of choice in IA [19]. In a randomized controlled trial of 144 patients (29.9% of which were HSCT recipients and 6.2% SOT recipients), voriconazole was compared to amphotericin B in IA. Voriconazole had a successful treatment outcome after 12 weeks of treatment of 52.8% versus 31.6%, respectively, and was associated with improved survival (70.8% in the voriconazole group and 57.9% in the amphotericin B group) [64].

Isavuconazole

Isavuconazonium sulfate is an advanced triazole compound, which is the prodrug of the active isavuconazole. This drug is a potent inhibitor of ergosterol biosynthesis and causes fungal membrane disruption by targeting enzyme 14-α-demethylase. This antifungal is available in oral and intravenous preparations. Isavuconazole is considered a sensitive substrate and a moderate inhibitor of CYP3A4, and accordingly, drug interactions with this antifungal should always be a consideration.

This water-soluble molecule does not need the excipient β-cyclodextrin for intravenous administration and has excellent bioavailability in its oral administration (98%) without any clinically relevant food effects. Isavuconazole is a broad-spectrum antifungal, with FDA approval for treatment of IA and invasive mucormycosis [65].

The efficacy and safety of isavuconazole in the primary treatment of invasive mold disease caused by *Aspergillus* and other filamentous fungi were assessed in a randomized controlled trial that included patients post HSCT or with active malignant diseases. Isavuconazole was found to be non-inferior to voriconazole, as determined using all-cause mortality through day 42 as the primary endpoint (19% vs. 20%, respectively) [66]. It demonstrated fewer drug-related effects than voriconazole (14% vs. 23%, respectively, including less hepatobiliary disorders and eye and skin disorders) [67]. Currently, data concerning the efficacy of isavuconazole in SOT recipients is limited. Isavuconazole can be used in lieu of voriconazole in the treatment of invasive aspergillosis.

Other Azoles

Itraconazole is not a first-line agent for the treatment of IA, as it is an inhibitor and substrate for CYP3A4 and can have serious drug-drug interactions with other chemotherapeutic agents (e.g., cyclophosphamide and vincristine). Additionally,

it has significant pharmacokinetic variation in the absorption and distribution of the drug between patients, due to the needs of an acidic environment for absorption, poor bioavailability, and significant drug interactions. Itraconazole has been shown to have a negative inotropic effect, with reports of congestive heart failure (CHF) associated with its use [75, 76]. The mechanism of itraconazole-induced CHF and its reversibility is unknown. In the presence of CHF, itraconazole should be used with caution. Itraconazole should be reserved for patients with less severe disease as an alternative agent [19].

Posaconazole is an extended-spectrum triazole with in vitro and in vivo activity against *Aspergillus* spp.

Although structurally similar to itraconazole, it has mainly been studied as prophylaxis for IA.

The efficacy of posaconazole as a monotherapy agent for IA has only been assessed in an open-label study of patients with IA and other mycoses, who were refractory or intolerant to conventional antifungal therapy. Posaconazole was compared with data from external control cases, collected retrospectively as a reference group. The overall success was 42% for posaconazole recipients and 26% for control subjects [67]. Posaconazole could be an effective agent for the treatment of IA, given its spectrum of activity and treatment success observed in this uncontrolled trial. However, more studies assessing the efficacy of this drug are needed. The use of posaconazole in primary therapy is further influenced by the fact that steady-state levels of the drug may take 1 week of therapy to be achieved.

Azole antifungal drugs exhibit a wide range and variety of drug-drug interactions, the most common of which are outlined in Table 5.

Echinocandins

Echinocandins are a group of antifungals that inhibit (1,3)-β-D-glucan, an integral component of the fungal cell wall. There are three echinocandins currently available in the market: caspofungin, anidulafungin, and micafungin. These agents have activity against *Aspergillus* spp., and they are considered to have equivalent efficacy. However, caspofungin is the only agent in this class that has been approved by the FDA for the treatment of IA in patients who are refractory to or intolerant of other antifungal therapies [69]. Echinocandins are effective as salvage therapy for IA; primary therapy with an echinocandin is not recommended [49].

The efficacy of caspofungin was assessed in a trial that included patients with IA who were refractory to or intolerant of amphotericin B lipid formulation or triazole therapy. They included patients that were HSCT recipients (25%) and SOT recipients (11%). Almost all of the patients previously received amphotericin B, and a favorable response to caspofungin therapy was observed in 45% of patients compared to 16% among historical controls [70].

Anidulafungin has not been studied as primary or salvage therapy for IA. So far, it has only been reviewed in combination therapy with voriconazole, in patient populations that included hematologic malignancies and HSCT recipients. The

Table 5 Interaction of azoles with other drugs [61, 65, 68, 77]

Azole	Interacting drug	Effect of interaction	Considerations
Voriconazole Itraconazole Posaconazole Isavuconazole	Alprazolam Midazolam	Alprazolam and midazolam serum levels concentrations may be increased	Consider lorazepam, oxazepam, temazepam
Voriconazole Isavuconazole	Atazanavir/ ritonavir Darunavir/ ritonavir Lopinavir/ ritonavir Nevirapine	Voriconazole AUC may be decreased	Follow voriconazole through level
Posaconazole	Amiodarone	Amiodarone serum concentrations may be increased.	Avoid co-administration
Isavuconazole	Lopinavir/ ritonavir	Drug levels of isavuconazole increase 96%	Consider avoiding the combination
Voriconazole Itraconazole	Clopidogrel	May decrease the efficacy of clopidogrel	Avoid co-administration
Voriconazole	Cyclosporine	Cyclosporine AUC increased by 70%	Reduce cyclosporine dose 50% and follow levels
Isavuconazole Posaconazole Itraconazole	Cyclosporine	Cyclosporine serum concentration might be increased	Monitor cyclosporine levels and adjust
Isavuconazole	Mycophenolate mofetil	Increased MMF exposure	Monitor possible MMF toxicities
Voriconazole	Omeprazole	Omeprazole AUC increased by 400% and voriconazole AUC increases 40%	Reduce omeprazole dose by 50% and follow voriconazole trough level
Posaconazole Itraconazole	Omeprazole Pantoprazole	Liquid formulation posaconazole: will decrease posaconazole levels, tablet not affected Itraconazole absorption decreased	Avoid co-administration with liquid azole formulations
Voriconazole Posaconazole	Rifabutin Rifampin	Rifabutin levels might be increased Voriconazole and posaconazole levels might be decreased	Avoid co-administration
Voriconazole	Simvastatin	Simvastatin levels might be increased	Consider pravastatin, atorvastatin or rosuvastatin
Isavuconazole Posaconazole	Atorvastatin	May increase atorvastatin levels	Use caution, monitor LFTs and CK.
Voriconazole Isavuconazole Itraconazole	Sirolimus	Sirolimus serum concentrations may be increased	Monitor sirolimus levels and adjust

(continued)

Table 5 (continued)

Azole	Interacting drug	Effect of interaction	Considerations
Voriconazole Isavuconazole Itraconazole	Tacrolimus	Tacrolimus AUC increased by 300% with voriconazole	Reduce tacrolimus dose to 1/3 of original dose and follow levels.
Voriconazole Posaconazole Itraconazole	Warfarin	Anticoagulation may be increased	Monitor INR

use of combination therapy was not superior to monotherapy with voriconazole. In post hoc analysis, combination of voriconazole and anidulafungin resulted in lower mortality rate among patients with positive galactomannan in the BAL [71]. Anidulafungin is an echinocandin that is not a substrate, inducer, or inhibitor of CYP450 isoenzymes and therefore has no significant drug-drug interactions. In addition, it is eliminated by nonenzymatic degradation and does not require dosage adjustments in patients with renal or hepatic disease [68].

Micafungin has been evaluated in patients with proven or probable IA, including patients with hematologic malignancies and HSCT and SOT recipients. Patients treated with micafungin as monotherapy had a response rate of 50% as primary treatment and 40.9% as salvage therapy [72].

Polyenes

Polyenes bind to ergosterol and disrupt the fungal cell membrane, resulting in leakage of intracellular contents. A notable example of this class is amphotericin B, of which there are currently three formulations: amphotericin B deoxycholate (D-AmB), liposomal amphotericin B, and amphotericin B lipid complex (L-AmB). Amphotericin B deoxycholate is no longer recommended as a therapy due to nephrotoxicity. The lipid formulations are less nephrotoxic and are preferred, even though they have not shown to have better outcomes compared to conventional amphotericin B [19]. Either option is appropriate for initial and salvage therapy of IA.

New Antifungals Currently Under Investigation

Rezafungin (formerly CD101) is an investigational echinocandin under development for the treatment and prevention of IFIs. With a half-life in humans of 130 h, it allows once-weekly treatment and possesses effective in vitro activity and in vivo efficacy against some *Aspergillus* species [78]. Rezafungin has demonstrated potent in vitro activity against *Aspergillus* spp., including azole-resistant *A. fumigatus* isolates, similar to caspofungin and micafungin. However, rezafungin has more potent activity against *A. calidoustus*, as compared to caspofungin [78]. Further studies are warranted to evaluate the in vivo efficacy and its role in the treatment of IA in HSCT and SOT.

Ibrexafungerp (formerly SCY-078) is the first representative of a novel class of structurally distinct glucan synthase inhibitors, "triterpenoids." While currently in phase II oral study for IA, preclinical studies demonstrated potent in vitro and in vivo activity against wild-type and azole-resistant strains of *Aspergillus* and indicated synergistic activity with other antifungal agents in vitro against *Aspergillus fumigatus* [79].

There are other antifungal compounds with novel targets in development which are currently unapproved compounds with novel structures. APX001 is a new compound that has the molecular target of glycosyl phosphatidylin-ositol synthesis (prevents attachment of mannose proteins to the outer cell wall) with potential broad-spectrum potency against *Mucorales*, *Candida*, *Aspergillus*, *Fusarium*, and *Scedosporium* species [77]. F901318 is a new compound that has the molecular target of dihydroorotate dehydrogenase and has potential activity against *Aspergillus* and *Scedosporium* species, currently undergoing phase II testing [77, 80].

Olorofim (F2G) is another drug that is in phase II development as an oral or intravenous agent for the treatment of mold infections, particularly *Aspergillus* and *Scedosporium*. It is a potent inhibitor of dihydroorotate dehydrogenase, an enzyme involved in the organisms' pyrimidine biosynthesis [80]. The work on host immune cell-targeted approaches is currently in its infancy. A detailed review of new antifungal agents currently in the pipeline was published by Perfect in 2017 [81].

In addition, there are other compounds that could be repurposed such as cyclosporine, tacrolimus, and rapamycin which are mTOR or calcineurin inhibitors already approved for posttransplant immunosuppression and have showed broad antifungal spectrum and could be used alongside existing antifungals [77].

Combination Therapy

Combination therapy in the treatment of IA is not routinely recommended as primary treatment. However, it is commonly used in patients who have not responded to their initial regimen of treatment. Most common combination therapies include voriconazole, as well as an echinocandin.

Voriconazole plus Echinocandin Therapy

The efficacy of voriconazole plus anidulafungin was compared with voriconazole monotherapy for the treatment of IA, in patients with hematological malignancy or HSCT with suspected or documented IA. At 6 weeks of treatment, the combination therapy showed decreased mortality (19.3%) compared to monotherapy (27.5%) (−8.2 percentage points [95% CI, −19.0 to 1.5]; $p = 0.087$) with a similar safety profile in both groups [71].

In a retrospective analysis of HSCT recipients with probable or proven aspergillosis, there was no difference in outcomes in patients who were treated with voriconazole and caspofungin as primary therapy, compared with patients treated with voriconazole as monotherapy [82].

In the SOT population, the combination of voriconazole and caspofungin was assessed as primary therapy for proven or probable cases of IA, compared to a historical control group who received lipid formulation of AmB as primary therapy. The survival rate at 90 days was 67.5% in the combination therapy group, compared to 51% in the control group (HR 0.58, 95% CI, 0.30–1.14, $p = 0.117$). Combination therapy was independently associated with reduced mortality in patients with renal failure and in those with *A. fumigatus* infection [83].

Liposomal Amphotericin B plus Echinocandin Therapy

The studies evaluating this combination of antifungals did not compare voriconazole-based regimens. It has only been evaluated in patients with hematological malignancies, not in HSCT or SOT populations.

Duration of Therapy

The duration of therapy for IA has not yet been established. It is recommended to be continued for a minimum of 12 weeks, depending on the degree and duration of immunosuppression, site of infection, and evidence of disease improvement [19].

Susceptibility Testing

The emerging resistance of antifungal agents is a developing global issue. Recently "AsperGenius" (PathoNostics, Maastricht, the Netherlands) a commercial PCR assay became available, which includes markers specifically for the detection of TR_{46}/Y121F/T289A and TR_{34}/L98H.

Susceptibility testing is of particular relevance in patients suspected to have an azole-resistant isolate, who are unresponsive to antifungal agents, or for epidemiological purposes [29]. Many species of *Aspergillus fumigatus* complex have been associated with high mixed inhibitory concentration (MIC) for amphotericin B (Table 6), and susceptibility testing should be considered. Such isolates should be referred to reference laboratories for MIC testing. The European Committee on Antimicrobial Susceptibility Testing (EUCAST) or the Clinical and Laboratory Standards Institute (CLSI) criteria can be used for determination of routine MICs to guide clinical management [19].

Table 6 Recommended antifungal regimens in cases of intrinsic resistance [17, 19, 29, 68]

Species	Susceptibilities	Intervention
Aspergillus fumigatus complex *A. lentus* *A. udagawae* *A. viridinutans* *A. thermomutatus* *A. novofumigatus* *A. hiratsukae* *A. pseudofischeri*	Emerging resistance has been reported. Consider local epidemiology of azole resistance	Recommend testing for susceptibility
Aspergillus flavus complex *A. alliaceus*	Partial resistance to amphotericin B. *A. alliaceus* higher MIC for AmB. Less activity of anidulafungin	Recommend testing for susceptibility Consider voriconazole
Aspergillus terreus	Resistant to amphotericin B More susceptible to newer azoles	Recommend using voriconazole, isavuconazole, posaconazole, or itraconazole
Aspergillus calidoustus	Resistant to azoles	Recommend lipid formulations of amphotericin B
Aspergillus tubingensis (*A. niger* complex)	Higher azole MIC common, but no data on clinical impact	Recommend options other than azole monotherapy
Aspergillus niger complex	Isavuconazole, posaconazole, and voriconazole MIC in general one dilution higher compared with *A. fumigatus*; itraconazole MIC in general two steps higher; limited clinical data	Recommend other than itraconazole and isavuconazole [29]
Aspergillus nidulans *Aspergillus tanneri*	May be resistant to amphotericin B	Recommend using voriconazole

Prevention

Given the high frequency of IA, prevention strategies are of great relevance as they increase the clinical success and outcomes of transplant by decreasing risk of IA. Universal prophylaxis and preemptive therapy are the main approaches for prevention. However, these two strategies have differing evidence for efficacy in

HSCT recipients and SOT recipients. Table 7 shows the current considerations of antifungals in IA prophylaxis.

"Universal prophylaxis" involves administration of antifungal therapy – usually for a prolonged period – to all transplant recipients, irrespective of their risk of IA. "Target prophylaxis" involves initiating antifungal therapy based on risk factors. Preemptive therapy is instituted based on the results of culture or biomarkers such as GM and/or β-D-Glucan assays.

HSCT Recipients

The current evidence suggests that the patient populations that benefit from antifungal prophylaxis are patients who have prolonged neutropenia (defined as >7 days of neutropenia) and have a high risk of IA [29] and also patients who are allogenic HSCT recipients with GVHD and have a high risk of IA. Posaconazole was more effective than fluconazole in HSCT recipients with GVHD (OR 0.31, 95% CI 0.13 to 0.75) [88]. Isavuconazole was previously studied in a retrospective study as prophylaxis in HSCT recipients, compared with other azole prophylaxis (voriconazole and posaconazole), isavuconazole showed no difference in cumulative indicence of breakthrough IFIs [84]. Currently, isavuconazole prophylaxis is under investigation in HSCT recipients.

SOT Recipients

While the average incidence of IA is lower in SOT recipients than in HSCT recipients, SOT recipients are treated with prolonged high doses of glucocorticoids or other immunosuppressants, some may be critically ill, and all have an end-stage organ disease. Furthermore, drug-drug interactions and toxicities are more likely to occur in SOT recipients. Accordingly, physicians need to balance the risk and benefit of giving antifungal prophylaxis to this patient population.

In liver transplant recipients, universal prophylaxis against IA is not routinely recommended, and instead targeted prophylaxis is suggested in patients with a higher risk of IA (Table 1) [19]. Targeted prophylaxis in liver transplant was studied in a retrospective cohort, showing that is feasible and safe. It prevented IFIs and reduced the number of patients exposed to antifungals [85]. At this moment, voriconazole and echinocandins have been studied as prophylaxis for IA in liver transplants; however, there is no conclusive evidence that one antifungal is superior in this patient population.

In heart transplant recipients, there is insufficient data to routinely recommend anti-*Aspergillus* prophylaxis, as a majority of the data on prophylactic strategies in heart transplant recipients is reported from single-center studies using targeted prophylaxis in patients with risk factors for IA, using itraconazole, voriconazole, or echinocandins.

Table 7 Recommended anti-*Aspergillus* prophylactic strategies in HSCT and SOT recipients [19, 49, 84–87]

Type of transplant	Prophylaxis strategy	Prophylaxis	Duration
HSCT recipients	Consider prophylaxis in patients with: Prolonged neutropenia Allogenic HSCT with GvHD	Posaconazole Voriconazole	3–4 months [82, 88]
Liver transplant recipients	Consider targeted prophylaxis in patients with any of the following risk factors: Re-transplantation or reoperation Rejection or change immunosuppression Acute kidney injury Renal replacement therapy Fulminant hepatic failure MELD >30 CMV infection	Anidulafungin Caspofungin Micafungin Voriconazole	10–21 days [85]
Heart transplant	Consider targeted prophylaxis *Aspergillus* colonization Reoperation Posttransplant hemodialysis Rejection or change immunosuppression Existence of an episode of IA in any patient within the heart transplant program, 2 months before or after transplant. Pretransplant diagnosis of COPD High duration of steroids CMV infection	Voriconazole Itraconazole Echinocandins Nebulized L-Amb	3 months [87]
Lung transplant recipients	1. Universal prophylaxis 2. Targeted prophylaxis in patients with any of the following risk factors: Single lung transplant Early airway ischemia Rejection or change immunosuppression Pretransplant colonization Induction with alemtuzumab or anti-thymocyte globulin Positive intraoperative *Aspergillus* culture in CF patient Hypogammaglobulinemia CMV infection And that will be followed with BAL cultures and BAL galactomannan	Nebulized L-Amb Voriconazole Posaconazole Isavuconazole	Universal and targeted prophylaxis usually 4–6 months [86, 87]

In lung transplant recipients, the optimal IA prevention strategy has not been defined. Although universal prophylaxis is a common practice in many transplant centers, several studies have used a risk stratification strategy for the use of antifungal prophylaxis in the first year following lung transplant. Currently, target therapy can be employed in centers which are able to follow their patients with BAL culture and BAL GM in patients who have increased risk factors for IA. In a systematic review and meta-analysis, 8.1% of patients receiving universal prophylaxis and 14.3% in the no-prophylaxis arm developed IA. No reduction of IA or *Aspergillus* colonization was seen with universal anti-*Aspergillus* prophylaxis [86]. Currently there is no evidence of the superiority of one antifungal therapy over another.

Conclusions

IA continues to be an important cause of life-threatening infection in HSCT and SOT recipients. Optimal management of this infection involves early diagnosis and early initiation of antifungal therapy. The diagnosis of IA in HSCT and SOT recipients is dependent on a combination of clinical and radiological findings with noninvasive tests such as serum GM and β-D-glucan and also invasive tests such as BAL specimens for fungal staining, culture, BAL GM, and tissue biopsies.

Currently, voriconazole is recommended as the primary therapy for IA. However, there are alternative regimens available, and the decision of which agent to choose depends on organ dysfunction, toxicities, and tolerability. The duration of therapy depends upon the location of the infection, the immunosuppression that the patient is receiving, and the response to therapy. The most effective approach for IA antifungal prophylaxis in SOT and HSCT recipients has not yet been determined and should be selected depending on the patients' risk factors and the logistics of each institution. While the diagnosis and management of IA have advanced significantly over the last few years, there are still many unanswered and unresolved questions.

Key Points

- Invasive aspergillosis has a higher incidence of infection in patients undergoing hematopoietic stem cell transplantation or solid organ transplantation.
- The diagnosis of invasive aspergillosis is based on a combination of host factors and imaging and microbiological findings.
- Improved survival has been noted with early diagnosis and early initiation of antifungal therapy.
- *Proven* infection is established histopathology – showing dichotomously branching septate hyphae, associated tissue damage, and growth of *Aspergillus* species from a culture taken from a normally sterile site.
- Biomarkers such as galactomannan, β-D-glucan, and DNA detection via PCR are useful for establishing the diagnosis of *Probable IA*.
- Voriconazole is recommended for primary therapy to treat all forms of IA.

- Isavuconazole and lipid formulations of amphotericin B (preferably L-AmB) can be considered alternative agents.
- Combination therapy is not recommended for routine use in HSCT and SOT populations; it can be considered in select cases such as disseminated or refractory disease.
- Duration of treatment should be guided by clinical response but is usually administered for a minimum of 12 weeks if it is well tolerated.

Introduction

Patients receiving allogeneic hematopoietic stem cell transplantation (HSCT) or solid organ transplantation (SOT), who may also be receiving intensive chemotherapy, are at increased risk of invasive fungal diseases (IFDs). Although the commonest IFDs are invasive aspergillosis and candidiasis, mucormycosis, or infections caused by Mucorales fungi, is the next most common filamentous fungal infection, and its incidence may be rising in these patient groups [1–4]. It is typically rapidly progressive in nature and requires urgent intervention to optimize outcomes [5]. Hence awareness of this condition and of its clinical and species epidemiology and disease patterns is essential. Knowledge of current as well as newer diagnostic and management modalities is also central to informing clinical practice.

This chapter will discuss the epidemiology of mucormycosis including patterns of disease in transplant patients; major pathogenic attributes of the Mucorales, particularly those that may impact developing therapies; and modern diagnostic approaches to these infections. We also focus on antifungal therapy and other management strategies including new therapies for these problematic infections. An appreciation of the pathogens that cause mucormycosis is integral to understanding these infections.

Mucorales: The Pathogens

The term mucormycosis describes infections caused by fungi of the order Mucorales. The term "zygomycosis" which previously was used interchangeably with "mucormycosis" refers also to infections caused by the order *Entomophthorales* and other fungi and is now obsolete for what we now recognize to be Mucorales infections [6, 7]. Across all patient groups including in transplant recipients, the most frequent pathogens are *Rhizopus* spp., *Mucor* spp., and *Lichtheimia* spp., (formerly of the genera *Absidia*), followed by *Rhizomucor* spp., *Cunninghamella* spp., *Apophysomyces* spp., and *Saksenaea* spp. [8, 9]. As there is significant geographic variation, the need to understand local epidemiology is underscored [2, 4, 9]. As such, species identification is essential for epidemiological studies, delineation of disease associations, and investigation of outbreaks of infection. Table 1 summarizes the main genera and species of Mucorales encountered in transplant patients. A number of recent publications detail the taxonomic descriptions of the Mucorales [6, 10].

Table 1 Causative agents of mucormycosis: major genera and species [6, 7, 10]

Genus	Major representative species or species complex
Rhizopus[a]	*R. microsporus*, *R. stolonifer, R. arrhizus* (or *R. oryzae*), *R. delemar* (*R. arrhizus* var. *delemar*)
Mucor	*M. circinelloides* (includes *M. circinelloides f. circinelloides*, *M. circinelloides f. lusitanicus*), *M. irregularis*, *M. indicus*, *M. ellipsoideus*
Lichtheimia	*L. corymbifera*, *L. ornata*, *L. ramosa*, *L. hyalospora*, *L. hylospora*
Rhizomucor	*R. pusillus*
Cunninghamella	*C. bertholletiae*, *C. echinulate*
Apophysomyces	*A. elegans*, *A. trapeziformis*, *A. variabilis*
Saksenaea	*S. vasiformis*, *S. erythrospora*, *S. oblongispora*

[a]The fungal species database Index Fungorum identifies 11 *Rhizopus* species (http://www.indexfungorum.org). However, most clinical *Rhizopus* isolates in culture collections belong to the four species/species complexes listed in Table 1: *R. microsporus*, *R. stolonifer*, *R. arrhizus* (or *R. oryzae*), and *R. delemar* (or *R. arrhizus* var. *delemar*)

Epidemiology

Mucormycosis is most commonly contracted from inhaled sporangiospores which are ubiquitous in air from decaying organic substances and soil in the environment and thus most often infects the airways, lungs, or sinuses [11]. Spores may peak in air after high temperatures or with construction work [12]. Infection may also be cutaneous through inoculation, gastrointestinal (GI) through ingestion, or disseminated affecting any organ including the lungs, heart, brain, liver, esophagus, GI tract, retroperitoneum, kidney, spleen, thyroid, and skin [11, 13].

The US TRANSNET surveillance study performed in 21 transplant centers between 2001 and 2006 revealed a 12-month cumulative incidence of 0.29% in HSCT and 0.07% in SOT, comprising 2% of all IFDs in this population [3]. In this study, the incidence of mucormycosis in HSCT recipients increased over time [3], and this trend was also noted in renal transplant recipients [14]. Both disease prevalence and species epidemiology vary with geography [3].

Causative Pathogens

A recent review identified that in general *Rhizopus* species (213/447 cases, 48%), in particular *Rhizopus arrhizus* (previously *R. oryzae*), are the most common pathogen, followed by *Mucor* spp. (63/447, 14%), consistent with the species distribution noted in earlier large studies including those in transplant patients [3, 15, 16]. Causative Mucorales vary by geographical region. For example, *Apophysomyces* infections are very uncommon in Europe or Africa, while conversely, those caused by *Lichtheimia* have been largely reported from Europe [summarized in 8]. *Saksenaea erythrospora* infections have been documented in North and South America, and the distribution of *Saksenaea vasiformis* infections appears to be

restricted to India, Spain, Australia, and the USA [8]. These epidemiological variations extend to transplant-associated infection.

Risk Factors

In SOT patients, classical risk factors determined by a case-control study were renal failure, diabetes mellitus with or without ketoacidosis, and prior voriconazole and/or caspofungin use, while the calcineurin inhibitor tacrolimus was associated with a lower risk of mucormycosis [16]. Others have also reported an association between malnutrition and mucormycosis [11]. In the US TRANSNET study, 48.1% patients experienced organ rejection in the 30 days before mucormycosis occurred [3]. Almyroudis et al. found that 40% of reported patients in a review of published mucormycosis cases in SOT had increased immunosuppression to prevent rejection within 1 month before onset of mucormycosis [13]. Additional predisposing factors identified in HSCT patients include corticosteroid use, neutropenia, lymphopenia, splenectomy, iron overload, and acute or chronic graft-versus-host disease [3, 11]. In case series not limited to transplant recipients, deferoxamine [15] and minor or major trauma [2, 8, 11, 15] are also associated with mucormycosis. Notably breakthrough cases of mucormycosis have been seen in HSCT and SOT patients receiving either isavuconazole or posaconazole oral solution prophylaxis [17, 18]. Recent studies have found genetic associations increasing risk for IFD focusing on polymorphisms of the interleukin-10 promoter, Toll-like receptor, long pentraxin 3, plasminogen, or mannose-binding lectin genes [12].

Health-care-associated outbreaks of mucormycosis have increasingly been recognized in transplant recipients due to contaminated equipment, intravenous catheters, or air. An outbreak of GI infections caused by *Rhizopus microsporus* affecting hematology patients including four HSCT recipients was linked to allopurinol tablets and packaged food [19]. Other outbreaks, most commonly affecting SOT recipients, have been associated with adhesive bandages, wooden tongue depressors, ostomy bags, water circuitry damage, building construction [20], and locating SOT patients in negative pressure rooms [21]. Contamination of hospital linen related to inadequate washing, drying, or storage has also been identified as a source for pulmonary or cutaneous nosocomial mucormycosis, often affecting transplant recipients [22, 23]. These outbreaks have isolated genetically identical *R. delemar* or *R. microsporus* from linens and affected cases [22, 23]. Mucormycosis in intensive care unit (ICU) patients including transplant recipients was linked to *R. microsporus* and *R. oryzae* contaminated linen carts [24]. A survey of linens in 15 transplant and cancer centers in the USA revealed Mucorales were recovered from $>10\%$ of linens and at 7 sites [25]. Natural disasters such as hurricanes and floods also pose a risk to transplant recipients. Recent reports indicate an increase of cases of mucormycosis in the month after Hurricane Harvey in Texas including two SOT recipients who developed cutaneous infection [26].

With the availability of new immunomodulating therapies and evolution of transplantation practice, transplant recipients may be exposed to new lymphocyte-

depleting monoclonal antibodies, immune checkpoint inhibitors, and small molecule protein kinase inhibitors prior to or after transplantation. It is likely that new risk factors for mucormycosis will emerge in the coming years [16].

Clinical Features

The most common site of mucormycosis in the transplant recipient is pulmonary (53% cases) followed by disseminated infection (13%), sinus (12%), and skin (9%) [3]. This distribution is reflected in other series [12, 13, 17]. Differences in timing and the distribution of sites affected have been seen with different SOT populations. Liver transplant recipients were more likely to have disseminated disease and developed mucormycosis earlier after transplantation than did other SOT recipients at a median of 0.8 versus 5.7 months [16], confirmed by Park et al. where the median onset in liver transplant recipients was 81 days compared with 533 days in other SOT recipients [3]. Mucormycosis occurred later in the lung than in other transplant recipients at a median of 180 days in one study [13]. In renal transplant recipients with mucormycosis, Song et al. found that males predominated (76% cases), diabetes was the most common underlying condition, and rhinocerebral disease was more common than pulmonary disease [14].

Signs and symptoms of mucormycosis in transplant recipients may be nonspecific, and in one review of published cases in renal transplantation, fever was absent in up to half of cases [14]. Symptoms of pulmonary infection include fever, cough, and respiratory distress [14], and in lung transplant recipients, the bronchial anastomosis may be involved [12]. Primary cutaneous infection can occur at the sites of incisions, drains, intravenous catheters, or after skin trauma and may appear necrotic or cellulitic. GI lesions may present as large solitary or multiple ulcerative lesions, frequently with necrotic borders with symptoms of pain, hematemesis, melena or hematochezia, and fever [13]. Rhinocerebral disease (ROCM) is associated with hyperglycemia and acidosis in the SOT recipient and can present with fever, local pain, nasal discharge, facial swelling, and a variety of cranial nerve deficits [13]. In renal transplantation, other signs include oliguria and graft dysfunction with graft mucormycosis occurring in 11.5% and often presenting as acute rejection [14].

In a recent review, compared with other genera, *Rhizopus* spp. were significantly more often isolated in patients with ROCM, while *Cunninghamella* spp. were more common in patients with pulmonary or disseminated disease. *Lichtheimia* spp. or *Saksenaea complex* were more commonly isolated in patients with cutaneous mucormycosis [8].

Risks for poor prognosis have been identified and include infection, host, and treatment factors [12]. Disseminated disease, rhinocerebral infection, malnutrition, renal or hepatic failure, and delayed initiation of treatment have been identified as poor prognostic factors [12, 13 16]. Conversely, the presence of limited surgically resectable infection, discontinuation or reduction of immunosuppression, and early treatment with liposomal amphotericin B have been associated with better outcomes

[12, 13, 16]. Combination antifungal therapy did not improve outcomes [16] (see section "Antifungal Therapy").

Diagnosis

Diagnosis of mucormycosis is often problematic because clinical features are non-specific, frequently mimicking invasive aspergillosis. Radiological features are also non-specific although there are certain signs that are highly suggestive (see section "Imaging"). A multifaceted diagnostic approach comprised of imaging techniques, histological examination of clinical specimens, and microbiological tests (culture- as well as molecular-based) is generally required.

Clinical evaluation of the patient as above to determine likelihood of disease and disease extent is essential to guide diagnostic investigations (Fig. 1). In neutropenic HSCT or SOT patients, the lung is the most common site of infection [3, 9] focusing investigations into the respiratory tract. Diagnostic procedures should be tailored to the site of infection.

Imaging

Respiratory symptoms should lead to early, high-resolution computed tomography (CT) scanning of the chest, which is still the mainstay procedure (Fig. 1). Although insensitive and non-specific, CT features consistent with mucormycosis include lung nodules, with or without the halo sign (a ring of ground-glass opacity surrounding a nodular infiltrate), lung mass, cavitation, and pleural effusion. Of note, pulmonary aspergillosis can also manifest these abnormalities. An early abnormality which may indicate pulmonary mucormycosis is the reversed halo sign – a focal ground-glass opacity associated with a ring or crescent-shaped consolidation [27]. When studied early in neutropenic leukemic patients and followed up by serial scans, sequential morphological changes were observed in one study: (i) reversed halo sign, followed by (ii) consolidation or nodule or mass with halo sign, and (iii) central necrosis and air-crescent sign [28]. In some reports, a diagnosis of mucormycosis was more likely than aspergillosis if a neutropenic patient exhibited >10 distinct nodular infiltrates. Boucier et al. found neutropenic patients were significantly more likely to have a reversed halo sign on their CT scans compared with non-neutropenic patients (79% vs. 31%, $p < 0.05$) [29].

Other imaging abnormalities include the "hypodense" sign on magnetic resonance imaging (MRI) [30] or a central hypodensity in a lung nodule or area of consolidation. The vessel occlusion sign on CT angiography (an interrupted vessel at the border of a focal lesion) is more sensitive and possibly more specific sign of pulmonary mucormycosis in patients with hematological cancer [31]. Imaging of other sites such as the sinus, brain, and abdomen should be performed to aid diagnosis and delineate extent of infection and be considered on a case-by-case

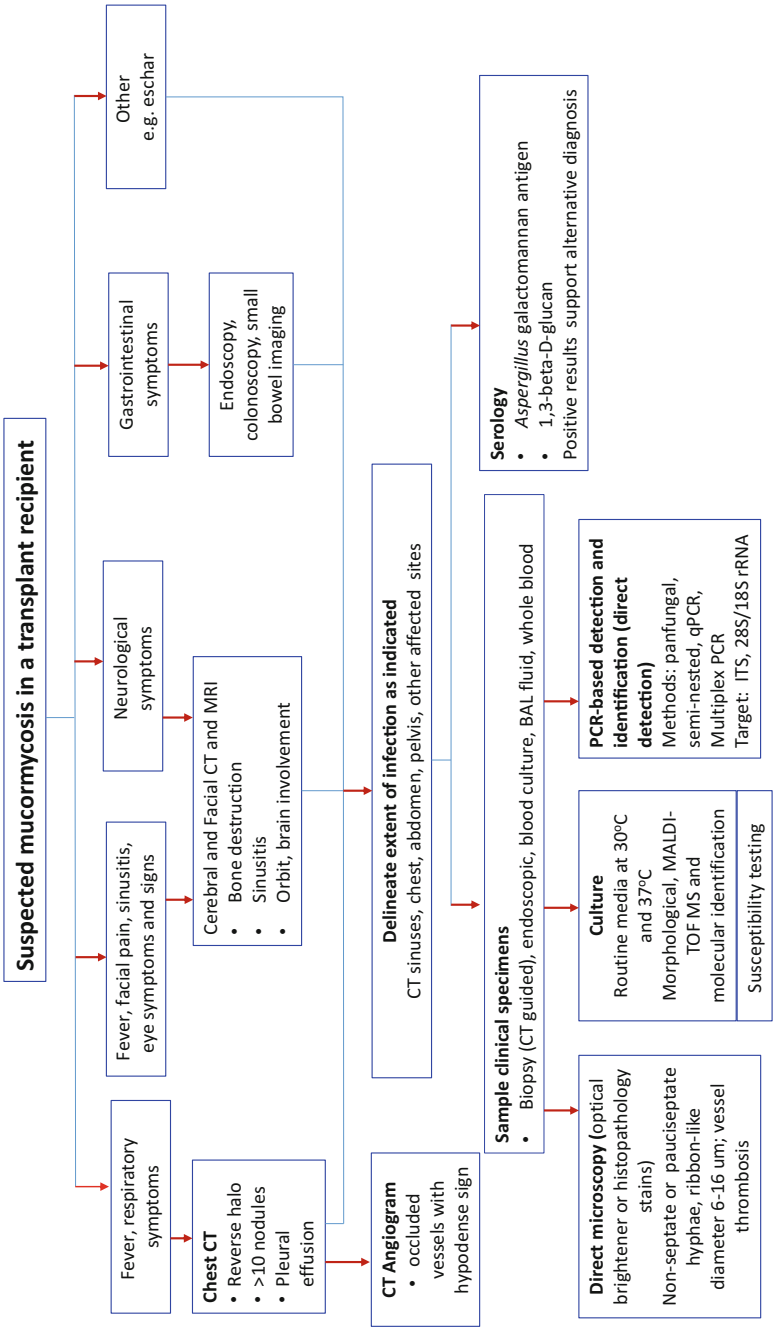

Fig. 1 Diagnostic pathways in a transplant patient suspected to have developed mucormycosis

basis. In some instances, cerebral magnetic resonance imaging (MRI) and imaging of the small bowel may be required. Disease may rapidly progress and follow-up imaging is recommended.

Histopathology

Histopathology and direct microscopy of clinical specimens remains a key diagnostic approach particularly with tissue biopsies (Fig. 2). This is still the case even if the procedure is not capable of identifying genus and species. As Mucorales hyphae are susceptible to physical trauma, care should be taken not to damage the specimen in transport to the laboratory. Of note, the visualization of the hyphae of Mucorales is required to call a "proven" diagnosis of mucormycosis (vs. a probable case or possible infection) [32].

Direct microscopy of specimens with optical brighteners (e.g., calcofluor white) or for histopathology, with hematoxylin-eosin (H&E), periodic acid-Schiff (PAS), and/or Grocott-Gomori's methenamine-silver (GMS) stains, is preferred. Visualizing non-pigmented hyphae associated with tissue invasion confirms an infection.

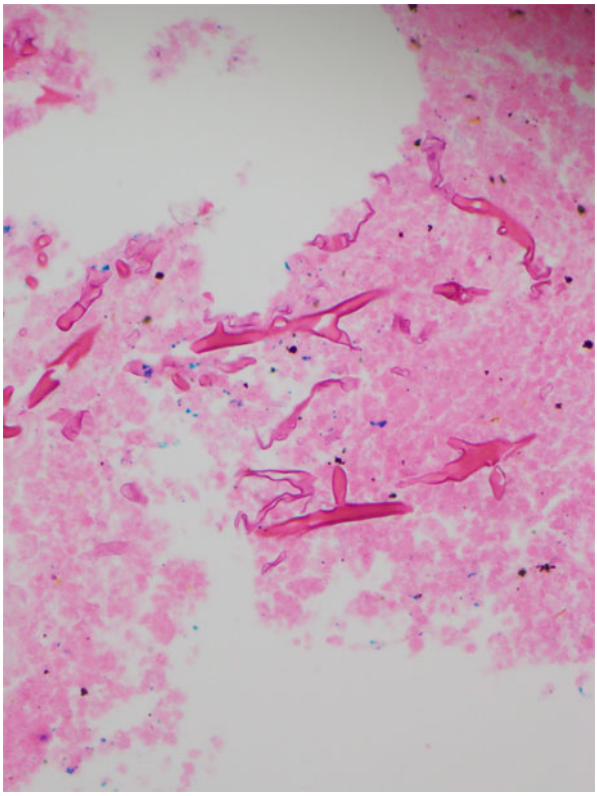

Fig. 2 Periodic acid-Schiff stain of lung tissue showing broad, pauci-septate irregular hyphae of a Mucorales fungus

Characteristic broad (6–25 μM diameter) ribbonlike, wide-angled branching, and pauciseptate or nonseptate hyphae assist in clinching the diagnosis [33] (Fig. 2). However, the specificity of some of these findings is not absolute as hyphae can artefactually appear to be septate or to be seen as having narrow-angle branching due to architectural distortion during processing. The most common cause of incorrect morphological diagnosis remains the misidentification of Mucorales as *Aspergillus* spp. where the non-concordance rate between culture (the gold standard) and histopathological diagnosis can be as low 15% [34]. The application of polymerase chain reaction (PCR) techniques in fresh or formalin-fixed paraffin-embedded tissue (PPFE) [summarized in 35, 36] has been shown to increase specificity, but sensitivity has varied.

Other typical findings in acute lesions of mucormycosis are hemorrhagic infarction, necrosis, and neutrophil infiltration (in non-neutropenic patients). In more longstanding infection, pyogranulomatous inflammation with giant cells and hyphae covered by eosinophilic material (the Splendore-Hoeppli phenomenon) may be seen.

Culture and Microscopy-Based Diagnostic Methods

Notwithstanding modern molecular methods, culture is still a mainstay method to diagnose mucormycosis. Further, it is the only method that enables both species identification and antifungal susceptibility testing. *All specimens from affected body sites should be cultured*. A positive culture from a sterile site, i.e., any tissue including skin lesions, pleural fluid, cerebrospinal fluid, and blood, confirms diagnosis, while a culture from a non-sterile site (e.g., BAL fluid, sinus material), while supportive, must be interpreted in the context of clinical and radiological findings.

Limitations of culture are acknowledged. An invasive procedure (e.g., biopsy, surgical resection) may not be feasible in transplant patients due to severe pancytopenia or other risks that advise against these procedures. Next, culture is insensitive. In one series, respiratory tract samples were culture-negative in 75% of proven pulmonary mucormycosis in cancer patients [37] although the yield of culture appears to have improved over time (50–71%) [9]. In a meta-analysis of diagnostic methods used from 2000 to 2017 [8], a Mucorales pathogen was grown in 79% of cases where culture was attempted; homogenization or grinding of tissue and other specimens leads to lower recovery rates [38].

Laboratories are able to alert clinicians quickly if there is fungal growth as Mucorales grow rapidly (3–5 days) on standard mycological media, visualizing typical cotton candy-like colonies. Identification of the pathogen to genus and species is still reliant on phenotypic methods to visualize fungal sporulation in many laboratories. Certain less common species such as *A. elegans* require special nutrient-poor media to sporulate [38]. Hence knowledge of local epidemiology is useful to inform laboratory practice. Descriptions of morphological structures for species identification using robust fungal identification keys can be found in reference publications [38].

Because identification of mucoralean fungi by morphological methods is difficult especially given the evolving taxonomy, molecular identification methods are often

required for species resolution. However, matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) approaches now can aid species or genus identification [39, 40]. Several studies reported good identification when in-house databases were used [39–41]. Commercial databases have performed less well where in one study that tested 111 Mucorales strains, only 49.5% were correctly identified [40]; a correct identification rate of 86% was observed in another study [42]. The establishment of a robust accessible MALDI-TOF MS database is necessary prior to its routine implementation for Mucorales identification.

Serology and Antigen Testing

Unlike the *Aspergillus* galactomannan (GM) test and the beta-1,3-D-glucan (BDG) assays that are used to assist in diagnosis of other fungal infections, there are no commercial serological tests to detect Mucorales in clinical samples. The above tests are typically negative in Mucorales infections and help rule out invasive aspergillosis, although a recent study reported serum BDG positivity in 3/6 patients with *R. arrhizus* infection. Clinical evaluation is of paramount importance given false-positive results and the possibility of mixed infections. *R. arrhizu*s is known to harbor beta-D-glucan synthase, the enzyme that leads to synthesis of BDG [43]. Usually BDG levels in *R. arrhizus* infections are below the limit of detection of the assay.

A recent study has reported an ELISA and lateral flow immunoassay (LFIA) directed against Mucorales mannan molecules that were able to detect *Mucor* spp., *Lichtheimia* spp., and *R. arrhizus* in serum and BAL fluid [44]. A potential rapid point of care test, further evaluation is required to determine its clinical utility.

Molecular-Based Methods

Advances in the field of PCR-based diagnostic methods have been made for the (i) direct detection of Mucorales in clinical specimens and (ii) species identification. Other than tissue specimens, research has focused on identifying Mucorales DNA in blood, BAL fluid, and CSF. Target selection is a key determinant of success. The internal transcribed spacer (ITS) is well-established to provide accurate results and is the preferred gene target [summarized in 45].

Detection in Fresh and Formalin-Fixed Tissue

Numerous studies have shown good clinical utility of PCR-based detection of Mucorales DNA directly from both fresh and FFPE tissue specimens [35, 45]. Most studies have employed in-house techniques, with various PCR formats (e.g., PCR +/− sequencing, quantitative PCR [qPCR]) and assays that remain unstandardized. Assays can be Mucorales-specific or pan-fungal in nature. As mixed fungal infections occur, and because the target fungus is often unknown, many laboratories choose to initially use a broad-range PCR.

Variable sensitivity appears to be the common theme among studies, but specificity is consistently high. Specimen type (and quantity) may affect test performance. Gomez et al. reported excellent performance with PCR and sequencing in an ITS2/D2-directed assay on fresh as well as FFPE tissue and body fluids. The diagnostic yield was higher from samples obtained with open biopsy (76.5%) compared with core needle biopsy (50%) and fine needle aspiration (0%) [46]. The yield is also dependent on whether hyphae are seen in tissue [46, 47]; if these are visualized, the test sensitivity (96.6%) and specificity (98.2%) are high. Indeed, many experts recommend that PCR should mainly be undertaken in tissue containing fungal hyphae. Test sensitivity is reduced with FFPE sections due to low fungal load or DNA fragmentation from formalin (sensitivity 56–65%) [47] although in another study, sensitivity of PCR in both fresh and FFPE tissue was >90% [46].

Detection in Blood and Body Fluids

Detection of Mucorales DNA in blood and other fluids in high-risk patients has been actively pursued for its utility in early diagnosis of mucormycosis. This approach makes clinical sense as infections are angioinvasive; overall, promising results have been observed. Landmark studies for detection of Mucorales DNA in blood fractions include a retrospective evaluation of a combination of three separate 18S rRNA-directed real-time qPCRs targeting *Mucor/Rhizopus*, *Lichtheimia*, and *Rhizomucor* species, for detecting confirmed mucormycosis in immunocompromised patients. In 9/10 patients, Mucorales DNA was detected in serum 3–68 days before standard diagnosis indicating the potential use of qPCR as a screening tool [48]; the utility of this assay for early diagnosis was confirmed in a larger follow-up study (sensitivity 81–92%) where declining DNA load correlated with favorable patient outcomes [49]. Ino et al. reported detection in the blood using broad-range real-time PCR of various Mucorales species from four hematology patients [50]. Genus-specific assays, e.g., a *C. bertholletiae*-targeted PCR, have also been developed for early diagnosis of infection [51].

Mucorales DNA has also been detected in cerebrospinal fluid and BAL fluid. Lengerova et al. validated a high-resolution melt analysis PCR to detect *Rhizopus, Lichtheimia*, and *Mucor* spp. in BAL fluid from hematology patients with pulmonary infiltrates with an assay sensitivity of 100% and specificity of 93% [52]. Both the cell pellet and supernatant fractions of BAL fluid should be tested for optimal yield. Recently, PCR amplification of the novel target *CotH*, a Mucorales-specific gene, yielded positive results when tested on serum, BAL fluid, and urine in patients with mucormycosis [53].

Position of PCR-Based Methodologies

For all clinical specimens, PCR methodologies then have good potential to enable early mucormycosis diagnosis with superior sensitivity and specificity compared with standard microbiological methods. None of these assays are standardized, although this is being studied by the International Society for Human and Animal

Mycology (ISHAM) fungal PCR consortium. The few commercial assays, too, lack sufficient clinical evaluation. These issues need to be addressed prior to more widespread use of PCR assays for mucormycosis diagnosis.

Molecular Techniques to Identify Mucorales from Cultures

Molecular identification techniques are the benchmark for species identification of Mucorales pathogens. Comparison of morphological vs. molecular identification has shown better performance with molecular approaches. As before, target selection is important, and ITS sequencing is the preferred approach for identification of species of Mucorales [54]. The few commercial PCR assays are currently of limited use as these are not designed to resolve species but detect the order Mucorales as a whole or a genus.

A reliable sequence database such as those of the Westerdijk Institute (http://www.westerdijkinsistitute.nl/Collections/BioloMICSSeqeunces.aspx) or ISHAM (http://its.mycologylab.org) should be used for sequence comparison and species identification. Other gene loci that have been evaluated include the 18S and 28S rRNA gene regions, cytochrome b, and *FTR1* genes [45], but there is less evidence of their usefulness.

Next-Generation Sequencing

Next-generation sequencing (NGS) technologies are rapidly changing the landscape of the characterization and tracking of fungal infections. Shelburne et al. reported a metagenomic shotgun approach to identify the uncommon Mucorales, *M. velutinous*, in a patient with acute myeloid leukemia that led to disseminated disease [55]. NGS is still in its early stages with lack of annotated genomes of Mucorales a key limitation. However, whole-genome sequencing approaches have established epidemiological links in outbreaks although the two examples here are not specific for transplant patients [56, 57].

Management of Mucormycosis

Timely treatment of mucormycosis is critical. This typically requires a multidisciplinary approach with a combination of systemic antifungal therapy, surgical resection, and adjunctive measures such as correction of predisposing conditions (e.g., diabetic ketoacidosis), augmenting the host immune response (e.g., with growth factors), and other treatments such as hyperbaric oxygen. *Antifungal agents and surgery are the mainstays of therapy.* Yet prospective clinical studies evaluating the efficacy of antifungal and other treatments for mucormycosis are scarce with only three clinical trials reported [58–60]. Hence guidance for treatment is based largely on case series, expert opinion, animal model studies, and in vitro susceptibility data.

Susceptibility Data

Mucorales are intrinsically resistant to many antifungal drugs, and knowledge of their in vitro susceptibility profiles is clinically relevant [61, 62]. However, there is much discussion on whether the minimum inhibitory concentration (MIC) value itself for a particular isolate-drug pair is helpful. As Mucorales share most (but not all) susceptibility patterns, it is arguable that an MIC is not generally not required. However, there are some differences in susceptibility depending on genus and even within species, and certainly in cases of treatment failure, susceptibility testing can guide alternate therapy. MIC values are essential to establish epidemiological data which can underpin future clinical practice. The use of standard susceptibility testing methods based on the European Committee on Antimicrobial Susceptibility Testing (EUCAST) or CLSI protocols is preferred [63, 64] as commercial methods, e.g., the E test (bioMerieux, Marcy-l'Étoile, France), produce variable results. Because clinical breakpoints have not been defined for these pathogens, isolates cannot be classified as "susceptible" or "resistant" [65]. Instead MICs are interpreted in the context of epidemiological cutoff values to assess if a drug MIC falls within the wild-type MIC range (i.e., harboring no resistance mechanism).

Overall, amphotericin B is the most active drug against the majority of Mucorales, as shown both in vitro and in vivo animal models of infection although *Cunninghamella* spp. have higher MICs [61]. Among the newer azoles, posaconazole has very good in vitro activity with low MICs (geometric mean [GM] MICs <2 mg/L) against most species except for *Cunninghamella* spp. (GM MICs >4 mg/L) [61]. Some *Rhizopus* strains may also have higher MICs to posaconazole; however the in vivo efficacy of posaconazole is well documented when used as both curative and prophylactic therapy in animals [66, 67]. Isavuconazole also has good activity; although MICs are higher than those of posaconazole (GM MICs 2–three-fold higher) [62, 68], isavuconazole achieves 3–4 times higher blood concentrations [69]. Variation in species susceptibility is demonstrated by isavuconazole showing reduced activity against *M. circinelloide*s [68]. Itraconazole has variable MICs against Mucorales, while voriconazole and the echinocandins exhibit high MICs for all species [61]. Various antifungal combinations against Mucorales have been studied in a few in vitro studies with synergistic effects in some species but with uncertain clinical relevance [70].

Antifungal Therapy

Prevention: Antifungal Prophylaxis

Primary antifungal prophylaxis offered to transplant patients is not directed specifically against mucormycosis but rather a broad range of fungal infections, most commonly candidiasis and aspergillosis. Prophylactic approaches are best established for HSCT recipients, in those with neutropenia and graft-versus-host disease, and are stratified by risk. This discussion is beyond the scope of this chapter but can be found in various expert guidelines [71, 72]. Protocols vary between institutions.

Of note, Mucorales infections have occurred in hematology-oncology patients receiving antifungal prophylaxis including those taking echinocandins and voriconazole [16, 73]. With the current use of posaconazole for prophylaxis, however, breakthrough mucormycosis has become rare with all forms including posaconazole oral suspension [74], posaconazole delayed-release tablets [75], and posaconazole intravenous (IV) infusions [76]. Should mucormycosis at an institutional level be of particular concern, prophylaxis with posaconazole delayed-release tablets is recommended due to their superior bioavailability over the oral suspension.

Data regarding antifungal prophylaxis in SOT recipients are less robust with relatively few clinical trials and no definitive recommendations. Based on clinical experience, various opinion bodies have published guidelines for prophylaxis according to transplant type and level of patient risk [77, 78]; the more pertinent data and their strength of recommendations [79] are summarized in Tables 2 and 3. All of the azoles, echinocandins, and amphotericin B formulations have been studied for antifungal prophylaxis with varying success; these may either be offered universally or targeted at high-risk subgroups. Protocols are often institution-specific, and there is no consensus on duration of prophylaxis.

In liver transplantation, recipients at high risk for invasive yeast and mold infections (Table 2) should receive antifungal prophylaxis [80] as in its absence; about 36% of these patients have developed an IFD. An inhaled amphotericin B formulation is one of the more commonly used drugs in lung transplantation although broad-spectrum azoles now offer a practical alternative [81] (Table 2). Amphotericin B has the advantage of having activity against the Mucorales, but the protective effect of inhaled formulations is limited to the airways. Both amphotericin B deoxycholate and lipid formulations of amphotericin B have been shown to be efficacious. Duration of use is highly variable ranging from 3 months to lifelong prophylaxis (in most transplant centers, 6–12 months). For systemic prophylaxis or where an azole is otherwise used, an appreciation of the complex drug pharmacokinetics, drug interactions with transplant rejection medications, and safety profiles is imperative.

Transplant physicians are often asked about secondary prophylaxis or whether to continue or recommence antifungal therapy in a patient who has had mucormycosis and who has responded to treatment, but who is scheduled for a new episode of immunosuppression. Expert opinion recommends continuation or restarting the last agent effective in that patient with or without surgical resection of the disease focus [82].

First-Line Antifungal Therapy

Investigations to confirm the diagnosis in suspected mucormycosis are essential but should not delay the initiation of therapy, as delay in treatment is an independent predictor of poor outcomes. More specifically, Chamilos et al. reported that delayed frontline amphotericin B-based therapy in hematology patients with mucormycosis resulted in a twofold increased mortality (83% vs. 49%) [5].

Table 2 Antifungal prophylaxis in sold organ transplant patients: recommendations according to transplant type. (Modified from Gavalda et al. and Kennedy et al. [77, 78])

Organ transplant	Population	Antifungal drug	Duration
Kidney	–	None	–
Pancreas	All	Fluconazole (A-III)[a]	1–2 weeks
Pancreas-kidney	*High risk*: Enteric drainage, hemodialysis, acute rejection and poor initial graft function, posttransplant laparotomy, vascular thrombosis, post-perfusion pancreatitis anastomotic problems	Echinocandin (A-III) or liposomal amphotericin B (A-III)	Varies with risk factors
Intestinal	All	Fluconazole (A-III)	3–4 weeks or until anastomosis healed and there is no rejection
Liver	*If one major or two minor criteria* Major: Re-transplantation, fulminant liver failure, MELD score ≥30, renal replacement therapy Minor: MELD score 20–30, split, living donor, choledochojejunostomy, transfusion requirement high, renal failure, early re-intervention, multifocal *Candida* colonization or infection	Micafungin or caspofungin (A-II) Liposomal amphotericin B (A-II) Amphotericin B lipid complex (A-II) Anidulafungin (B-III)	2–4 weeks or until all risk factors have resolved
Lung and lung-heart	Either all patients OR Guided strategy (induction with alemtuzumab or thymoglobulin, acute rejection, single-lung transplant, *Aspergillus* colonization pre or during first year post transplant, acquired hypogammaglobulinemia	Nebulized liposomal amphotericin B 25 mg (A-II): 3 times/week until healed bronchial suture, once/week for 2–6 months, once every 2 weeks >6 months. If guided prophylaxis, load 25 mg 3 times a week for 2 weeks and then once a week Nebulized amphotericin B lipid complex 50 mg (B-II). Load once every	Nebulized liposomal amphotericin B: Indefinitely or minimum 12 months or guided by presence of risk factors Nebulized amphotericin B lipid complex: Minimum 12 months or guided by risk factors Voriconazole: Determined by risk factors, minimum 4 months

(continued)

Table 2 (continued)

Organ transplant	Population	Antifungal drug	Duration
		2 days for 2 weeks and then 50 mg once a week Voriconazole (B-II)	
Heart	High risk: Acute rejection hemodialysis, re-exploration	Itraconazole, (A-III) Voriconazole (B-III) Posaconazole (B-III) Echinocandins (B-III)	Minimum 3 months

[a]Grading: according to ESCMID scoring systems, based on strength of recommendation and quality of evidence [79]

Table 3 Definition of strength of recommendation and quality of evidence [79]

Strength of recommendation	**Definition**
Grade A	Strong support for a recommendation for use
Grade B	Moderate support for a recommendation for use
Grade C	Marginal support for a recommendation for use
Grade D	Support for a recommendation against use
Quality of evidence	**Definition**
Level I	Evidence from at least 1 properly designed randomized, controlled trial (orientated on the primary endpoint of the trial) Note: Poor quality of planning, inconsistency of results, indirectness of evidence, etc. would lower the SoR
Level II	Evidence from at least 1 well-designed clinical trial (incl. Secondary endpoints), without randomization; from cohort or case-controlled analytic studies (preferably from >1 center); from multiple time series; or from dramatic results of uncontrolled experiments Note: Every level II evidence must have at least one added index
Level III	Evidence from opinions of respected authorities, based on clinical experience, descriptive case studies, or reports of expert committees

Antifungal drugs presently used to treat mucormycosis are limited to amphotericin B formulations, posaconazole, and isavuconazole [58]. The principles and preferred antifungal treatment of mucormycosis in transplant patients are similar to those in other populations. Guidelines for antifungal therapy have been published [79, 83], but these were written prior to the clinical studies of isavuconazole. In the hematology and HSCT setting, the recommendations from ECIL (ECIL-6) were updated in 2017 [84].

Commensurate with in vitro data and across all three guidelines mentioned above, the preferred first-line agent for all forms of mucormycosis is a lipid formulation of amphotericin B – all favor liposomal amphotericin B (L-AMB) at a dose of 5–10 mg/kg/day (Table 4). Small case series and registry data have reported use of L-AMB with good outcomes although response rates remain at ≤50% for primary

Table 4 First-line antifungal monotherapy for treatment of mucormycosis in transplant patients and other populations (adapted from the ECIL-6, ESCMID, and the Australian and New Zealand Mycoses Interest Group (ANZMIG) guidelines) [79, 84, 85]

Antifungal therapy	Dose if known	Grade of recommendation	Comment
Liposomal amphotericin B	5–10 mg/kg/day	B II [95] B [94] AII [89]	Liposomal amphotericin B is preferred over other formulations in renal failure and in central nervous system infection Higher initial dose in CNS disease (BIII); 10 mg/kg/day
Amphotericin B, lipid complex	5 mg/kg/day	B II [95]) A II or AIII [89]	Has been used in solid organ transplant patients
Amphotericin B colloidal dispersion	3–4 mg/kg/day	CII [95]	Not available in the USA
Amphotericin B deoxycholate	1–1.5 mg/kg/day	DII [89]	If lipid formulations are unavailable
Isavuconazole, orally or intravenous	3 × 200 mg days 1–2 then 1 × 200 mg/day from day 3	BII [89]	$N = 21$ patients −11 hematology, 4 diabetes mellitus, overall mortality comparable to amphotericin B formulations
Posaconazole Delayed-release tablet or intravenous formulation	2 × 300 mg day 1 then 1 × 300 mg from day 2	BII [89]	Higher trough levels than posaconazole oral suspension Intravenous use if oral dosing is not possible
Posaconazole oral suspension	4 × 200 mg/day or 2 × 400 mg/day	CIII [95] CII [89]	No data to support its use as first-line treatment

mucormycosis [9, 59, 85–87]. There is no requirement to escalate doses over several days; the full daily dose should be given from the first treatment day. If significant renal toxicity ensues, the dose may be reduced though expert opinion does not recommend doses under 5 mg/kg/day [79]. A prospective non-comparative trial assessed the efficacy and safety of first-line high-dose L-AMB at 10 mg/kg/day for the first month of treatment [59]. Although patients receiving this high dose tended to have higher response rates (45%), this requires confirmation before the dose can be recommended. Renal function should be monitored as the use of doses of 10 mg/kg/day resulted in increased (albeit mostly reversible) serum creatinine levels [59, 87]. The use of high-dose L-AMB at 10 mg/kg/day in CNS involvement is supported by clinical data [9].

Other amphotericin B formulations have also been used with good outcomes. For decades, amphotericin B deoxycholate has been the cornerstone of therapy with successful use in multiple publications [9, 15, 88]. However, its efficacy is limited by substantial toxicity, particularly at the doses and long treatment durations needed for mucormycosis [79] and particularly in the context of kidney transplantation. Although discouraged, if lipid formulations or other alternatives are not available,

it should not be withheld as first-line therapy. Amphotericin B lipid complex at a dose 5 mg/kg/day has been used successfully in kidney transplant patients, although there are fewer data on efficacy compared with L-AMB [9, 89]. Use of amphotericin B is limited by the need for IV administration.

The latest marketed triazole, isavuconazole, has received much interest in efficacy studies in mucormycosis following promising in vitro and preclinical data. In a small comparative matched control study against amphotericin B formulations ($n = 33$ patients, historical cohort), the efficacy of isavuconazole as first-line treatment ($n = 21$ patients) was similar [58]. To this end, isavuconazole (either IV or oral) has been licensed for first-line treatment of mucormycosis in the USA. Posaconazole oral suspension has also been used successfully in first-line treatment [9, 86]. The advent of the delayed-release tablet with improved bioavailability exposure and the IV infusion formulation [76] both lend themselves to future comparative drug efficacy studies. At present, if amphotericin B formulations cannot be used and isavuconazole is not available, then posaconazole delayed-release tablets or infusion could be considered for first-line treatment (Table 4) [90]. However, in the ECIL-6 guidelines, posaconazole is positioned as an option in maintenance or salvage therapy [84].

In a recent review of management strategies of mucormycosis [88] in 851 patients, an amphotericin B formulation was given as initial therapy as monotherapy in 88% of cases, with posaconazole oral suspension as initial therapy in 11 cases (800 mg daily in divided doses); death was only observed in 1 patient. Of 174 cases of mucormycosis in renal transplant patients, the overall survival in those receiving either posaconazole or lipid amphotericin B was significantly higher than that in patients receiving amphotericin B deoxycholate (92.3% vs. 73.4% vs. 47.4%); however the timing of initiation of these therapies was not described, and the authors concluded that a lipid amphotericin B formulation is preferred [14].

Drug toxicity with the azoles is well appreciated, in particular hepatotoxicity. In contrast to other mold-active azoles, isavuconazole is less hepatotoxic although it can cause shortening of the QTc interval [91].

Step-Down Therapy

Commonly, after initial treatment with amphotericin B therapy and when the patient is clinically stable, step-down therapy to an oral agent is instituted. The use of posaconazole delayed-release tablets is preferred. Alternatively, isavuconazole may also be used. Posaconazole oral suspension can be used but is discouraged now that formulations with higher exposure are available. In a large review of 96 cases of mucormycosis (2003–2011) where posaconazole was a component of therapy, the complete response rate was 64% and partial response rate 7.3%. Posaconazole was predominantly used in combination with another antifungal or as second-line treatment [88, 92].

Is There a Role for Up-Front Antifungal Combination Therapy?

There are no robust data from large comparative studies to guide recommendations for combination antifungal therapy. In animal models, both polyene-echinocandin

and polyene-azole (primarily, posaconazole) combinations have shown improved survival rates with no antagonism observed [93].

Data from case reports and a few small patient series report promising results with use of combinations of polyenes and azoles or polyenes plus echinocandins [94, 95]. Combined amphotericin B lipid complex and caspofungin offered superior survival over amphotericin B alone in 1 study in 11 ROCM patients (6 had diabetes) [94]. In another study of 36 patients, 52% had combination L-AMB and caspofungin therapy with a more favorable prognosis [95]. However, other studies in hematology patients failed to demonstrate benefits of double or triple antifungal combinations [96]. Data from two IFD registries – the SEIFEM and FUNGISCOPE – indicated that combination L-AMB and posaconazole may have benefits in very aggressive forms of mucormycosis [97]. Hence combination therapy may be rationally administered with possible though unproven benefit. Disadvantages include drug interactions, toxicity, and cost. It would be important to study the potential clinical benefits of polyene combined with either delayed-release posaconazole tablets or IV posaconazole.

Salvage Antifungal Treatment

Treatment failure is often multifactorial, with both drug and host factors contributing to slow or absent clinical response. Source control and augmentation of host immune response where possible are all essential. Drug-related reasons for treatment failures are disease that is truly refractory to the antifungal used or toxicity or intolerance to the first-line antifungal agent(s). For amphotericin B formulations, renal toxicity is especially relevant, while azole-induced hepatotoxicity is not uncommon.

Because only two drug classes – the polyenes and azoles – have proven efficacy in mucormycosis, salvage treatment mostly indicates a switch to use of the other class. In patients failing amphotericin B or where this cannot safely be used, isavuconazole salvage treatment had yielded favorable patient outcomes [58]. Salvage therapy with posaconazole oral suspension achieved cure in a number of case series and two non-randomized clinical studies [9, 90, 92, 98]. These data strongly support the use of both isavuconazole and posaconazole as salvage treatments when amphotericin B is no longer an option. As before, posaconazole delayed-release tablets or infusions are strongly preferred over posaconazole oral suspension. In cases of primary treatment failure with isavuconazole or posaconazole, lipid-based amphotericin B formulations have been used with efficacy [90].

Treatment Duration

The duration of therapy for treatment of mucormycosis is not well-defined. As transplant patients are often seriously ill, typically a minimum of several weeks to months of therapy are given or treatment continued until the risks are reduced due to recovery of neutrophil counts or immunosuppression reduced or discontinued. In addition, there should be resolution of signs of infection and substantive improvement of radiological abnormalities. Radiologic improvement may be difficult to determine after surgical resection because of postoperative scarring or distortion of

anatomical structures. Findings of gross surgical assessment are also important. In all cases, treatment duration follows a personalized approach.

Data from studies employing isavuconazole therapy have reported the median duration of isavuconazole first-line or salvage treatment to be 84 days in a single-arm open-label study combined with a retrospective case-control analysis [58]. Among posaconazole oral suspension studies, treatment duration ranged from 1 week to almost 3 years (mean 6 months) [99]. This wide range of duration is expected due to both the diversity of clinical manifestations and the complexity of the underlying diseases.

Therapeutic Drug Monitoring (TDM)

Triazole antifungals may have unpredictable pharmacokinetics in patients with mucormycosis due to unpredictable bioavailability and/or drug-drug interactions. In some cases, these factors may lead to treatment failure or drug toxicity. Although the therapeutic range of posaconazole for mucormycosis is unknown, routine TDM is strongly recommended in patients receiving treatment with posaconazole. Based on preclinical data and following simulation, serum trough posaconazole concentrations of 1–1.5 mg/L (where MICs are up to 0.25 mg/L) up to 4 mg/L (for isolates with elevated MICs, e.g., 2 mg/L) are recommended to reduce the risk of treatment failure [99]. Notably, serum levels of >2 mg/L may only be achievable in patients with non-licensed doses of posaconazole tablets or the IV formulation. Such supratherapeutic levels have been linked with liver toxicity, hypokalemia, and hypertension [100].

At present, there is no clinical evidence to indicate a need for routine TDM with isavuconazole. However, measurement of drug concentrations could be useful in suspected treatment failure or if there are drug interactions, suspected drug toxicity, uncertain pharmacokinetics (e.g., in obese patients), or after switching from IV to oral therapy**.** In the SECURE isavuconazole clinical trial for aspergillosis, in patients where TDM was performed, >90% of patients achieved predicted target exposure (>1 μg/ml), but there was no association between serum levels and treatment response or liver toxicity [101].

Surgical Treatment

Surgery is essential for local control of mucormycosis, prevention of disease extension to adjacent structures, and removal of necrotic tissue. This is especially pertinent as antifungal agents penetrate poorly into devitalized tissue. Disseminated disease, or involvement of difficult-to-access sites such as the central nervous system, however, poses limitations.

Procedures that have been shown to be helpful include lung resection or lobectomy, debridement of rhino-orbital-cerebral mucormycosis (ROCM), debridement of skin/soft tissue infection, and resection of affected viscera, such as the spleen, GI tract, or even transplanted organs. Often transplant recipients are too ill to undergo surgery, but this option should still be considered as several studies report higher

survival rates with surgical intervention [9, 26]. A review of 106 mucormycosis cases in solid organ transplant recipients from 1970–2002 found reduced mortality (34.3%) among patients receiving both surgery and antifungals compared with those with antifungal therapy alone (62.5%) [13]. In a case-control study of 50 solid organ recipients (infection sites, 48% lung, 26% ROCM, 22% cutaneous/soft tissue), surgical resection was strongly associated with treatment success by multivariate analysis [16]. Song et al. observed survival rates of 70.2% in renal transplant patients receiving combined surgery and antifungals compared with 32.4% and 36.4% in those receiving antifungal drugs alone and surgery alone, respectively (36.4%) [15]. The ECIL-6 guidelines strongly recommend surgical intervention for cutaneous/soft tissue infection and ROCM and moderately recommend surgery of pulmonary lesions [84].

The principles of surgical management include early, extensive, and frequent debridement, careful assessment of resection margins, and minimizing morbidity of surgery. In ROCM, as near to complete debridement of affected tissue increased survival in solid organ transplant recipients [102]. It is important to customize the extent of surgery along the tissue planes of affected sites to reduce cosmetic disfigurement. In lung infection, excision is difficult where disease is multifocal; however resection of lesions in unifocal disease will not only debulk disease but may prevent bleeding and has been associated with increased survival [9, 103]. In hepatic mucormycosis, liver resection per se has been feasible as has removal of liver abscesses with good outcomes. In the event of SOT graft mucormycosis, the transplanted organ should be removed; whether re-transplantation is feasible should be considered on a case-to-case basis.

Surgery is a mainstay for cutaneous and soft tissue infection and should be prompt and aggressive as infection is rapidly progressive. While resection of all grossly abnormal tissue is essential, removal of some adjacent surrounding healthy-looking tissue also appears to be important for best outcomes. However, defining a margin of clearance is not straightforward, and sometimes, sacrifice of limbs or expendable bony structures (e.g., ribs) is necessary. Although frozen sections may be low-yield, the presence of fungal elements often necessitates immediate re-excision and can guide planning of repeat debridement. Ideally the same surgeon performs the debridements in order to achieve consistent reassessment [26].

Adjunctive Treatments

Topical Antifungals

The use of topically administered amphotericin B in conjunction with systemic antifungals in the management of various forms of mucormycosis has been described [summarized in 88]. Amphotericin B has been administered into the eye (for retinitis), into wounds, impregnated into bone cement, and inhaled or locally instilled into the lung via bronchoscopy. Instances of intrathecal administration percutaneously or via an Ommaya reservoir are also reported. However, data supporting these approaches are lacking given the inadequate descriptions of drug

doses and methods of solution preparation as well as a paucity of information regarding the stability and safety of these formulations.

Iron Chelators

Iron is essential for the metabolism of many fungi, and strategies to starve Mucorales of iron such as through the use of iron chelators make logistic sense. However, despite extensive study, the utility of these compounds in the treatment of mucormycosis remains uncertain.

Deferasirox (Exjade, Novartis) is one chelator that cannot be used as a siderophore by Mucorales. The drug has been shown to be efficacious and safe, largely in patients with diabetes [104]. However, a double-blind randomized controlled study showed increased mortality in deferasirox-treated patients as compared to those treated with an amphotericin B formulation [60]. This study enrolled mainly patients with hematologic malignancy and cautioned against the use of deferasirox. Deferasirox is known to be potentially toxic to the bone marrow and kidneys and may cause harm to neutropenic patients with mucormycosis [105]. Future research in this space is warranted, though for the current time adjunctive deferasirox use should be avoided.

Augmentation of Host Immunity and Reversal of Host Risk Factors

In neutropenic or highly immunosuppressed hematologic malignancy and SOT patients with mucormycosis, granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF) has been added to antifungal treatment in a small number of patients with good results [106]. A report of successful use of combination of the immunomodulator nivolumab and interferon-γ in a patient with intractable abdominal mucormycosis was recently published [107]. Overall, data suggest that growth factors may be useful in neutropenic patients with mucormycosis. In patients with diabetes mellitus, correction of hyperglycemia and ketoacidosis is essential.

Hyperbaric Oxygen

Clinical experience with the use of hyperbaric oxygen as adjunctive therapy for mucormycosis is limited to case reports or small case series [108] and has involved a wide spectrum of clinical presentations with only small numbers of hematologic malignancy and transplant patients. At present, data indicate that there is insufficient evidence to define the efficacy of this expensive treatment, but it may be considered in refractory disease.

Conclusions

In conclusion, Mucorales infections in transplant patients are uncommon. However, the disease progresses rapidly with dissemination and high mortality. Epidemiology varies with geographic region, and the population of patients at risk is

expanding with the introduction of newer more intense immunosuppressive therapies. Early diagnosis is essential for optimal outcomes. There have been recent advances in molecular-based methods for direct detection of Mucorales DNA in clinical specimens including in blood of high-risk hematologic malignancy patients.

There are no specific preventative or antifungal prophylaxis measures against mucormycosis. Large studies or randomized controlled trials investigating the efficacy of treatment regimens are still lacking. Surgical debridement should be performed whenever feasible. The drug of choice remains liposomal amphotericin B ($\geq$5 mg/kg/day), with dose adjustment in renal failure if necessary. In cases of extensive disease or rapid progression, the addition of isavuconazole or posaconazole may be considered. Isavuconazole or posaconazole may be administered as maintenance therapy. Treatment should be continued until resolution of clinical or imaging findings and reconstitution of the host immune system.

Key Points

- Mucorales infections are emergent in both stem cell as well as solid organ transplant recipients whereby those receiving intense anti-rejection therapies or newer immunomodulating therapies may be at increased risk. Outbreaks of infection can occur.
- *Rhizopus spp*. remain the most common causative agent worldwide.
- Diagnosis should be multifaceted involving imaging, histopathology of affected sites for visualization of characteristic broad pauci-septate hyphae, culture, and molecular-based tests.
- Cases of suspected or diagnosed infection require a rapid or immediate response to imitation of therapy as mortality is high and infection is rapidly progressive.
- Management is multidisciplinary involving early surgical resection or debridement-affected sites and areas of necrosis, antifungal therapy, and reversal of immunosuppression where possible.
- There are no robust data from randomized controlled treatment trials; hence, recommendations for antifungal therapy are based on relatively small comparative studies, open-label studies, and expert opinion.
- The first-line antifungal agent (drug of choice) is liposomal amphotericin B 5–10 mg/kg/d. Alternatively, isavuconazole (either IV or oral; 600 mg/d for days 1–2, then 200 mg/d)) has been licensed for first-line treatment of mucormycosis in the USA. If amphotericin B formulations cannot be used and isavuconazole is not available, then posaconazole delayed-release tablets or infusion (600 mg/d for day 1, then 300 mg/d) could be considered for first-line treatment.
- In cases of particularly aggressive or disseminated infection, combination antifungal therapy should be considered. Polyene-azole (posaconazole typically) combination has been used with varying success, whilst polyene-echinocandin

combinations have been used with good result in small numbers of patients with rhino-orbital-cerebral disease.
- Data strongly support the use of both isavuconazole and posaconazole both as (i) "step-down" therapy following amphotericin B use, and (ii) as salvage treatments when amphotericin B is no longer an option.
- The use of iron chelators to treat mucormycosis is not recommended.

Introduction

Non-*Aspergillus* fungal infections in recipients of organ (SOT) and stem cell (HSCT) transplantation are uncommon yet present unique challenges. The variety of clinical presentations and often refractory nature of the infections compounds the difficulty in managing these patients. In this chapter, we will focus on a group of fungi that are seen rarely in clinical practice, though increasingly reported in recent years due to an increased number of immunocompromised patients at risk. Outside the commonly recognized filamentous fungi such as *Aspergillus* and *Mucorales* are a large and heterogenous group of fungi that are associated with diverse clinical

presentations. For the purposes of this discussion, we will consider the dematiaceous fungi (associated with phaeohyphomycosis), *Fusarium* (*F.*) spp., *Scedosporium* (*S.*) spp., and Microsporidia, which have been recently reclassified as fungi. Phaeohyphomycosis is caused by a large group of darkly pigmented fungi that are difficult to categorize into a simple framework and represent dozens of unique organisms [1]. Although rare, these infections are being increasingly seen in a variety of clinical syndromes in both immunocompromised and normal individuals. Transplant patients in particular are at high risk due their prolonged immunosuppression. *Fusarium* spp. are often associated with plants and traumatic inoculation and may be drug resistant [2]. *Scedosporium* spp. are emerging as important causes of invasive and refractory mycoses in immunocompromised patients [3]. Microsporidia have typically caused gastrointestinal disease, though in highly immunocompromised patients, disseminated infection is not uncommon [4]. As the numbers of immunocompromised patients from transplantation increases, management of these unusual infections will continue to present a challenge for clinicians.

Epidemiology

The most common fungal infections after SOT and HSCT are candidiasis and aspergillosis, characteristically presenting as fungemia and pulmonary infection, respectively. However, non-*Aspergillus* infections account for 7–10% of fungal infections and have varied clinical presentations [5]. Lung transplant patients have the highest rate of invasive mold infection at 12.5%, followed by small bowel transplants (11.6%), lung (8.6%), and liver (4.7%), with renal transplants having the lowest risk (1.3%) though most infections occur in renal transplants due to the higher number of transplants performed [5]. Non-*Aspergillus* mold infections usually present 10–14 months after transplant. Liver transplant recipients may have earlier infections, with an average presentation less than 3 months after transplant [5]. Risk factors for fungal infections in general include prolonged surgery, hepatic and renal dysfunction, and concurrent cytomegalovirus (CMV) and HHV-6 infection. Specific organ transplants have unique risks. For lung recipients risks include airway colonization with mold (typically *Aspergillus*), CMV infection, and anastomotic ischemia. Risks for kidney recipients include pretransplant dialysis, diabetes, tacrolimus, and prolonged and high-dose steroid use. Fungal infection risk in heart recipients is increased with CMV disease, posttransplant dialysis, and the presence of *Aspergillus* in bronchoalveolar lavage [6]. In general, these uncommon fungal pathogens are found in soil, associated with plants, or in environmental water sources, and distributed worldwide.

Dematiaceous fungi are a large and heterogeneous group of primarily molds. Some studies have suggested that dematiaceous fungal infections are more common in warmer climates [7]. Specific fungi appear to be geographically restricted, such as *Rhinocladiella (R.) (*formerly *Ramichloridium) mackenziei*, which has primarily been seen in patients from the Middle East [8]. Exposure is likely from inhalation or minor trauma, which is typically not noticed by the patient. Surveys of outdoor air

for fungal spores routinely observe dematiaceous fungi [9]. As they are ubiquitous in the environment, individuals are constantly exposed to them, though they remain uncommon causes of disease. Most life-threatening infections due to these unusual fungi are seen in immunocompromised patients, with the possible exception of CNS infection caused by dematiaceous fungi. Incidence of phaeohyphomycosis is 0.16–3.6%, depending on the type of transplant [7, 10]. Cases are fairly evenly divided between HSCT and SOT patients. Average diagnosis is made at 20 months posttransplant [11]. In one large series, the most common genus was *Exophiala*, and overall mortality was 19%. Cases were sporadic, and no clear pattern was observed [12].

Fusarium and *Scedosporium* are uncommon in HSCT patients (3.8%) and distinctly rare in SOT, accounting for 0.2–0.7% of cases of fungal infection [13]. Rates have been low and generally stable over time, though mortality is high. *F. solani* is the most common species causing disease [14]. Exposure is generally thought to be from environmental sources such as plants and soil, though food has been implicated as a risk factor, as *Fusarium* can be isolated from a variety of foods, including fruit, nuts, vegetables, and cereals [15]. Other molds have also been isolated but with unclear significance. *Scedosporium* is found in the environment, typically in soil and water sources [16]. Near-drowning is frequently associated with pneumonia and even disseminated infections due to this fungus. Multiple species are in this genus with recently changing taxonomy. Common species are *S. apiospermum* and *S. boydii* [16]. Median time to diagnosis is 4 months after transplant [14].

Microsporidia are commonly found in water sources and typically cause self-limited diarrheal illness, though in transplant patients, dissemination can be seen [4]. Though there are over 1400 species of Microsporidia, only about 1% are known to infect humans, including *Enterocytozoon bieneusi* and *Encephalitozoon cuniculi* [4].

Diagnosis

The diagnosis of infections due to non-*Aspergillus* fungi requires a high degree of clinical suspicion, especially in transplant patients. Careful assessment of signs and symptoms should lead to further imaging and/or acquisition of appropriate tissue samples for diagnostic testing. Radiologically, nodular lesions are the most common finding in the lung, though the "halo sign" is less frequent than in neutropenic patients with aspergillosis [6]. Biopsy of relevant lesions is also essential, as blood and sputum cultures are usually unrevealing. It is important to recognize that the histology of *Fusarium* and *Scedosporium* infections is similar to Aspergillus, so that results of culture are often critical to making a specific diagnosis [14]. In contrast, the histologic appearance of phaeohyphomycosis is often characterized by irregular hyphal elements and beaded, yeastlike forms [1]. However, it may still be difficult to differentiate this pathologically from infection due to other molds. In such cases, the Fontana-Masson stain, which is specific for melanin, can usually be used to confirm the presence of dematiaceous hyphae [1]. Currently, the diagnosis of these infections initially relies on pathologic examination of clinical specimens and careful

gross and microscopic examination of cultures, occasionally requiring the expertise of a mycology reference lab for unusual or newly described pathogens. Despite the various testing methodologies available in the modern clinical laboratory, culture remains the mainstay of diagnosis.

Unfortunately, no specific diagnostic tests are available to identify these fungi, particularly to the species level. No specific serologic, antigen, or polymerase chain reaction (PCR) methods are routinely available, which is partly due to the tremendous diversity of these pathogens. However, antigen tests that have been primarily useful for *Candida* and *Aspergillus*, such as serum β-D-glucan and serum or bronchoalveolar lavage (BAL) galactomannan, occasionally may be cross-reactive with this group of fungi, but this is not consistent [17, 18]. Galactomannan may be positive in *Fusarium* infections, and serum β-D-glucan, which is found in most fungal species, has also been positive in cases of phaeohyphomycosis, *Fusarium*, and *Scedosporium* infections [19, 20]. A recent study examined the utility of bronchoalveolar lavage β-D-glucan levels and found that BAL measurements were no better than serum levels in diagnosis [21]. One useful aspect of antigen testing was the finding that serum β-D-glucan may have good negative predictive value [6].

Studies have also begun to examine the potential of identifying species within this diverse group of fungi using PCR of highly conserved regions of ribosomal DNA [22]. Molecular identification has become more useful as one study demonstrated by identifying eight non-sporulating clinical isolates of dematiaceous fungi to the species or genus level by a combination of internal transcribed spacer (ITS) and D1/D2 rRNA typing [23]. Various PCR methodologies are under development for *Fusarium* and *Scedosporium*, but not currently available for routine clinical use [24]. Quantitative PCR for fungal diagnosis from tissue samples using specific primers has been able to detect *Fusarium* and *Scedosporium*, including a *Fusarium* isolate from tissue samples initially considered consistent with *Aspergillus*. PCR was found to be positive in 80% of cases with negative culture [25].

Matrix-assisted laser desorption ionization time-of-flight (MALDI-ToF) mass spectrometry is a useful method for microbial identification [26]. It is broadly effective across different groups of organisms grown in different conditions. It is rapid, providing results within a few minutes, though samples from an actively growing culture are needed. Sensitivity is good, needing only 10^4 organisms for detection [26]. However, difficulties in identifying molds arise due to differences in spores vs hyphae and the inherent biological complexity of fungal organisms. Clinically important fungi have been included in most databases, though uncommon molds are generally not reliably identified [26, 27]. Further database refinement is needed in order to be clinically useful, though this is time-consuming and laborious. MALDI-ToF for rare mold identification is still a work in progress.

The diagnosis of microsporidial infection is generally through microscopic examination of tissue samples or stool and use of specific stains [4]. Electron microscopy of tissue samples is very sensitive but time-consuming and not readily available [4]. PCR diagnosis of *Enterocytozoon bieneusi* and *Encephalitozoon cuniculi* has been described and may be more sensitive than microscopy but is not routinely available [28].

Clinical Disease

Many infectious syndromes are observed with these fungi (Table 1), ranging from superficial infections such as keratitis and subcutaneous nodules to invasive infections such as brain abscess and disseminated disease [1, 6]. In particular, phaeohyphomycosis encompasses many clinical syndromes due to a wide variety of dematiaceous fungi [29]. Clinical presentation may be indolent, particularly in solid organ transplant patients. Superficial infections are the most common form of infection due to these fungi, predominantly subcutaneous nodular lesions [12]. Although they rarely lead to life-threatening disease, significant morbidity can occur depending on the site of infection and response to therapy. There are numerous case reports of subcutaneous infection due to a wide variety of species [30, 31]. Minor trauma is the usual inciting factor, though it may be unrecognized by the patient. Lesions typically occur on exposed areas of the body and often appear as isolated cystic or nodular lesions. Occasionally, dissemination can occur, which can be refractory to therapy with high mortality [31, 32]. Keratitis is an uncommon but is a serious infection due to these fungi. Dematiaceous fungi account for up to 8–17% of cases, particularly in tropical regions, though *Fusarium* is common as well [33]. Deep local infection such as septic arthritis and osteomyelitis is rare and often difficult to treat, frequently requiring both surgical and combination medical therapy [34]. Pneumonia usually occurs in highly immunocompromised patients and may be due to a wide variety of species [35]. It is unclear what specific risk factors may contribute to pulmonary infection with these fungi, which are commonly found in the environment, though studies have found an association between pretransplant colonization and subsequent pneumonia in lung transplant patients [6]. Central

Table 1 Clinical syndromes associated with specific non-*Aspergillus* fungi and suggested therapy

Clinical syndrome	Commonly associated fungal genera (species)	Therapy
Subcutaneous nodules	*Exophiala* *Alternaria* *Fusarium*	Surgery +/- Voriconazole
Keratitis	*Curvularia* *Fusarium*	Topical natamycin +/- Itraconazole Voriconazole
Pneumonia	*Ochroconis* *Exophiala* *Scedosporium*	Voriconazole
Brain abscess	*Cladophialophora (bantiana)* *Rhinocladiella (mackenziei)* *Ochroconis*	Consider combination therapy – see discussion
Disseminated disease	*Lomentospora (prolificans)* *Curvularia* *Fusarium*	Consider combination therapy – see discussion
Microsporidiosis	*Encephalitozoon (cuniculi)* + others *Enterocytozoon (bieneusi)*	Albendazole Fumagillin

nervous system infection is a rare clinical manifestation, though it remains one of the most difficult to cure and mortality rates are high. The pathogenesis may be hematogenous spread from an initial, presumably subclinical pulmonary focus. Brain abscess is the most common presentation, with *Cladophialophora (C.) bantiana* the most common species isolated [36, 37]. Disseminated infection is the most uncommon manifestation of infection seen with dematiaceous fungi [38]. *L. prolificans* is the most common cause, but other species can be seen [32, 38]. In contrast to most invasive mold infections, blood cultures are positive in over half the cases, usually seen with *L. prolificans* [3, 38]. Infection with this species was also associated with septic shock. Infection with *L. prolificans* was associated with nearly 100% mortality in the absence of recovery from neutropenia [3, 39]. Survival in transplant patients with *L. prolificans* infection was associated with surgical resection (where feasible) and recovery of neutropenia, but not antifungal therapy [13].

Fusarium and *Scedosporium* cause disease with various clinical presentations and may also cause disseminated infection, though primarily in HSCT patients [14, 24]. *Fusarium* generally causes subcutaneous lesions and pneumonia, with the latter having high mortality, especially in lung transplant recipients [40]. Fungemia is also seen and, while mortality is high, can be treated successfully, even with subsequent HSCT [41]. However, disseminated *Fusarium* infection during HSCT is generally fatal, despite aggressive therapy [42]. Overall mortality rates are high, reported as 79% for *Fusarium* in a large registry and 58–72% for *Scedosporium* in SOT patients [3, 13].

Microsporidiosis in transplantation is uncommon but can be associated with severe disease. Chronic diarrhea is a typical presentation, especially in renal transplants [43, 44]. Graft dysfunction may be the presenting feature in renal transplants, in the absence of other symptoms [45]. Interestingly, donor-derived infections have also been described, with a predominantly encephalitic presentation [46, 47]. Dissemination is also observed but can be treated effectively if diagnosed promptly [47].

Therapy

There are no standardized therapies for infections caused by these uncommon fungi, though guidelines by the *European Society of Clinical Microbiology and Infectious Diseases* (ESCMID) and the American Society of Transplantation (AST) have been published, mostly based on animal models, case series, and expert opinion [48, 49]. There is no single antifungal agent that is effective against all these fungal species in all clinical settings. The choice of drug is made more difficult by the fact that these are rare infections, with no randomized clinical trials to guide therapeutic decisions. However, triazole agents demonstrate the broadest in vitro activity, including voriconazole, posaconazole, isavuconazole, and itraconazole. However, the dematiaceous fungi *L. prolificans* and *Scopulariopsis brumptii* are generally resistant to all available antifungals [50]. Length of therapy is generally based on clinical response and ranges from several weeks to several months or longer, including potentially lifelong suppressive therapy in immunocompromised patients with

infections such as brain abscess or endocarditis due to refractory pathogens [51]. The diversity of the pathogens and hosts makes it impossible to find a "one-size-fits-all" therapeutic strategy.

Voriconazole, posaconazole, and isavuconazole are better tolerated than itraconazole with a broader spectrum of activity and would be the preferred drugs for the non-*Aspergillus* molds. Though there is greater clinical experience associated with itraconazole, particularly against dematiaceous fungi, voriconazole and posaconazole are generally more active in vitro, particularly against *Fusarium* and *Scedosporium*. Voriconazole is the only agent FDA approved as salvage therapy for *Fusarium and Scedosporium* infections and may have improved clinical response vs other agents [3]. Voriconazole may also have advantages for central nervous system infections due to its ability to achieve good cerebrospinal fluid levels, unlike itraconazole [52]. All azoles likely achieve adequate brain tissue levels [53]. Posaconazole is very well tolerated with broad activity, particularly against *Aspergillus* and other molds, including *Fusarium* and *Scedosporium* [54]. Isavuconazole is the most recent broad-spectrum azole with tolerability comparable to fluconazole and less drug interactions than voriconazole and itraconazole [55]. Although clinical data are very limited, some efficacy with these uncommon fungi has been shown in small studies [56]. Itraconazole has in vitro activity against the vast majority of dematiaceous fungi and extensive clinical experience [1], but recent use has been limited due to adverse effects which have led to a black box label from the US Food and Drug Administration (FDA) cautioning against use in patients with ventricular dysfunction due to itraconazole's negative inotropic effects.

Therapy in patients with organ transplantation should be continued longer than in other settings, and the use of surgery (when appropriate) should be strongly considered. Management of drug interactions is critically important when using triazole antifungals, as all the above have significant effects on many drugs used in transplant patients, notably calcineurin inhibitors [57]. Monitoring of drug levels of both immunosuppressives and triazoles (except perhaps isavuconazole) should be routinely performed.

Superficial and Deep Local Infections

Superficial infections are the most common form of infection due to these fungi in transplant patients. Oral systemic therapy with an azole in conjunction with surgery is usually employed and often successful, though relapses can occur [12, 23, 29]. Surgical excision alone has also been successful in a number of cases [23, 30]. Keratitis is often treated with topical polyenes, such as natamycin and amphotericin B, but oral and topical itraconazole has been found to be useful as well, particularly in refractory cases [1]. Recent clinical experience suggests voriconazole and posaconazole are potentially useful agents as well [58]. Penetrating keratoplasty can be performed in those patients failing initial therapy, though many patients are left with residual visual deficits [1]. Deep local infection such as septic arthritis and osteomyelitis is rare and often difficult to treat, frequently requiring both surgical and combination medical therapy [59].

Pneumonia

This usually occurs in highly immunocompromised transplant patients and may be due to a wide variety of species [35]. Mortality rates are high in these cases. Experience with voriconazole is accumulating, and it would be favored in this setting given its efficacy in pulmonary aspergillosis [13, 14]. Posaconazole has also been reported as successful in a case report of *Phaeoacremonium* pneumonia [60].

Central Nervous System Infection

Though this is a rare clinical manifestation of infection, it remains one of the most difficult to cure, and mortality rates are high, regardless of therapy. *C. bantiana* is the most common species isolated, usually seen in brain abscesses [29]. In general, available evidence and recommendations suggest combination therapy is preferred, though it remains unclear which combination is optimal. One review showed that amphotericin B, flucytosine, and itraconazole may be associated with improved survival, though it was used in a small number of cases [8]. Guidelines suggest voriconazole, flucytosine, and an echinocandin, with or without amphotericin B, based on animal models and case reports [48]. Complete excision of brain abscesses appeared to have better outcomes than aspiration or partial excision [61]. Outcomes are poor, with an overall mortality >70% [61]. Posaconazole has also been used successfully, including cases of *Rhinocladiella* and *Scedosporium* brain abscess [62, 63]. Some patients are placed on indefinite suppression with voriconazole or posaconazole once the infection has been successfully treated [51].

Disseminated Infection

This is the most uncommon manifestation of infection seen with these fungi. There are no antifungal regimens associated with improved survival in disseminated phaeohyphomycosis, including multiple combination therapies [13, 29]. Anecdotal reports of successful treatment may be instructive, however [29]. *Fusarium* and *Scedosporium* may also cause disseminated infection, though primarily in hematopoietic stem cell transplant patients [13, 14]. Combination therapy with voriconazole and amphotericin B or an echinocandin has shown promising results in fusariosis, though with limited data [24, 40, 41].

Therapy for microsporidial infections is limited to albendazole and fumagillin, based on small studies. Albendazole may be effective for most species, except *Enterocytozoon bieneusi* [4], where fumagilin has been used with success [43]. Duration of therapy varies widely, depending on the severity of infection and host immune status, ranging from 2 weeks to 12 months [45]. Albendazole is better tolerated and can be given for prolonged therapy. Fumagillin is associated with thrombocytopenia and neutropenia, and therapy is usually 2–4 weeks [64].

Alternative Therapy

There are few useful alternatives to triazole antifungal agents against these uncommon fungal infections. Amphotericin B (AmB) may be useful for severe disease given its broad fungicidal activity against most pathogens, though isolates of *Fusarium* and *Scedosporium* are frequently resistant [24]. However, use of lipid AmB preparations allows for much higher doses than possible with standard amphotericin B, which may improve their efficacy against these fungi. The pharmacodynamics of these formulations are different from standard amphotericin B and may also affect their overall efficacy for specific infections [65]. However, given the need for parenteral administration, use of these agents is mostly confined to serious infections in unstable patients. Once the infection is under control, longer-term therapy with a broad spectrum oral azole is often reasonable until complete response is achieved.

Terbinafine inhibits ergosterol synthesis but acts on a different target than azoles. It is also considered fungistatic, and its clinical role has been relegated to treatment of dermatophyte infections. However, in vitro activity is quite broad and includes many non-dermatophyte molds [66]. There has been recent interest in potentially expanding its clinical spectrum [66]. However, its extensive binding to serum proteins and distribution into skin and adipose tissue have diminished enthusiasm for its use in treating serious systemic fungal infections [66]. However, terbinafine was used to successfully treat a case of *E. jeanselmei* subcutaneous infection in a heart transplant patient after failing itraconazole [67].

Miltefosine, originally developed as an antineoplastic agent and used in protozoal infections, also has significant antifungal activity against a broad range of pathogens [68]. Clinical experience is anecdotal, though a case of refractory infection due to *Scedosporium prolificans* appeared to respond to the addition of miltefosine [69].

Combination therapy is a potentially useful strategy for refractory infections, though it has not been studied extensively and is not routinely recommended except in cases as mentioned above. Terbinafine in particular appears to provide synergistic activity with azole antifungals, and this may be a useful strategy against refractory subcutaneous infections [66]. The mechanism is presumably potent inhibition of ergosterol synthesis at two different steps of the pathway by these agents. In addition, case reports have suggested that the combination of itraconazole or voriconazole with terbinafine may be synergistic against *S. prolificans* and improve outcomes, though more recent studies cast doubt on this finding [29].

Echinocandins do not have significant activity against filamentous fungi other than *Aspergillus* and would not be recommended as single agents. However, a case of refractory bone and joint infection due to *S. prolificans* was treated effectively with the combination of voriconazole and caspofungin [70].

There are no controlled trials to determine when surgery is most effective for these infections. However, for several of the above clinical presentations, surgery may be curative or significantly improve outcomes. For subcutaneous abscess in

particular, surgery alone has been effective, though in immunocompromised patients, follow-up antifungal therapy is often given. Outcomes for brain abscess may be improved with the use of surgical drainage and/or excision, if possible. Frequently, single lesions are present, which may make surgical resection more feasible. Granulocyte transfusions have been used in patients with refractory fungal infections and neutropenia, though meta-analysis did not show a mortality benefit [71]. Further studies are ongoing, though no randomized controlled studies are available.

Prophylaxis

Voriconazole is commonly prescribed as prophylaxis in high-risk transplant patients (particularly lung), with itraconazole, posaconazole, and aerosolized amphotericin B as alternatives. Duration is usually 3–12 months, depending on the institution [72]. Detection of *Aspergillus* in the first 3 months should be a consideration for preemptive therapy, though non-*Aspergillus* molds have not been associated with post-transplant infection [72]. There are no studies that specifically examine outcomes of prophylaxis for these rare molds. However, the newer azoles with activity against *Aspergillus* would be expected to be effective in prophylaxis for these fungi as well. As these are uncommon infections, even large trials are unlikely to show a significant trend in these infections.

Infection Control

Dematiaceous fungi are routinely found in ambient air, and prevention from this source is not practical, except perhaps in immunocompromised patient units with HEPA filtration precautions for other, more common fungi such as *Aspergillus* [73]. In one hospital study, *Fusarium* was isolated from over half of water system samples, with patient isolates matching some environmental isolates by molecular typing [74]. No person-to-person transmission has been demonstrated.

Conclusion

Non-*Aspergillus* fungi are rarely seen in clinical practice, though they are important agents of disease, particularly in transplant patients. A high index of suspicion is needed when evaluating patients who have undergone organ or stem cell transplantation for possible fungal infection. These fungi often have unique clinical manifestations and appearance in tissue, though often are not detected with routine antigen tests. Culture remains the mainstay for diagnosis. Newer methods of diagnosis, such as PCR or MALDI-ToF, are promising, but not widely utilized. Therapy is individualized, especially for disseminated infections, with combination therapy commonly employed. Though azoles such as

voriconazole and posaconazole have the most recent clinical experience, optimal therapy for most of these infections is unclear, due to a lack of randomized trial data.

Key Points

- Non-*Aspergillus* molds have varied clinical presentations in transplant patients.
- Specific diagnostic testing is not routinely available, but serum galactomannan and β-D-glucan may be positive.
- Therapy is not standardized, though voriconazole and posaconazole are active and have accumulating clinical experience.
- Combination therapy may provide improved outcomes in selected patients.

Introduction

Cryptococcus species are encapsulated yeasts responsible for a broad range of infections. There are two major species within the cryptococcal genus, *Cryptococcus neoformans* and *Cryptococcus gattii* [1]. These vary with regard to geographic distribution, populations affected, disease manifestations, and severity [1, 2]. Pulmonary and central nervous system (CNS) diseases are well-known presentations of cryptococcosis, with meningoencephalitis the most frequent and serious manifestation, especially in SOT and HSCT recipients [3]. Infection less frequently involves

other sites such as the blood, skin, skeletal system, and prostate [4]. Diagnosis is made with antigen testing from serum or cerebrospinal fluid or culture or histopathology from infected tissues. Treatment of cryptococcosis is based on anatomic site of disease, severity of disease, and the underlying immune status of the patient. Cryptococcal meningitis is treated with induction therapy of an amphotericin B formulation and flucytosine, followed by a prolonged course of fluconazole. For pulmonary disease alone that is less severe, fluconazole for a minimum of 6 months is effective therapy in most patients. Chronic maintenance therapy with fluconazole may be required in transplant patients who remain immunosuppressed and at risk for relapse.

Disease Epidemiology

More than 30 species of the genus *Cryptococcus* have been described, but few are recognized as causing infection in humans [5]. Infection is caused primarily by two species, C*ryptococcus neoformans* and *Cryptococcus gattii*. *C. neoformans* is a fungus that is ubiquitous in the environment. It was isolated initially in nature from peach juice in 1894 by Francisco Sanefelice and was first isolated from soil by Emmons in 1951 [6]. *C. neoformans* has since been isolated from multiple geographic sites worldwide, many of which are contaminated by pigeon or other bird excrement [7]. *C. neoformans* has been isolated less commonly from other sources including fruits and vegetables, decaying wood, dairy products, and excrement from a wide variety of avian species [7].

Cryptococcus gattii, previously regarded as being limited to primarily tropical and subtropical regions, has recently been described throughout the world with the emergence of *C. gattii* infection in Vancouver Island and British Columbia, Canada, and in the Pacific Northwest of the United States since the late 1990s [8–15]. Ecologically, *C. gattii* is found in soil and in association with eucalyptus trees and in other tree species native to biogeoclimatic zones in British Columbia and the Pacific Northwest [1, 16, 17]. With more awareness and use of molecular testing, *C. gattii* is increasingly been identified in areas around the world, with marked genotypic diversity [18].

C. neoformans and *C. gattii* were first distinguished by their antigenic diversity according to serotypes based on structural differences of the polysaccharide capsule: *C. neoformans* strains are classified as serotypes A and D and *C. gattii* strains classified as serotypes B and C [5]. Molecular testing methods have confirmed great diversity within the *C gattii-C neoformans* complex, and new taxonomy has been proposed: *C. neoformans*, divided into *C. neoformans* (serotype A, formerly *C. neoformans* var. *grubii*), and *C. deneoformans* (serotype D, *C. neoformans* var. *neoformans*); *C. gattii* would be recognized as five separate species, namely, *C. gattii* (VGI), *C. deuterogattii* (VGII), *C. bacillisporus* (VGIII), *C. tetragattii* (VGIV), and *C. decagattii* (VGIV) [19]. Several other cryptococcal species, *C. albidus* and *C. laurentii*, have been reported to rarely cause disease in humans [20]. Other rare

cryptococcal species that can cause human infection and may be encountered in SOT recipients include *C. albidus* and *C. laurentii* and may only be diagnosed on culture.

In the majority of cases of cryptococcosis, initial infection occurs by inhalation of the organism from an environmental source. Disease typically results from reactivation of dormant infection [21, 22]. Local inoculation can cause skin infection, but skin lesions most often result from disseminated infection from an initial lung source [23, 24]. Presumed human-to-human transmission has been described: one case involved corneal transplantation and another resulted from inoculation of blood from a patient with cryptococcemia [25, 26].

There have been a number of presumed donor-to-donor transmissions of cryptococcosis via solid organs with disease manifestations presenting up to 3 months post-transplant [27–29]. Donor-derived cryptococcosis should be considered when the diagnosis occurs in the recipient within 30 days of transplant, when cryptococcosis is diagnosed in more than one organ recipient from a single donor, or if *Cryptococcus* is documented at the surgical or graft site [3, 27].

Evidence supporting zoonotic transmission of *Cryptococcus* has also been reported [30–32]. In one description, a clinical isolate from a renal transplant recipient with cryptococcal meningitis was indistinguishable on the basis of molecular genotyping from an isolate present in the feces of the patient's pet cockatoo [30].

Epidemiology and Risk Factors in Solid Organ Transplant

Cryptococcosis is the third most common invasive fungal infection in solid organ transplant recipients, less frequent than candidiasis and aspergillosis [33]. Typically, the overall incidence of cryptococcosis in SOT recipients ranges from 0.2% to 5%, and cryptococcosis comprises 8% of all fungal infections [34, 35]. Cryptococcosis is typically a late-occurring infection; with the median time to onset post-transplant ranging from 16 to 21 months [35]. The time to onset is typically earlier (<12 months) for liver and lung transplants, when compared to kidney transplant recipients [36].

Immunosuppression is an important risk factor for cryptococcosis. Among patients without HIV infection, corticosteroid use is associated with an increased risk of cryptococcosis [37–39]. For SOT patients, it remains unclear what dose is related to increased risk [40]. Other immune suppressants such as alemtuzumab and antithymocyte globulin are also associated with increased risk of cryptococcosis [41, 42]. Calcineurin inhibitors (CNI) do not appear to increase the risk of cryptococcosis, but may affect outcomes in patients with cryptococcosis [43, 44]. Receiving a CNI-based regimen was associated with lower odds of disseminated cryptococcal disease when compared to a non-calcineurin-based regimen [44]. This finding may be related to the anti-cryptococcal activity of CNIs, which target the fungal homologs of calcineurin [44, 45].

Additional independent risk factors for cryptococcosis in SOT patients include older age, diabetes, and lung transplant (compared to other SOT types) [36].

Epidemiology and Risk Factors in Stem Cell Transplant

Cryptococcosis is an uncommon infection among HSCT recipients, with fewer than 15 cases reported [34, 35, 46, 47]. The decreased incidence in this population, in contrast to SOT patients, may be related to the widespread use of azole antifungal prophylaxis or differences in immunosuppression [34]. To date, infections by *C. neoformans*, *C. albidus*, *C. laurentii*, and *C. adeliensis* have been reported [34]. The timing of cryptococcosis has ranged from pre-transplant to 6 months post-transplant [34, 47]. Cases have been more common among recipients of autologous stem cell transplants, possibly related to a dominant T-helper 2 phenotype making autologous transplant patients more susceptible [34]. In most cases, disseminated disease (brain, blood, skin) was present.

Clinical Impact on Transplant

The symptoms and signs of cryptococcal infection among transplant patients are typically non-specific; they can be insidious or severe. In patients with pulmonary infection, disease manifestations range from colonization to asymptomatic infection to severe pneumonia with fulminant respiratory failure and acute respiratory distress syndrome (ARDS) [48–50]. However, the diagnosis of colonization in the transplant patient should be interpreted with caution. Because of the propensity of *Cryptococcus* for dissemination to the central nervous system (CNS), a thorough evaluation for extrapulmonary sites of cryptococcal involvement in the transplant patient is recommended [3, 4].

Symptoms of pulmonary cryptococcosis are non-specific and may include fever, chills, cough, malaise, night sweats, dyspnea, weight loss, and, rarely, hemoptysis. Radiographic features are varied and may reveal single or multiple nodular lesions, patchy consolidations, interstitial infiltrates, mass lesions, mediastinal or hilar adenopathy, or, less commonly, pleural effusions [48, 51–53]. Because of these non-specific radiographic findings, it is important that the differential for causative agents is broad. Radiographically, *C. gattii* pulmonary infection in HIV-negative patients may be associated with mass-like lesions that may be mistaken for malignancy [54].

The most common clinical manifestation of cryptococcosis in transplant patients is CNS infection, manifested typically as meningitis, which can be subacute or chronic in nature [55]. A wide range of symptoms and signs can be present with CNS cryptococcosis, but complaints are often mild or non-specific and include headache, nausea and vomiting, malaise, altered mental status, and fevers. Unlike in bacterial meningitis, meningismus is uncommon. Cranial nerve dysfunction may result from increased intracranial pressure, cryptococcal invasion of cranial nerves, or brain parenchymal lesions (cryptococcomas) [5]. Seizures, often a reflection of increased intracranial pressure or focal mass lesions, tend to occur later in the course of disease [56, 57].

Increased intracranial pressure associated with cryptococcal meningitis a prominent finding and causes increased morbidity and mortality [58]. Cryptococci may cause outflow obstruction by blocking passage of CSF across arachnoid villi. In addition, soluble cryptococcal capsular polysaccharide may accumulate in arachnoid villi, leading to alterations in CSF drainage, with subsequent elevation of intracranial pressure potentially leading to hydrocephalus, blindness, deafness, or death [58, 59]. An opening CSF pressure of >250 mm water is found in approximately half of transplant patients. Consequently, routine assessment of suspected cryptococcal meningitis should always include manometry [3, 4]. Brain CT imaging is also important to evaluate for hydrocephalus related to elevated ICP or potential mass lesions (cryptococcomas); however, it has suboptimal sensitivity for evaluating cryptococcomas when compared to MRI. In a recent study evaluating neuroimaging findings in transplant patients with cryptococcosis, outcomes tended to be worse in patients with parenchymal lesions when compared with meningitis or hydrocephalus [55]. Cerebral cryptococcomas are more common in patients with *C. gattii* infection than in patients with *C. neoformans* infection [13, 60].

Other sites where cryptococcal lesions may occur include the skin and soft tissues, prostate gland, liver, kidney, bones, and joints [61, 62]. Cryptococcal skin lesions are seen in up to 10% of transplant patients with cryptococcosis [63, 64]. Disease may manifest as a variety of skin lesions, including pustules, papules, purpura, ulcers, cellulitis, superficial granulomas or plaques, abscesses, and sinus tracts. The majority of lesions are found on the lower extremities and often associated with CNS disease [64]. While cutaneous lesions largely represent hematogenous dissemination in transplant patients, the skin may also be a portal of entry for *Cryptococcus* and a potential source of subsequent disseminated disease in transplant recipients [24].

Cryptococcosis in transplant patients is usually disseminated (extrapulmonary) at time of diagnosis. The majority of patients have meningitis and pulmonary or extrapulmonary infection [43, 44, 65]. In a recent observational study of SOT patients, 61% had disseminated disease: 54% pulmonary and 8.1% skin, soft tissue, or osteoarticular disease [44]. Among SOT organ types, liver transplant recipients were at increased risk for developing disseminated disease. Cryptococcemia is also common among SOT patients, found in up to a third of this patient group [43, 44, 66]. Patients with CNS disease are more likely to be fungemic than those without CNS disease [55].

In the current era, mortality in SOT patients with cryptococcosis ranges from 5% to 30% [34, 36, 67]. In contrast, higher mortality, up to 70%, has been seen in patients infected with *C. gattii* [60]. Prognostic factors for cryptococcal meningitis have been characterized for various patient groups [5, 66, 68]. In general, these include the underlying disease or predisposing condition, the burden of organisms, titers of CSF cryptococcal antigen, mental status at baseline, and the ability to mount an inflammatory response in CSF. Among SOT patients, one study identified altered mental status, absence of headache, and liver failure as predictors of mortality [66]. Among patients living with HIV, lack of inflammation on CSF examination, low CSF glucose, and high cryptococcal antigen are associated with increased

mortality [69]. A factor related to lower mortality is receipt of a calcineurin inhibitor, which may be attributable in part to their synergistic interactions with antifungal agents [44, 70].

Diagnosis

When diagnosing cryptococcosis, it is important to evaluate for site and extent of infection, which may help to inform choice of antifungal agent and duration of therapy [4, 71]. For diagnosing pulmonary cryptococcosis, detection of the organism can be made from tissue biopsy specimens or bronchoalveolar lavage fluid [72]. On routine hematoxylin and eosin staining of lung and other tissues, *C. neoformans* is difficult to identify. Gomori methenamine silver (GMS) or periodic acid-Schiff (PAS) staining allow for identification; the organism can be recognized by its oval shape and narrow-based budding [73]. Mucicarmine staining, which stains the capsule rose to burgundy in color, can help to differentiate *C. neoformans* from *Blastomyces dermatitidis* and *Histoplasma capsulatum* [73]. Prostate or kidney infection may be diagnosed by yeast in the urine, and clinical suspicion is needed to make this diagnosis [61]. Biopsies with histopathology culture of other tissues will confirm the diagnosis of cryptococcosis.

Transplant patients with suspected or proven cryptococcosis should undergo a thorough evaluation for extrapulmonary sites of infection, including a lumbar puncture and cultures of blood, urine, or other tissues, as indicated by clinical signs and symptoms. Blood cultures for *Cryptococcus* may be helpful, as they are positive in up to 45% of patients with meningitis [55]. For evaluation of suspected CNS infection, opening pressure should be determined and CSF samples tested for Gram's and fungal stains, cell count, glucose, protein, fungal culture, and cryptococcal antigen. Culture of the organism will allow for species identification (*C. neoformans* or *C. gattii*); susceptibility testing can be performed if indicated. In research settings, quantitative CSF cultures have been utilized which provide valuable clinical information for determining treatment outcomes [74]. The CSF quantitative culture is a simple technique using a 100 μL input volume of CSF with five 1:10 serial dilutions in water, plating on Sabouraud dextrose agar, and then quantitative culture counting on the plate with the least growth [74]. The change in quantitative culture growth with subsequent serial lumbar punctures gives clinicians valuable feedback on the rate of CSF *Cryptococcus* clearance and when the CSF may be sterilized with treatment.

India ink staining is an inexpensive, rapid method to detect *Cryptococcus* in the CSF [75]. The stain is not taken up by the thick *Cryptococcus* capsule, forming a halo of light by which it can be visualized using a light microscope [75]. However, the sensitivity is not ideal, up to 80% [76]. In patients with early disease and a lower burden of infection (*Cryptococcus* CFU values $<$1,000 per ml of CSF), sensitivity is less than 50% [76].

Cryptococcal antigen testing from CSF and serum has become the preferred method of diagnosis in transplant patients [4]. Latex agglutination (LA) testing

and the lateral flow assay (LFA) are currently available. The LA test for diagnosis of cryptococcal meningitis is sensitive and specific (>90%), but less sensitive for diagnosing *C gattii* infection [13, 60, 77]. Typically, titers using LA are higher with leptomeningeal than intraparenchymal brain lesions, but lower in SOT recipients when compared to patients living with HIV [66]. The LA test requires additional laboratory time and is less useful in resource limited areas [77]. In contrast, the LFA is a point-of-care test that requires no specimen preparation. LFA is more sensitive to polysaccharide across the four cryptococcal serotypes than the LA test. However, this increased sensitivity may lead to false-positive results in patients with low titers (1:2), so clinical correlation is important [78]. Given this and its low cost, LFA is the preferred method [76, 79]. It is important to note that a prozone effect may occur in high cryptococcal burden states [80, 81]. High serum cryptococcal antigen titers are typically present in patients with disseminated and/or CNS disease and lower in patients with isolated pulmonary disease [53]. Cryptococcal antigen testing to evaluate for pulmonary disease is still useful, as there is up to 83% sensitivity of cryptococcal antigen testing in SOT patients with pulmonary involvement [53].

The identification of cryptococcal species (*C. neoformans* vs. *C. gattii*) has become increasingly important, as it may affect choice of antifungal therapy and perhaps outcomes [18, 60, 82]. Currently histopathologic methods and cryptococcal antigen testing are not sufficient to distinguish *C. neoformans* and *C. gattii*. Other options such as canavanine glycine bromothymol blue (CGB) agar, PCR, matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) or loop-mediated isothermal DNA amplification, high resolution melt analysis, or multilocus sequence typing will determine the correct species but may be available only in specialty laboratories [13, 83–86].

The FilmArray ME panel (Biomerieux, North Carolina), a multiplex PCR test, is approved for the rapid diagnosis of *C. neoformans* and C. *gattii* from CSF. The test can detect up to 20 other viral and bacterial targets and the turnaround time is 1 h [87]. However, there have been concerns about the accuracy of this test in clinical specimens [88]. For example, the FilmArray ME panel demonstrated an overall percent positive agreement (PPA) of only 52% (26/50) for *Cryptococcus neoformans/C. gattii.* The percent positive agreement of the FilmArray assay for *C. neoformans/C. gattii* was 92.3% (12/13) when the results were compared directly to the results of routine fungal smear or culture from initial presentation [88]. The FilmArray ME test for detection of *Cryptococcus* is best when organisms are seen on CSF; however, this is slower and far more expensive than the LFA (Table 1). The concern is that the FilmArray may not be as sensitive when no organisms are present. Even with antifungal therapy, PCR should still detect remnants of cryptococcal organisms [89]. Therefore, a negative PCR should not preclude performing an LFA simultaneously to exclude cryptococcal meningitis [90].

Another multiplex PCR testing panel is the YEAST panel, which targets 21 clinically important fungal organisms [91]. Although not commercially available, a study using reference strains showed that multiplex PCR was 100% specific in identifying *Cryptococcus* [91].

Table 1 Summary of diagnostic tests for *Cryptococcus*

Test	CSF	Serum	*C. gattii*	*C. neoformans*	Turnaround time	Cost	Others	Comments
Approved								
Culture	+	+	+	+	3–14 days	+	CGB test for *C. gattii* identification	Useful for susceptibility testing and species identification
Quantitative culture counting	+	–	+	+	Minutes	+	Good for monitoring treatment responses	Mostly being used in clinical trials but being proposed as clinical marker
Mucicarmine	–	–	+	+	1–2 days	+		Only from tissue
India ink	+	+	–	–	Minutes	+		Low sensitivity, may miss diagnosis in 14% of cases or in low burden infections
Latex agglutination	+	+	+/–	+	1–2 hours	+	Good for following treatment responses	False negatives if high CSF protein or elevated RF in serum. Less sensitive with *C. gattii* infections
Lateral flow assay	+	+	+	+	5 minutes	+	Useful for following treatment response	False positives at low titers. Caution with prozone effect in high burden disease
Multiplex PCR	+	–	+	+	30 minutes	+++ +	Best for diagnosis and not following treatment response	Concern for false negatives, especially if antifungal therapy started

MALDI-MS	+	+	+	+	20 minutes[a]	+		Needs cultures currently which delays diagnosis. Equipment is expensive, but test is cheap
Beta-D-glucan	–	+	+	+	1–2 days[b]	+++		Does not speciate. May be useful for following treatment response. Non-specific
Experimental								
Next-generation sequencing	+	+	+	+	1–2 days	+++ +		Accurate, good for typing and exploring outbreaks
Flow cytometry	+	–	–	–	1–2 days	+++ +		For quantifying burden of disease

Cost: + = <$5; ++ = $6–20; +++ = >$21 and <$100; ++++ = $101–1500

[a]20 minutes is after colony available on culture

[b]Depends whether available locally or sent to specialty laboratory

The other role of PCR is the rapid differentiation of *C. neoformans* from *C. gattii*. Given that CBG agar testing could take some time, the rapidity of real-time PCR could enhance clinical and epidemiological decisions. Currently most testing is available from specialty laboratories [92]. Tavares and colleagues targeted the intergenic spacer 1 (IGS1) region from rDNA locus of *Cryptococcus* with their primers. The minimum limit of detection of both primers was 100 plasmid copies per reaction, and they were highly specific and accurate for each species [92].

MALDI-MS can detect directly from culture organisms within 20 min. Currently, advanced panels can distinguish between *C. gattii* and *C. neoformans*. In a retrospective study of cryptococcal isolates, MALDI-MS was able to identify seven of the eight organisms; however, the one missed was a *Cryptococcus curvatus* isolate, which is currently not in the MALDI-MS database and rarely a human pathogen [86]. Next-generation sequencing (NGS) is able to sequence thousands of organisms in parallel, including having the ability to combine many samples in a single sequencing run and obtain high sequence coverage per sample. NGS-based metagenomic sequencing can detect very low-abundance members of the microbial community that may be missed or are too expensive to identify using other methods. The NGS has a large database that can utilize 150/150 base pair paired-end sequencing to identify small quantities of organisms [93]. The benefit of NGS could be to detect early cryptococcal infection from blood or CSF specimens before infection is evident [93]. Also, when immune reconstitution syndrome occurs, a negative NGS result could help resolve whether to continue antifungal therapy or manage with corticosteroids [93]. It is important to note that these data have not yet been applied to transplant patients. Flow cytometry of the CSF has been used in HIV patients as a way to determine the fungal burden of infection and clinical response to treatment [94].

Serum testing for beta-D-glucan (BDG) has not been considered a diagnostic tool for cryptococcal infections, as early data suggested that it was not expressed in cryptococcal cell walls. However, among HIV-infected Ugandan and South African patients with cryptococcal meningitis, BDG concentrations in the CSF showed 89% sensitivity and 85% specificity from 117 diagnostic CSF specimens [95]. Moreover, CSF concentrations of BDG >500 pg/mL were associated with three times increased risk of 10-week mortality [95]. BDG seems to rapidly normalize with clearance of infection and may be more useful in monitoring treatment response or distinguishing paradoxical IRIS from a relapse of cryptococcal meningitis [95].

Antifungal susceptibility testing of *C. neoformans* has been standardized by the US Clinical and Laboratory Standards Institute (CLSI), but the relationship of MIC to clinical outcomes is not yet validated [96]. The routine use of antifungal susceptibility testing for cryptococcal infection is not recommended. In patients with *C. gattii* infection where genotypes have been associated with increased fluconazole MIC, for those with *C. neoformans* in whom primary therapy has failed or who have relapsed infection, or in patients with cryptococcal infection and recent antifungal exposure (i.e., fluconazole prophylaxis), antifungal susceptibility testing for fluconazole, at a minimum, is recommended [4, 60, 97–99].

Management

Data that inform current treatment guidelines for cryptococcosis in transplant patients are extrapolated from clinical trials among HIV patients and data collected retrospectively from other patient cohorts [3, 4]. The treatment of cryptococcosis is based on site of involvement, severity of illness, and the underlying immunologic status of the patient (Table 2). For patients with CNS disease, the aims of therapy are to eradicate or control the infection, adequately manage elevated intracranial pressure, and prevent long-term neurologic sequelae. For patients with pulmonary disease, the aims of therapy are to eradicate disease and to prevent dissemination to the CNS. The recommendations herein are consistent with guidelines from the Infectious Diseases Society of America (IDSA) [4].

Studies among HIV-negative patients with cryptococcal meningitis were important in defining the efficacy and safety of combination therapy with amphotericin B and flucytosine and the duration of therapy among immunocompromised patients [100, 101]. Combination therapy resulted in higher rates of cure, fewer relapses, and more rapid sterilization of CSF. Treatment recommendations for HIV-negative patients with CNS cryptococcal disease have been adapted from results of more recent studies in patients living with HIV [102, 103]. Specific issues addressed by these studies include use of higher doses of amphotericin B (0.5–1.0 mg/kg/day); use of lipid amphotericin B formulations in patients with renal insufficiency; and treatment with an "induction" regimen of amphotericin B plus 5-flucytosine for

Table 2 Treatment recommendations in transplant patients

CNS, disseminated disease, or moderate to severe pulmonary disease	
Induction	Duration of therapy
Preferred therapy	
Liposomal amphotericin B 3–4 mg/kg/day or amphotericin B lipid complex 5 mg/kg/day plus 5-flucytosine 100 mg/kg/day[a]	Minimum of 2 weeks
Alternative therapy	
Liposomal amphotericin B 3–4 mg/kg/day, or amphotericin B lipid complex 5 mg/kg/day	Minimum of 4–6 weeks
Consolidation	
Fluconazole 400–800 mg/day	8 weeks
Maintenance	
Fluconazole 200–400 mg/day	Minimum of 6–12 months
Pulmonary disease	
Asymptomatic or mild to moderate disease	
Fluconazole 400 mg/day	6–12 months
Severe pulmonary disease, or azole use not an option Same as for CNS disease, above	

[a]Dosages of flucytosine and fluconazole outlined above are in the absence of renal insufficiency. Both require dose reduction for renal insufficiency. Monitoring of flucytosine levels is recommended

2 weeks followed by a "consolidation" regimen with fluconazole for an additional 8–12 weeks [4].

In transplant patients with CNS disease, disseminated disease, or moderately severe to severe pulmonary disease, fungicidal therapy with a lipid formulation of amphotericin B and 5-flucytosine is recommended (Table 2) [4, 104]. The use of a lipid formulation of amphotericin B is preferred over amphotericin B deoxycholate due to decreased nephrotoxicity. Additionally, mortality at 90 days in SOT recipients with CNS cryptococcosis was lower with the use of lipid formulations of amphotericin B when compared to amphotericin B deoxycholate [105]. A lack of 5-flucytosine as induction therapy is an independent risk factor for mycologic failure at week 2 in SOT patients [55, 106, 107]. To avoid adverse effects of flucytosine, including bone marrow suppression and nephrotoxicity, monitoring and maintenance of flucytosine levels (2-h post-dose level of 30–80 μg/mL) are recommended [4, 96, 106].

The recommendation for the management of neurological disease, disseminated cryptococcosis, or moderately severe to severe pulmonary disease is at least 2 weeks of induction therapy with liposomal amphotericin B (3–4 mg/kg/day) or amphotericin B lipid complex (5 mg/kg/day) plus flucytosine (100 mg/kg/day in four equally divided doses every 6 h, adjusted for creatinine clearance). This should be followed by 8 weeks of consolidation therapy with fluconazole (400–800 mg/day). Once induction treatment is completed, 6–12 months of maintenance therapy with fluconazole (200–400 mg/day) is recommended (Table 1). The duration of induction therapy should be extended in patients who are clinically deteriorating, those who fail to improve and have persistently elevated intracranial pressure, those who remain comatose, and those with persistently positive CSF cultures [8]. Fluconazole maintenance therapy may need to be extended in selected patients based on clinical progress or net state of immunosuppression.

Cryptococcal infection of the brain causes a significant inflammatory response resulting in elevations in intracranial pressure that may lead to hydrocephalus, loss of hearing or vision, or death [59]. Raised intracranial pressure (ICP) is a significant factor linked to patient morbidity [108]. Approximately 50–70% of patients with cryptococcal meningitis have elevated ICP [109]. Among HIV patients, therapeutic lumbar punctures were associated with 69% relative survival protection [110]. Lumbar puncture is needed to identify CNS disease and elevated ICP, with CSF samples sent for appropriate diagnostic studies. Repeat lumbar puncture after 2 weeks of induction therapy is helpful to confirm organism clearance with antifungal therapy. Sterile cultures at this time are associated with favorable outcomes in HIV patients [4, 109, 110]. In cases with CSF pressure $\geq$25 cm of CSF or symptoms of increased ICP during induction therapy, serial lumbar punctures should be performed as necessary, with a goal of reducing the CSF pressure by 50% if elevated, or to a normal pressure (<20 cm of CSF). If ICP remains high (>25 mmHg) and symptoms persist, placement of temporary lumbo-peritoneal or external ventricular drains to normalize and monitor CSF pressure should be considered [4, 110, 111]. Permanent ventriculoperitoneal shunting may be indicated if other conservative measures to reduce ICP have failed [4, 111].

Fluconazole 400 mg/day for 6–12 months is recommended in asymptomatic transplant patients and patients with mild to moderate pulmonary disease (Table 2) [3, 4]. Patients with moderate to severe pulmonary disease should be treated similarly to patients with CNS or disseminated infection [4]. Extrapulmonary disease should always be excluded [4, 43]. Positive *C. neoformans* cultures from sterile and non-sterile sites (i.e., sputum) warrant treatment even if the patient is asymptomatic. This is true in lung transplant recipients where *Cryptococcus* may be colonizing the donor allograft; without treatment, infection may become invasive due to post-transplant immunosuppressive therapy [112]. After 6 months of fluconazole therapy, relapse of cryptococcosis is uncommon; therefore the typical duration of therapy is 6–12 months [113]. However, the decision to stop treatment must be based on clinical signs and symptoms, resolution of radiographic abnormalities, and the net state of immunosuppression. Extended treatment with fluconazole is safe in transplant recipients with careful monitoring of drug-drug interactions between fluconazole and calcineurin inhibitors and attention to changes in the QTc interval [114].

Extended-spectrum azoles such as itraconazole, voriconazole, posaconazole, and isavuconazonium offer no advantages over fluconazole for the treatment of *C. neoformans*. These agents are generally more costly and less safe and demonstrate more potential drug interactions with immunosuppressive agents. Itraconazole has been shown to be inferior to fluconazole in the treatment of HIV-associated cryptococcosis [115]. Case reports and case series evaluating voriconazole, posaconazole, and isavuconazonium for treatment of cryptococcosis have been published [116, 117]. Though in most cases these drugs are effective, their role in treatment is unclear, other than an alternative when fluconazole cannot be used. These newer azoles may be useful in the treatment of *C. gattii* genotypes with reduced susceptibility to fluconazole. In vitro data demonstrate their potency against *C. gattii* and suggest that extended-spectrum azoles may offer an oral alternative in transitioning from induction to maintenance therapy [60, 97]. Tacrolimus and sirolimus levels must be closely monitored with co-administration of azoles; dose reduction of these immunosuppressants may be appropriate at the time of azole initiation and discontinuation [118, 119].

The utility of dexamethasone as adjunctive therapy for the management of acute cryptococcal meningitis is not established. In a large randomized controlled trial of cryptococcal meningitis in HIV-infected patients, addition of dexamethasone to standard therapy resulted in slower clearance of the CSF, an increase in serious infections, and no mortality impact compared to placebo [120]. However, clinical data are lacking in transplant recipients and some data are suggestive of clinical benefit after infection clearance [121]. Sertraline, an antidepressant with in vitro activity against *Cryptococcus*, demonstrated increased fungal clearance in one clinical study, though the benefit to SOT patients is unclear [122–124].

Infection management in transplant recipients requires attention to the net state of immunosuppression. Whenever possible, immunosuppression should be reduced during therapy, though this may not be feasible in patients who previously received T cell-depleting agents such as alemtuzumab and thymoglobulin [125]. Ideally, a gradual tapering of immunosuppression can occur while on antifungal therapy,

Table 3 Criteria for diagnosis of IRIS in patients with cryptococcosis

1. New or worsening appearance of any of the following manifestations: a) CNS: clinical or radiographic manifestations consistent with inflammatory process, such as contrast-enhancing lesions on neuroimaging studies; CSF pleocytosis, defined as >5 white blood cells; or increased intracranial pressure, i.e., opening pressure ≥20 mm of water (with or without hydrocephalus) b) Lymph nodes, skin or soft tissue lesions c) Pulmonary lesions detected by chest radiography or CT d) Other focal tissue involvement with histopathology showing granulomatous lesions
2. Symptoms occurring during receipt of appropriate antifungal therapy and could not be explained by a newly acquired infection
3. Negative results of cultures for *C. neoformans* during the diagnostic workup

resulting in eradication of infection with preservation of allograft function. Rapid reductions in immunosuppression may precipitate organ rejection or emergence of immune reconstitution inflammatory syndrome (IRIS). Optimal immunosuppression reduction protocols are not yet established [126].

Restoration of host immunity, particularly if abrupt, may result in adverse outcomes including symptomatic immune reconstitution [127]. The rapid reduction of immunosuppressive therapy in conjunction with initiation of antifungal therapy in transplant recipients may lead to the development of IRIS, with clinical manifestations mimicking worsening cryptococcal disease (Table 3) [62, 113]. IRIS may manifest in many ways, including lymphadenitis, cellulitis, aseptic meningitis, cerebral mass lesions, hydrocephalus, and new pulmonary nodules [62, 113]. Clinically, CNS IRIS appears to have less inflammation and has been found on lumbar puncture to be associated with protein levels ≤50 mg/dL and less than 25 white cells/μL [128]. In evaluating patients living with HIV with IRIS after starting antiretroviral therapy, there was lower interferon gamma (IFN-γ), interleukin (IL-10), and CXCL10 production in patients with higher mortality [129]. These chemokines might enhance T and myeloid cell trafficking into the CNS, resulting in the excessive TH1-type immune responses seen during IRIS [130].

Immunosuppressive agents administered to transplant recipients such as calcineurin inhibitors and corticosteroids exert their effect by preferentially inhibiting Th1 (IL-2 and IFN-α) compared to Th2 (IL-10) responses [131, 132]. Tacrolimus inhibits Th1 to a greater extent than cyclosporine A [133, 134]. The biologic basis of IRIS in SOT recipients is believed to be reversal of a Th2 to Th1 pro-inflammatory response upon withdrawal or reduction of immunosuppression. A potential role of Tregs and Th17 regulatory pathways in the pathogenesis of IRIS in SOT recipients has also been proposed [135]. Potent T cell lymphocyte-depleting agents such as alemtuzumab have also been recognized as a risk factor for IRIS [136].

In SOT recipients with cryptococcosis, IRIS is relatively uncommon, with an incidence of 5–12% [137]. Risk factors independently associated with IRIS are CNS disease and discontinuation of the calcineurin inhibitor [137]. Typically the onset of IRIS is between 4 and 6 weeks after initiation of antifungal therapy [113]. The impact of IRIS on allograft function is just as important with high rates

of graft rejection and allograft failure [137, 138]. Clinically, IRIS in an SOT recipient may present with worsening of clinical symptoms, especially headache. The LP may have elevated opening pressure and white cells, but no growth on cultures and a low level cryptococcal antigenemia. It is a diagnosis of exclusion of relapsed or progressive disease [5]. Currently there are no laboratory markers or clinical criteria that can diagnose IRIS reliably, but exclusion of recurrent or worsening cryptococcosis is important before treatment [126].

There is no proven therapy for IRIS associated with cryptococcosis. Modifications in antifungal therapy are typically not warranted unless viable yeasts are documented in culture. Corticosteroids have been employed anecdotally with success in *Cryptococcus*-associated IRIS in SOT recipients [62, 137]. Corticosteroids in doses equivalent to 0.5–1 mg/kg of prednisone may be considered for major complications related to inflammation in the CNS or severe manifestations of pulmonary or other sites [62]. The efficacy of thalidomide and nonsteroidal anti-inflammatory agents remains unproven [139].

Emerging Treatment Modalities

There is ongoing work to develop new strategies using currently available and approved antifungal agents and to identify more specific anti-cryptococcal drugs based on their ability to neutralize the organism. Current treatment regimens (Table 2) have proven efficacy but are limited by toxicity to both the transplanted organ and patient as well as by cost. Although 5-FC has been available for over 60 years, it has become cost prohibitive in many regions. In addition, lipid formulations of amphotericin B are expensive, as is laboratory testing to monitor safety.

There are several ongoing studies in HIV-infected patients with cryptococcal meningitis that use alternative treatment strategies with amphotericin B, fluconazole, and 5-FC. The AMBITION-CM study (Trial Registration: ISRCTN, ISRCTN72509687) is an open-label, phase 3 randomized controlled non-inferiority trial that is currently being conducted in sub-Saharan Africa [140]. The trial compares cryptococcal meningitis induction therapy with (1) three-dose arm consisting of a single dose (10 mg/kg) of L-AmB given plus 7 days of fluconazole (1200 mg/day) with flucytosine (100 mg/kg/day) to (2) two-dose arm consisting of 7 days of amphotericin B deoxycholate (1 mg/kg/day) with 7 days of flucytosine (100 mg/kg/day). Both groups received 7 days of fluconazole (1200 mg/day) after induction. The primary endpoint is all-cause mortality at 10 weeks, with the study due to close at the end of 2019.

A similar phase 2 study administered short-course, high-dose liposomal amphotericin B in the same setting (Clinical Trial Registration: ISRCTN 10248064). HIV-infected adults with cryptococcal meningitis were randomized to (i) L-AmB 10 mg/kg on day 1 (single dose); (ii) L-AmB 10 mg/kg on day 1 and 5 mg/kg on day 3 (two doses); (iii) L-AmB 10 mg/kg on day 1 and 5 mg/kg on days 3 and 7 (three doses); or (iv) L-AmB 3 mg/kg/day for 14 days (control). All patients received oral fluconazole 1200 mg/day for 14 days. This study looked at early fungal

activity in the CSF of these regimens rather than mortality and showed in a small cohort that single-dose L-amphotericin B with 1200 mg fluconazole was non-inferior. This study is progressing to a phase 3 study [141]. It is unlikely that either of these investigations will be replicated in the transplant populations, but safety and efficacy data could inform alternative treatment strategies in patients not tolerating standard regimens.

Several compounds are in early-stage drug development (Table 4) or have shown efficacy in in vitro or in vivo models. The first is an oral formulation of the standard intravenous therapy. There is an oral encochleated amphotericin B, which is a proprietary cochleate lipid-crystal nanoparticle drug delivery technology. This offers promise of an effective oral antifungal agent for the treatment of cryptococcal meningoencephalitis (Clinicaltrials.gov identifier: NCT03196921).

Punicalagin extracted from *Lafoensia pacari* A. St.-Hil. (Lythraceae) is an ellagitannin from the plant in Brazil, where it has been used for medicinal purposes [142]. In vitro studies show that punicalagin decreased cryptococcal colonies in vitro and was nontoxic. This compound showed promise, but although it slowed growth, it was more fungistatic than fungicidal, suggesting a role as an adjunctive compound rather than primary therapy [142]. VT-1129 is a tetrazole that targets the fungal Cyp51 inhibitor with potent in vitro activity against susceptible and fluconazole-resistant *Cryptococcus* species [143]. VT-1129 acts by inhibiting the fungal cytochrome P450 enzyme Cyp51 (lanosterol 14-α-demethylase), thus inhibiting the biosynthesis of ergosterol in a highly selective manner compared to that of clinically available azole antifungals [143]. This compound in an in vivo study showed that the oral formulation was very potent with persistent clearance of the CSF up to 3 weeks after dosing had stopped; it was compared to fluconazole [143]. The drug has a long half-life (>6 days) and a loading dose achieved high levels in the CSF [144]. Further clinical studies are pending, but this compound offers highly orally bioavailable targeted killing of *Cryptococcus*. It has very few drug interactions which may make it an excellent compound to use in transplant recipients. Lastly, APX001A and its prodrug, APX001, are currently in clinical development for the treatment of cryptococcal meningitis. These compounds target the conserved Gwt1 enzyme required for the localization of glycosylphosphatidylinositol (GPI)-anchored cell wall mannoproteins in fungi [145]. These compounds appear to have synergy, and in vitro studies suggest that the combination with fluconazole can eradicate cryptococcal infections [145]. The development of these new novel and potent compounds with low toxicity and oral bioavailability for the treatment of cryptococcal meningitis is exciting, but clinical study results are at least several years away.

Prevention and Control

Prevention of cryptococcal infection is difficult because *C. neoformans* is ubiquitous in the environment and causes sporadic disease that is relatively uncommon. Primary prophylaxis has been studied in AIDS patients [146, 147]. Although prophylaxis may reduce the frequency of primary cryptococcal disease among those who have CD4

Table 4 New antifungal drugs or synergistic additions to standard antifungal therapies in development

Name	Action	Route	Clinical trial number	Comments
Encochleated amphotericin B	Ergosterol layer	Oral	NCT03196921	Nanoparticle delivery system
Punicalagin	Ellagitannin	Unknown	None	May be adjunctive therapy
VT-1129	Fungal Cyp51 inhibitor – ergosterol	Oral		Potent antifungal activity
APX001A	Target cell wall mannoproteins	Oral		Synergistic with fluconazole
Sertraline	Unknown – possible mTOR	Oral	NCT01802385	Combined with standard therapy. Achieved high CNS levels
Tamoxifen	Unknown – immunomodulation	Oral	NCT03112031	Combined with standard therapy. Fungicidal in vitro with fluconazole and has excellent CNS penetration
Failed or disappeared therapies				
Efungumab (Mycograb)	Heat shock protein 90 inhibitor	IV	NCT00847678	Synergy with amphotericin B in vitro. Study stopped due to poor enrollment
Genaconazole	Ergosterol	Oral/IV	NCT00000677	Not developed
Recombinant interferon-gamma 1b	Increase biologic response converting TH2 to TH1 response	Subcutaneous	NCT00012467	In vivo models only. Closed due to poor enrollment
Lobradimil (RMP-7)	Bradykinin agonist	IV	NCT00002316	Stopped in phase 1. Also did not work with brain cancer

Studies accessed at clinicaltrials.gov as of 10 May 2019

counts <50 cells/μL, there is little survival benefit [147]. For transplant patients, we do not currently recommend routine antifungal prophylaxis specific for cryptococcosis.

Among patients living with HIV in areas where cryptococcal disease incidence is high, preemptive strategies with use of serum cryptococcal antigen testing to identify asymptomatic infection have been effective at reducing the morbidity and mortality

associated with cryptococcal meningitis [147]. This strategy has not been reported from clinical trials among transplant recipients. Although a positive serum cryptococcal antigen in an SOT recipient correlates with CNS infection, even with use of a highly sensitive assay, a negative screening serum cryptococcal antigen may not exclude CNS disease [57, 148]. If there is a high suspicion for CNS infection, a CSF cryptococcal antigen test is warranted.

In transplant recipients with previous resolved cryptococcosis needing enhanced immunosuppression and at risk for relapse of cryptococcosis, consideration for resuming secondary prophylaxis should be made on an individual case basis. For SOT recipients who experience graft failure with or after cryptococcosis, the ideal timing of re-transplantation is unknown. In kidney transplant recipients, where there is the possibility of a hemodialysis bridge, transplant is reasonable to consider if they have received at least several months of antifungal therapy, have no signs or symptoms attributable to active cryptococcal disease, and have negative cultures from the original site of infection. In SOT populations where no bridging option is available, we prefer that the candidate has completed induction antifungal therapy at a minimum, has no signs or symptoms attributable to active cryptococcal disease, and has negative cultures from the original site of infection.

Because of the rarity of cryptococcosis in the general population, we do not recommend routine screening for cryptococcosis in pretransplant candidates [27]. However, pretransplant candidates with unexplained meningoencephalitis or pulmonary disease and risk factors for cryptococcosis should undergo serum and CSF cryptococcal antigen testing, or further testing such as lumbar puncture or bronchoscopy as indicated by clinical signs and symptoms. For transplant candidates with active cryptococcal disease at the time of evaluation for listing, limited data are available to guide timing of transplant or appropriate candidacy [149]. The recommendations are the same as those for patients with graft failure. In the event that donor cryptococcal disease is discovered or confirmed in the recipient after transplant, fluconazole preemptive therapy is recommended for a minimum of several months and evaluation and monitoring for invasive infection should be performed [27].

Conclusion

Cryptococcosis, mainly caused by *C. neoformans* and *C. gattii*, is the third most common invasive fungal infection in SOT recipients, but is rare among patients with HSCT. The most common manifestations are meningitis and pneumonia. As clinical onset may be insidious and non-specific, headaches, fevers, and mental status changes should warrant diagnostic testing for meningitis. The lateral flow cryptococcal antigen assay of CSF and serum has become an important diagnostic method. Currently, lipid amphotericin B plus 5-flucytosine is used as initial treatment of meningitis, disseminated infection, and moderate to severe pulmonary infection, followed by fluconazole as consolidation therapy. Fluconazole is effective for mild to moderate pulmonary infection. Investigational therapies and newer treatment strategies have shown promise in the treatment of meningitis.

Key Points

- Cryptococcosis is the third most common invasive fungal infection in SOT recipients. It is rare among patients who receive HSCT.
- The most common clinical manifestations of cryptococcosis in transplant patients are CNS infection, typically presenting as meningitis, and pulmonary infection.
- Patients with suspected or proven cryptococcosis should have a thorough evaluation for extrapulmonary disease, including lumbar puncture, blood, and other relevant tissue cultures.
- A lumbar puncture should be performed for diagnosis of CNS disease and evaluation and management of intracranial pressure.
- Cryptococcal antigen testing from blood and CSF is a sensitive test for the diagnosis of cryptococcal meningitis and should be performed using the lateral flow assay over the latex agglutination assay.
- Cryptococcus organisms should be identified to the species level (*C. neoformans* vs. *C. gattii*), as this information may impact treatment choice and duration of therapy.
- Susceptibility testing is recommended for patients who fail primary therapy, have relapse of disease, or develop cryptococcosis with prior antifungal exposure (i.e., fluconazole prophylaxis) or in patients with *C. gattii* genotypes that have been associated with elevated fluconazole MICs.
- A lipid formulation of amphotericin B plus 5-flucytosine is preferred as induction therapy for CNS disease, disseminated disease, or moderate to severe pulmonary disease.
- Fluconazole is preferred for consolidation and maintenance therapy for CNS disease and is the preferred therapy for asymptomatic or mild to moderate pulmonary disease.
- Serial lumbar punctures should be performed for the management of elevated ICP. Temporary or permanent CSF drainage should be considered for in patients where serial lumbar punctures fail to normalize ICP.
- Immune reconstitution syndrome can occur within weeks of start of antifungal therapy and reduced immunosuppression. Exclusion of clinical failure with repeat cultures is warranted before initiating corticosteroid treatment.
- Available data do not support the receipt of antifungal prophylaxis against cryptococcosis in transplant patients.

Introduction

Pneumocystis jiroveci pneumonia (PJP) is at once a classic infection of immunocompromised patients and an emerging fungal infection in transplant recipients. It has been recognized as a problem of medically immunocompromised patients for over half a century, landing into the national consciousness during early days of the human immunodeficiency virus (HIV) epidemic era over 30 years ago, and continues to provide new challenges. The recent epidemiology of PJP has shifted such that about half or more of new cases are in non-HIV-infected patients including solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients. Moreover, the clinical manifestations and outcomes differ between those seen in HIV and transplant recipients. Infection tends to be of more rapid onset, patients are more likely to require ICU care, and death rates are higher.

The goal of this chapter is to help clinicians caring for SOT and HSCT patients understand the changing epidemiology of PJP, be better able to identify whether their patient is at risk for developing it or actually has active disease, and know how to prevent and treat it.

Microbiology

The causative organism of PJP is the fungus *Pneumocystis jiroveci.* Historically, *Pneumocystis species* were classified as protozoa based on their life cycle, morphologic features (large cyst with progeny rupturing to release small trophic forms), and absence of ergosterol in the cellular membrane. However, rRNA analysis and whole genome sequencing have placed these species squarely in the fungal kingdom as ascomycetous fungi [1, 2]. Nevertheless, the protozoal terms cyst and trophozoite continue to be used. For decades, the cause of PJP was referred to as *Pneumocystis carinii*. Advances in understanding the biology of the actual fungus causing PJP have led to taxonomic changes, and the etiological agent of PJP is now recognized to be *P. jiroveci*. In this chapter we will refer to the infection as PJP, but the reader should be aware that it is also sometimes referred to as *Pneumocystis carinii* pneumonia (PCP).

Pneumocystis species have a unique tropism for the lungs and reside within the alveoli. Dissemination beyond the lung, sometimes seen when aerosolized pentamidine prophylaxis is used for prophylaxis, is extremely rare even in profoundly immunocompromised hosts. The human lower respiratory tract is the natural environment for *P. jiroveci*. While there are multiple species within the genus *Pneumocystis*, only *P. jiroveci* is known to cause disease in humans. Other animals can be infected with "their own" species of *Pneumocystis* [3]. *Pneumocystis carinii* for example causes infections in rats. The fungus grows well on epithelial cells within alveoli. Cultivation of the organism in continuous ex vivo axenic culture has not been achieved, although growth of *Pneumocystis* in co-culture with host cells has been described [4, 5].

There are two main fungal forms: trophozoite and cyst. The trophozoites accounts for >90% of pulmonary pneumocystis, with the cyst form making up the rest.

The trophozoites have a single nucleus, multiply by binary fission, are pleomorphic in shape, and are typically about 2 μm in diameter. They have a cell membrane, pseudohyphae, which may help them to attach to host cells, and a fragile cell wall [6]. In active infection, the trophozoites fill up the alveolar space [4].

The cysts (spores) are formed by conjugation of two opposite mating trophozoites. The cysts have a thick outer wall that contains beta-glucans and are much bigger than trophozoites (8–10 μm in diameter). The cysts contain two, four, or eight nuclei. Rupture of the mature cyst, which contains eight intracystic bodies, results in their release to become new trophozoites. The hardy cyst is the transmissible form, deposited into air by an infected individual [7]. Such cysts may then be inhaled by another person and then deposited to the alveoli and release eight spores that subsequently develop into trophic forms and begin the life cycle again [8]. The replication of *Pneumocystis* is generally slow, approximately 7–10 days, a characteristic which is helpful in prophylaxis strategies that use intermittent therapy.

Pneumocystis cell membranes do not have ergosterol. Hence, they cannot be treated with typical antifungal agents like azoles which impair production of ergosterol and amphotericin B, which bind to it. Moreover, it is only the cyst form that contains beta-glucans in its fungal cell wall. Hence the echinocandins are effective against the cyst form but much less so against trophozoites. The role of echinocandins for prophylaxis is currently being evaluated; rezafungin is a novel long-acting echinocandin that currently undergoing clinical testing.

An important characteristic of this fungus is its dependence on synthesizing its own folic acid. Two enzymes are important for this process: dihydropteroate synthase (DHPS) and dihydrofolate reductase (DHFR). DHPS is inhibited by sulfonamides such as sulfamethoxazole (SMX). DHFR is inhibited by trimethoprim (TMP) but is actually relatively poor at that function. So, while TMP/SMX is the key anti-pneumocystis agent, it is the SMX component that does the lion's share of the work [8].

Variations in genes coding for these enzymes have been instrumental in studying the epidemiology of *P. jiroveci* [8]. Mutations in DHPS are more common than in DHFR and are felt to be driven by drug pressure. The clinical significance of mutation is unclear though as some studies suggest worse outcome in infections with *P. jiroveci* carrying such mutations, but others have not.

Host-Pathogen Interactions

The natural habitat of *P. jiroveci* is at the epithelial layer of human airways, there are no known environmental reservoirs, and the fungus has a worldwide distribution. As detailed above, transmission is via person-to-person spread. It is not necessary to have symptomatic disease to transmit the organism. Aerosols generated by coughing, sneezing, or wheezing serve to propagate the infectious (cyst) form of the fungus [8]. Spread is usually from asymptomatic carriers but can also be from

those in the prodromal or active phases of infection whose fungal burden is higher. Contact with a person who goes on to develop PJP is a risk factor for susceptible hosts to develop clinical disease in the future [9]. The implications of this will be discussed later in the chapter as they pertain to outbreaks and prevention.

Once acquired, pneumocystis infection remains subclinical in non-immunocompromised people, setting up a transient carrier state that is usually cleared within 6 months [10]. Infection in young children is extremely common and is generally cleared spontaneously. Infected adults likely reacquire the infection, perhaps multiple times. The prevalence of asymptomatic infection may reach 20% in non-immunocompromised adults and even higher in those with chronic lung diseases [10]. Carriage in renal transplant recipients has been reported in the 10–20% range [11, 12]. The prevalence and intensity of colonization and the risk for clinically evident infections increase with net state of immunosuppression. The time from acquisition of organism to clinical infection likely varies, but animal studies suggest a period of about 2–3 months from exposure to heavy infection [13]. In sum, infections are predominantly due to recently acquired infection (typically reinfection) and possibly from reactivation of latent infection [14].

Under normal circumstances *P. jiroveci* survives and propagates within the lungs while "flying under the radar" and not causing obvious damage. In chronically immunocompromised patients, organism burden can increase, a brisk inflammatory response can develop, and gas exchange becomes impaired. Patients then present with clinical and radiographic manifestations of disease. At the alveolar level, this is manifested by direct attachment of *Pneumocystis* to respiratory epithelial cells, accumulation of mixture of organisms, cell debris and a foamy exudate in the alveolar lumen, and impaired lung repair all of which lead to symptomatic disease [6].

The critical contribution of the inflammatory reaction to *P. jiroveci* has important ramifications. Fungal components (including beta glucans in the cyst forms) activate an inflammatory reaction that can be profound. The severity of disease correlates more closely with the degree of pulmonary inflammation than with lung fungal burden [6]. Hence in transplant recipients, where the fungal burden is often lower than in those with HIV but the inflammatory response typically stronger, the clinical manifestations can be more severe, even in some cases while the bronchoalveolar lavage fluid stains negative for organisms. Moreover, because inflammation is such an important driver of disease severity, adjunctive treatment with corticosteroids can be a crucial modality.

Epidemiology and Prevention (Tables 1 and 2)

The epidemiology of PJP has shifted multiple times and is currently evolving once again. In the 1940s and 1950s, PJP was identified as an important cause of outbreaks of respiratory failure in premature infants and very young children [15]. Over the next three decades, it was increasingly recognized as a cause of pneumonia in the then growing population of immunocompromised patients. Most cases were in

Table 1 Factors predisposing to *Pneumocystis*

Transplant related	
Solid organ	First 6–12 months after transplant Treatment for rejection
HSCT	First 6–12 months after transplant Systemic treatment for acute or chronic GVHD
Medication related	
Large molecule	Antithymocyte globulin, alemtuzumab, rituximab
Small molecules	Steroids: ≥20 mg prednisone/day for ≥2 weeks Calcineurin inhibitors (cyclosporine, tacrolimus) mTOR inhibitors (sirolimus, everolimus) Antimetabolites (mycophenolate, azathioprine) Kinase inhibitors (ibrutinib and idelalisib)
Other	
Cell count	Absolute neutrophils ≤500 Absolute lymphocytes ≤500 CD4+ T cells ≤200
Cytomegalovirus (CMV) infection	
Exposure to person with PJP infection while having the above risk factors	

patients with hematological malignancies and in those treated with corticosteroids or cytotoxic chemotherapy. Children seemed to be particularly impacted [14]. In the 1980s and 1990s, PJP became intrinsically associated with uncontrolled HIV, and it became nearly synonymous with that diagnosis. In recent years with improvements in HIV care in a growing population of immunocompromised patients (including solid organ and bone marrow transplant recipients), the epidemiology has once again shifted. While uncontrolled HIV infections remain the most common condition associated with PJP, recent data indicate that the proportion of cases and number of deaths in non-HIV PJP (particularly in those with cancer) are surpassing those of HIV-associated infection [16–18]. In France, for example, 59% of PJP cases occurred in non-AIDS patients with 31% in SOT and 8% in HSCT, and non-HIV patients are more likely to require ICU care and have higher death rates [18]. In the USA, over half of PJP deaths are now in non-HIV patients [17].

The main risk factors for PJP are qualitative and quantitative defects in cellular immunity and prolonged use of high doses of steroids (Table 1). Without prophylaxis up to 25% of patients can develop PJP with as little as 16 mg daily of prednisone after 8 weeks or less [19]. Other implicated factors relevant to bone marrow and solid organ transplant recipients, and especially for those with relapsed lymphoid malignancy or posttransplant lymphoproliferative disease (PTLD), include duration and intensity of chemotherapy and duration of neutropenia [20–22].

Antimicrobial prophylaxis is highly successful at preventing PJP in transplant recipients. Prophylaxis is recommended in situations where the risk for PJP is estimated to be more than 3.5% [23]. For that reason, a thorough understanding of the epidemiology of pneumocystis and risk factors for infections is essential when developing prophylaxis protocols for a transplant program. Unlike the situation in

Table 2 Approach to prevention

Drug	Comments	Side effects
TMP/SMX 80/400 (SS) daily, 160/800 thrice weekly	**Agent of choice** (documented superior efficacy) Additional prophylaxis against multiple other organisms (e.g., *Toxoplasma*[a], *Isospora*, *Cyclospora*, susceptible strains of *Streptococcus* spp., *Staphylococcus* spp., *Haemophilus*, *Salmonella*, *Listeria*, *Enterobacteriaceae*[a])	Hypersensitivity (including anaphylaxis and rash), acute nephritis, urinary crystals, hyperkalemia, hypoglycemia, hepatitis, pancreatitis, nausea, vomiting, aseptic meningitis, fever Occasionally, hemolytic anemia in those with G6PD deficiency
Dapsone 100 mg/day	Less activity against *Toxoplasma* Should be avoided in those with severe TMP/SMX reactions due to cross-reactivity	Hemolytic anemia (in those with G6PD deficiency), methemoglobinemia, hepatitis Potential hypersensitivity in those with severe reactions to TMP/SMX "Sulfone syndrome": Fever, rash, lymphadenopathy, hepatitis, and methemoglobinemia
Atovaquone 1,500 mg daily	Less activity against *Toxoplasma* More expensive, less palatable than other options	Rash, nausea, diarrhea, headache, elevated liver enzymes Requires fatty intake for proper absorption
Pentamidine (aerosolized) once monthly	Less effective than TMP/SMX or dapsone Requires trained personnel for administration	Cough, bronchospasm, excessive salivation, sore throat Possible TB transmission, need for TB screening
Pentamidine 4 mg/kg by IV once monthly	Not FDA approved for prevention	Hypotension, pancreatitis, anaphylaxis

[a]Daily dosing preferred

HIV, there are no definitive laboratory markers such as CD4+ count that automatically trigger initiation of PJP prophylaxis. Some have proposed a CD4+ count cutoff of <300/μL; however, patients can develop PJP even with much higher CD4+ counts [22, 24]. Outside of HIV, low CD4+ counts are not sensitive or specific enough to predict susceptibility in transplant patients and should not be use as the sole marker to initiate prophylaxis [14, 25].

For solid organ transplant recipients not receiving effective prophylaxis, the reported PJP rates range from 0.6 to 14% for the kidney, 3–11% for liver, 2–41% for heart, and 6.5–43% for lung transplants [21]. With current prophylaxis protocols, the rate is approximately 1–2% [26]. Moreover, with widespread adaptation of prophylaxis during higher-risk periods, the timing of infection has been pushed further out, and most cases now occur in the first to second year of transplant, which is typically after prophylaxis has been stopped.

Factors leading to elevated risk of infection are often multiple and overlapping [27]. The highest-risk periods are when immunosuppression is at its most intense,

during the first few months posttransplant, and with treatment for acute graft rejection. In those with lung or small bowel transplant, the risk for PJP seems to extend beyond 12 months posttransplant period. The combination of calcineurin inhibitors such as tacrolimus or cyclosporine, mycophenolate, and higher doses of corticosteroids (i.e., ≥20 mg of prednisone per day for ≥2 or more weeks) and T-cell-depleting agents such as thymoglobulin or alemtuzumab substantially increases the odds of developing PJP.

We recommend that programs develop prophylaxis protocols and orders sets such that a period of PJP prophylaxis (e.g., 6 months) is automatically triggered by organ transplantation surgery, receipt of thymoglobulin, alemtuzumab, or high-dose steroids. In those with lung transplantation, the risk for PJP seems to extend beyond 12 months posttransplant; therefore lifelong prophylaxis has been recommended [21]. Lifelong prophylaxis should also be considered for small bowel transplant recipients and prior PJP [28]. Prophylaxis against other organisms such as *Toxoplasma* in heart transplant recipients may also help determine the duration.

Additional risk factors for infection can be more challenging to implement as part of prophylaxis protocol but are nonetheless important. These include older age, CMV infection, lymphopenia (especially absolute lymphocyte count <500), prolonged neutropenia, low CD4+ count, multiple episodes of rejection, and receipt of rituximab [21, 26, 28–33]. Newer data suggest considering PJP prophylaxis in patients with active CMV viremia/disease [34–36].

HSCT recipients are also at substantial risk. Without prophylaxis, the risk for PJP is ~5–16% [21]. As is the case with SOT, TMP/SMX prophylaxis is highly protective. The overall rate for autologous stem cell transplants with prophylaxis is ~0.3% and ~ 0.6–1.0% for allogeneic transplant [37, 38]. As with solid organ transplant, widespread utilization of PJP prophylaxis for at least 6 months post-engraftment or discontinuation of all immunosuppression has led to delayed onset disease, typically beyond 6–12 months after transplant, and mostly in those patients receiving high doses of steroids for treatment of graft-versus-host disease (GVHD) [21]. Timing of infection, however, ranges from within a month to over a year after transplant. In one series, patients developed PJP prior to engraftment (when they were not getting prophylaxis), after prophylaxis was stopped, or when on atovaquone [39].

The highest risk is typically in the first year after transplant and during times of intense immunosuppression. In that regard, acute or chronic GVHD are an important risk driven by use of steroids and other immunosuppressive drugs to control the GVHD, lymphopenia, and low-circulating CD4+ T cells [38]. Published guidelines recommend PJP prophylaxis during at least the first 6 months post-engraftment for allogeneic HSCT and during periods of enhanced immunosuppression [21, 40]. Failure to prescribe or to adhere to a prophylaxis regime during vulnerable periods is an important risk for developing infections [38].

The underlying diseases also impact risk for PJP. Acute lymphoblastic leukemia, chronic lymphocytic leukemia, non-Hodgkin's lymphoma, and multiple myeloma are all associated with PJP. Even in the absence of transplant, patients with **hematologic malignancies** are at risk, albeit lower than transplant recipients. High-intensity chemotherapy regimens (e.g., R-CHOP14, ABVD, high-dose

methotrexate), receipt of nucleoside analogues (e.g., fludarabine, cladribine), or T-cell-depleting agents (e.g., alemtuzumab, rituximab, bendamustine) place patients at moderate risk. Some guidelines are recommending prophylaxis for up to 6 months after completing treatment [23, 41]. Moreover, since many BMT recipients have residual disease and/or are receiving treatment to prevent recurrences of such diseases, those conditions may carry additional risks.

In that context, while prophylaxis for patients receiving an autologous stem cell is controversial, it should be provided to those with underlying lymphoma or leukemia, intense conditioning regimens, or prior/current treatment with purine analogs (fludarabine, cladribine); it is generally given for 3–6 months posttransplant [40].

Pneumocystis (and other fungal infections) has also been observed in patients receiving the Bruton tyrosine kinase (BTK) inhibitor ibrutinib. Since these patients typically have chronic lymphocytic leukemia (CLL) or lymphoma, it is difficult to definitively determine the specific contribution of this agent to causing such infections. Nevertheless, studies in mice suggest that BTK inhibition increases susceptibility to PJP [42]. Similarly, there is a small but increased risk of PJP during treatment with idelalisib, which is a phosphatidylinositol-3-kinase delta (PI3Kδ) inhibitor used in combination with rituximab for CLL, as well as with Janus Kinase (JAK) inhibitors used in the treatment of myelofibrosis [43, 44].

Transplant recipients who acquire a solid tumor may encounter risk owing to cancer chemotherapy. In the absence of transplant, the incidence of PJP is generally low in patients with solid tumors. Important exceptions are patients receiving temozolomide or high doses of corticosteroids for brain malignancies. The package insert for temozolomide includes a black box warning recommending PJP prophylaxis with its use [23]. Similarly, for patients receiving high-dose steroids as part of cancer therapy, prophylaxis should also be instituted for 6 weeks after tapering doses of steroids containing >16 mg of prednisone or >4 mg of dexamethasone daily for more than 4 weeks [23].

Pneumocystis has long been associated with outbreaks. Molecular epidemiological analyses have indicated that patient-to-patient transmission is the key driver of these outbreaks [45, 46]. Most of the outbreaks have been reported from kidney transplant recipients, but well-documented clusters of cases in other transplant patients and in those with hematological malignancies have also been reported [45]. A key feature of these outbreaks is that infected patients received inadequate or no prophylaxis prior to developing PJP. Control of the outbreaks is typically gained by institution of chemoprophylaxis [47]. The role of isolation precautions is as yet unclear. Those with higher organism burden in their airways might be particularly efficient spreaders. CDC and others advise avoiding placement of someone with PJP in in the same room as an immunocompromised patient [45].

The agent of choice for PJP prophylaxis is *trimethoprim-sulfamethoxazole* (TMP/SMX) due to its superior efficacy when compared to other agents; a large study looking at PJP infections in HSCT recipients found that seven patients developed PJP while on prophylaxis, five of them were on aerosolized pentamidine (AP), and the other two on dapsone; no episodes of PJP were noted on those taking TMP/SMX [48]. Similarly, studies in liver, kidney, and heart transplant recipients

found no cases of PJP in those receiving TMP/SMX [49, 50]. Therefore, TMP/SMX should be used unless there is a clearly documented reaction. If reactions such as rash occurs, desensitization protocols have been successfully applied in up to 80% of patients [40, 51, 52]. This approach should be avoided in those with severe immediate reactions.

In post-HSCT patients, TMP/SMX may delay engraftment due to its myelosuppressive effects, and, therefore, initiation of prophylaxis should be delayed until engraftment occurs. If engraftment is delayed, other agents can be used. Other toxicities include hypersensitivity including rash which could mimic GVHD and even anaphylaxis, hyperkalemia, hypoglycemia, acute interstitial nephritis, hepatitis, nausea, vomiting, pancreatitis, and aseptic meningitis [21, 40]. A study showed no significant difference in adverse events between groups taking TMP/SMX versus placebo; severe adverse events were noted in 3.1% and included severe rash, leukopenia, and thrombocytopenia [53, 54]. Mutations in targets for TMP/SMX (genes encoding dihydropteroate synthase and dihydrofolate reductase) have been detected, as detailed elsewhere in this chapter. But prophylactic failure has not been consistently associated with such mutations [21].

Other less effective options are shown in Table 2 and include dapsone, atovaquone, and aerosolized pentamidine. *Dapsone* is considered a second-line agent when compared to TMP/SMX; there have been reports of breakthrough PJP [41, 48, 55]. A significant proportion of patients with hypersensitivity to TMP/SMX will also react to dapsone (up to 50%), so it should be avoided in those with life-threatening reactions to TMP/SMX [14]. More recently, a study found no breakthrough PJP or cross-reactivity with TMP/SMX; however, it included only a small number of patients [56]. Other toxicities include methemoglobinemia, hemolytic anemia in those with glucose-6-phophate dehydrogenase deficiency, aplastic anemia, agranulocytosis, rash, nausea, and hepatitis. Higher incidence of infections otherwise covered by TMP/SMX was noted in those on dapsone prophylaxis [57].

Atovaquone is tolerated by some patients but not by others. Its taste is unpleasant, and the drug can be expensive; hence patients' adherence can be suboptimal. Absorption may also be compromised in those with poor fat intake, thus limiting its efficacy in those with gastrointestinal disorders such as GVHD [41]. The main side effects include nausea, diarrhea, headaches, and possible liver test elevations. At doses of 1,500 mg daily, it has comparable efficacy to dapsone and aerosolized pentamidine [58, 59]. Mutations in target for atovaquone (cytochrome *b*) have been detected, but prophylactic failure has not been consistently associated with such mutations [21].

Aerosolized pentamidine is less effective and may lead to cough and bronchospasm, which can be overcome by premedicating with beta-adrenergic agonists [21, 40]. Access to a facility that can deliver this type of treatment is not universally available. All patients receiving aerosolized pentamidine need to be screened for tuberculosis, as there have been reports of transmission due to post-administration cough [60]. Cases of disseminated PJP have been reported with aerosolized pentamidine [61]. Small studies which included a total of 96 HSCT patients on aerosolized pentamidine did not report any cases of PJP or discontinuation due to adverse

events [62–64]. However, larger studies have shown otherwise [48, 65]. Pentamidine may also be given by IV as prophylaxis. Typical dose in adults is 4 mg/kg once monthly. Potential side effects include anaphylaxis, hypotension, and pancreatic injury.

Clinical, Radiographic, and Diagnostic Considerations (Fig. 1)

Clinical Findings

The constellation of cough, fever, shortness of breath, and hypoxemia in the context of typical radiographic findings (see below) is the classical presentation of PJP. The cough tends to be dry in nature, fever may be low grade or altogether missing in transplant recipients, and hypoxemia may not be initially present. Fever, tachypnea, tachycardia, and dry rales are the classic constellation of physical exam findings. Progression of disease, sometimes to respiratory failure, can be rapid, evolving over just a few days. Sometimes, however, the progression can be slower playing out over 1–2 weeks or longer. Chest pain and abnormalities on chest auscultation are seen in a

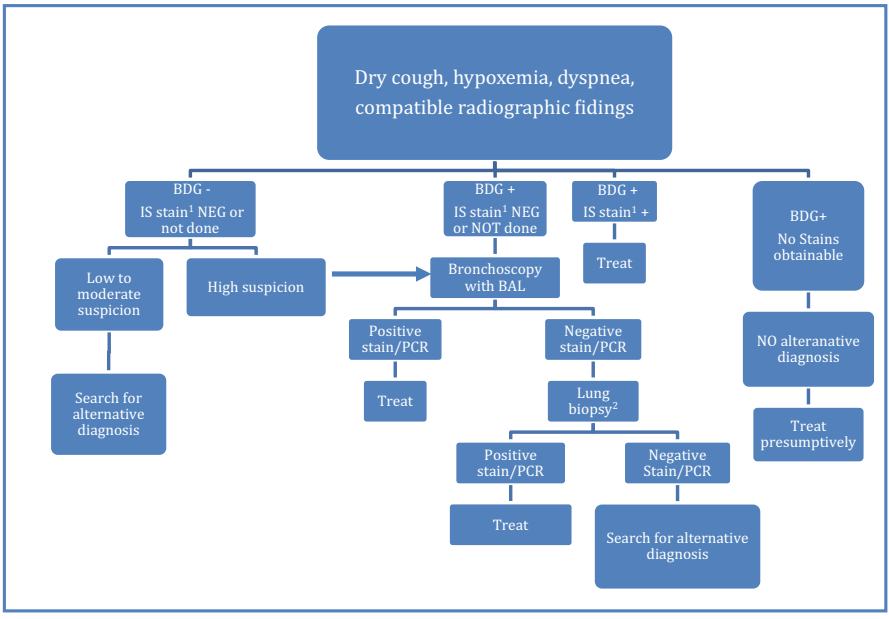

Fig. 1 Suggested diagnostic algorithm. BDG, 1,3-β-D-glucan; BAL, bronchoalveolar lavage; GGO, ground-glass opacities; IS, induced sputum; PCR, polymerase chain reaction; and SOB, shortness of breath. [1]Testing of induced sputum for PJP is associated with multiple false-negative tests and may delay diagnosis. Many go right to bronchoscopy to try to establish the diagnosis via bronchoalveolar lavage. [2]Lung biopsy: transbronchial, video-assisted thoracoscopy (VATS), open lung biopsy

minority of patients (~20–30% of the time). Pneumothorax is a well described, yet rare presentation of PJP and lymphadenopathy is uncommon.

ICU admission is required in nearly 50% of patients, most of which require mechanical ventilation and continuous renal replacement therapy (CRRT). Inhospital mortality is nearly 40% and twice that for patients in ICU. While not diagnostic of PJP, LDH levels of ~500 or higher are associated with worse outcomes (e.g., requirement for ICU level of care and morality) [66].

Radiographic Manifestations

Typical findings in PJP are bilateral interstitial or alveolar/interstitial opacities on chest radiographs and diffuse ground-glass opacities on computed tomography (CT) scans. Septal lines, centrilobular nodules, and, less commonly, focal consolidation, subpleural nodules, cysts, blebs, and pneumothoraxes may also be seen [18]. Pleural effusions are uncommon, and, if present, one should consider an alternative (or additional) diagnosis. The most common radiographic manifestations of PJP are multifocal ground-glass pulmonary opacities, best seen on high-resolution CT scans. These opacities are due to accumulation of intra-alveolar fibrin, debris, and organisms [67]. The appearance of the ground-glass opacities is typically with small nodules (<5 mm), reticulation, and mosaic pattern. Midsize nodules (5–10 mm), which are often due to granulomatous inflammation, may be seen in HIV but are less common in transplant patients [68]. With more advanced disease, lung consolidations can occur, reflecting pulmonary damage from the host immune response. These are more common and occur more rapidly in non-HIV PJP. Pulmonary cysts of varying shape, size, and wall thickness may occur in transplant patients but are more common in HIV [67].

Direct Microscopy

The cornerstone of PJP diagnosis is direct microscopic examination. Appropriate clinical samples include induced sputum, bronchoalveolar lavage (BAL) fluid, or lung tissue. Examination of hypertonic saline-induced sputum is the least invasive approach and may establish the diagnosis in about 50% of HIV PJP patients [69]. However, the yield may be far lower in transplant patients owing to lower organism burden. Yields are better with examination of bronchoalveolar lavage (BAL) obtained via bronchoscopy, and this has been the traditional go-to approach when suspicion is high but induced sputum is either unavailable or negative. Rarely, lung biopsy via transbronchial sampling during bronchoscopy, via video-assisted thoracoscopic surgery (VATS), or even an open lung procedure is used to establish the diagnosis [2, 70].

Multiple stains are helpful for identifying the organism. We recommend using a combination of stains that target both cysts and trophic forms [71]. The trophic forms, which make up over 90% of the organism burden, can be visualized with

Papanicolaou, Wright-Giemsa, or Gram-Weigert stains. The cyst forms, which usually make up about 5–10% of the organism burden, are best visualized by Gomori methenamine silver, cresyl echt violet, toluidine blue O, or calcofluor white stain cysts [21]. Hematoxylin-eosin staining is useful for demonstrating the characteristic foamy, eosinophilic material within the alveoli in lung tissue biopsy samples [14]. Direct or indirect immunofluorescence stains capture both forms and are especially helpful for induced sputum, where their sensitivity and specificity are superior to other stains; the difference is less apparent in BAL samples [2, 70]. However, microscopic exam can be difficult requiring highly skilled personnel, particularly when the fungal burden is low as may be the case in transplant patients. When the pretest probability is high, a negative microscopic exam does not rule out pneumocystis [71, 72].

Molecular Methods

Use of polymerase chain reaction (PCR) to detect *Pneumocystis* has greater sensitivity and specificity than conventional staining in both induced sputum and BAL samples. It is more frequently positive than microscopy in non-HIV patients where the organism burden is lower [72–77]. Traditional PCR positivity suggests presence of the fungus in the respiratory tract but cannot effectively differentiate whether it is causing disease or an innocent bystander. Positive results should be interpreted with particular care in asymptomatic individuals [14, 74, 78, 79]. Negative PCR can effectively rule out PJP with a negative predictive value close to 100% [23, 71, 72, 74, 76, 80]. Other specimens could be used for PCR testing, such as induced sputum, oral washings, nasopharyngeal aspirates, and nasal swabs, but these may result in false-negative tests as fungal burden is highest in the alveoli [71].

Attempts at using quantitative PJP PCR (qPCR) in BAL have been made to try to distinguish colonization versus infection; however, different PCR techniques, and the presence of both trophic (single genomes) and cyst (multiple genomes) forms with unknown ratios, make quantitation difficult to interpret [72, 80]. In addition, there might be a continuous from colonization to active infection which hinders discrimination between the two entities [71]. There are no clear PCR thresholds to distinguish infection versus colonization. Guidelines for the validation of qPCR assays may overcome some of this issues by creating more homogeneous and comparable testing that may allow an international standard [71, 81].

Serum samples can be used for PCR testing; however, sensitivity is very low at 6% [82]. A study using cell-free DNA PCR (cfPCR) in blood samples showed similar sensitivity but higher specificity than BAL and sputum samples; this technique may prove useful in those patients who cannot undergo invasive diagnostic procedures [83]. Specific PCR techniques have the capability of detecting mutations in genes encoding dihydropteroate synthase (DHPS, target for trimethoprim), which has been previously associated with possible prophylaxis and treatment failure [84, 85].

Beta-Glucan Testing

1,3-β-D-glucan (BDG) is a cell wall polysaccharide present in many pathogenic fungi including *P. jiroveci*. Serum levels are typically elevated in PJP. Several commercial tests have been developed, but only Fungitell (Associates of Cape Cod Inc., East Falmouth, MA, USA) is FDA approved. Studies in immunocompromised patients have shown high sensitivity and negative predictive value for PJP, with positive BDG values even 10 days prior to microbiological diagnosis, but low positive predictive values [82]. Elevated BDG results may be due to another fungal infection or a non-fungal trigger (e.g., *Pseudomonas aeruginosa*, severe mucositis, and recent intravenous immunoglobulin). Cutoffs for PJP should probably be higher than the 60–80 pg/mL used for other infections [84].

A meta-analysis including 13 studies found a sensitivity of 0.91 (95% CI 0.88–0.93) and specificity of 0.75 (95% CI, 0.8–0.81); studies included both HIV and non-HIV population. When only non-HIV patients were analyzed, sensitivity dropped to 0.85 (95% CI, 0.77–0.94) and specificity to 0.73 (95% CI, 0.61–0.85) [86]. Two other meta-analysis including 12 and 14 studies, respectively, found similar sensitivity and specificity (96%/84% and 95%/86%, respectively); only one of these looked grouped HIV and non-HIV patients but found no significant differences [87, 88].

Some studies have found that the level of BDG might reflect organism burden; it is therefore postulated that the lower sensitivity might be due to lower organism burden in the non-HIV population [86, 89]. In critically ill patients with PJP presenting as acute respiratory distress syndrome (ARDS), BDG testing was found to be highly reliable with generally high levels and a negative predictive value of 96% [90].

In summary, we recommend BDG testing as an adjunctive diagnostic test that can be used as part of a diagnostic/treatment algorithm along with PCR, but caution about lack of specificity and that such an approach has not been validated in clinical studies [23, 71, 91]. Additionally, we urge caution in overreliance on a negative BDG test in transplant recipient with clinical and radiographic findings consistent with PJP, as a negative result may not exclude the diagnosis due to its lower sensitivity; diagnosis in this setting should be ruled out by other testing.

Of note, BDG might be useful in predicting favorable clinical course by documenting decreasing BDG levels during treatment; however, increasing or persistently elevated BDG levels do not necessarily correlate with treatment failure and may persist long after clinical resolution [92, 93].

Other Tests

Elevated serum lactate dehydrogenase (LDH) (>300 IU) is usually present, although other pulmonary processes leading to lung injury may also cause elevated LDH. Antibody testing is generally not useful (IgM and IgG), as most asymptomatic adults will test positive [14].

Treatment (Table 3)

Timely initiation of treatment for PJP is particularly important in transplant recipients. As detailed above, such patients experience a faster progression of illness, more severe hypoxemia, greater need for intensive care and invasive mechanical ventilation, and higher prevalence of shock and have higher death rates. Delay in initiation of treatment is independently associated with death in such patients [18]. Without treatment, an immunocompromised patient's infection will continue to progress ultimately resulting in respiratory failure and death. Even with appropriate treatment, about 50% of transplant patients will go on to require intensive care unit level of care with mortality rates up to 78% [66].

Hence, while treatment should absolutely be initiated when there is definitive evidence for PJP, it must also be strongly considered before the diagnosis has been firmly established (i.e., empiric therapy). As detailed in the diagnostics section, definitive diagnosis requires direct visualization of the organism. However, therapy commonly needs to be started before a definitive diagnosis is established. This can become complicated as pulmonary edema, which can be a common issue in transplant patients, may mimic PJP. Moreover, patients are often too unstable to undergo bronchoscopy right away, and even when done, the results may be negative despite disease. Published guidelines suggest initiation of empiric therapy in hematological malignancy patients (including BMT) who have risk factors for PJP in conjunction with signs and symptoms and radiographic abnormalities compatible with disease

Table 3 Treatment options for moderate to severe disease

Drug	Comment
Trimethoprim and sulfamethoxazole (IV or PO) 15–20 mg/kg/day in three to four divided doses (based on TMP component)	Side effects as detailed in Table 2 Monitor renal function, electrolytes, CBC, liver function tests
Clindamycin (IV or PO) 600 mg 4 times/day (or 900 mg thrice daily) And Primaquine (PO) 30 mg/day	Second-line therapy. Efficacy may be suboptimal in severe disease Clindamycin side effects include GI intolerance, *Clostridium difficile* infection. Primaquine side effects include hemolysis with G6PD deficiency and methemoglobinemia Check G6PD level, monitor CBC
Pentamidine (IV) 4 mg/kg/day	Second-line therapy. Safety concerns (serious side effects in >50% of patients) including GI intolerance, hypoglycemia, pancreatitis, hyperglycemia, arrhythmias, hypotension, renal dysfunction Monitor cardiac rhythm, blood pressure, renal function, electrolytes, and pancreatic function

Note: Options for mild to moderate disease include atovaquone 750 mg twice daily and trimethoprim 5 mg/kg thrice daily + dapsone 100 mg daily

[94]. The length of treatment is usually 14–21 days, but longer may be required in more severe cases.

Specific Agents

Trimethoprim-sulfamethoxazole (TMP/SMX) is the first-line agent for treatment of PJP. The standard dose is 15–20 mg/kg of TMP component (adjusted as needed for renal function) daily in 6- to 8-h intervals [28]. The bioavailability of TMP/SMX is excellent, so it can be given either by IV route or by mouth providing the enteric absorption is good. We recommend initial therapy by the IV route in moderate to severe disease. In cases of milder disease, when therapy is given as an outpatient or during times of IV TMP/SMX shortages, treatment may be initiated by the oral route. Standard doses for oral therapy are two-double strengths tablets (TMP/SMX 160 mg/800 mg) 2–3 times daily. Another appealing feature of oral therapy is that unlike IV TMP/SMX, it does not require the infusion of large volume of fluids. This issue is particularly important in patients with propensity for fluid overload, which can be an issue for many solid organ and bone marrow transplant recipients.

As detailed earlier TMP/SMX is associated with multiple side effects. In addition to the allergic reactions and gastrointestinal symptoms common to many antibiotics, there are other potential toxicities that could be more relevant to transplant patients. Hyperkalemia is a potential problem for patients with abnormal renal function, which is a common situation in solid organ and bone marrow transplant recipients and when co-administered with drugs that impact potassium metabolism (e.g., angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and potassium-sparing diuretics). Elevations in serum creatinine are another issue. TMP/SMX can cause true renal dysfunction and/or mild elevations in creatinine that are not related to reduced glomerular filtration rate; it can lead to urinary crystal formation with ensuing obstruction leading to acute failure. This can be particularly challenging to interpret in renal transplant patients.

Cytopenias (e.g., leukopenia, anemia, and thrombocytopenia) are another problem that may be particularly relevant for bone marrow transplant recipients but also for patients on mycophenolate and other bone marrow suppressing agents (e.g., ganciclovir or valganciclovir). Drug-induced liver injury including cholestasis can be an issue. In patients with hematological malignancy who might be receiving methotrexate, TMP/SMX should be avoided because of potentially serious adverse drug effects [94]. Other side effects include aseptic meningitis, Steven-Johnson syndrome/toxic epidermal necrolysis, and drug fever. One approach to reduce the chance of side effects is to use a lower dose. This was evaluated in a retrospective study of non-HIV PJP. When compared to the typical regimen (15–20 mg/kg/d), a reduced dose (median 10.8 mg/kg) had similar efficacy and fewer side effects [95].

Clindamycin 600 mg IV or PO 4 times daily (or 900 mg thrice daily) and oral primaquin 30 mg daily are a second-line option for PJP [28]. Data for this regimen has largely been extrapolated from the HIV literature. The major side effects are GI in nature (including *Clostridium difficile* infection) and neutropenia. Screening for glucose-6-phosphate dehydrogenase (G6PD) deficiency is required prior to primaquine use.

Intravenous pentamidine given at a dose of 4 mg/kg/day is the other major second-line agent. IV pentamidine has multiple side effects. It should be given over 1–2 h to avoid infusion-related hypotension. Additional common toxicities include arrhythmias, electrolyte abnormalities, renal injury, bone marrow suppression, and pancreatitis. The latter can cause either low or high blood sugars and may lead to diabetes mellitus due to irreversible damage to islet cells. This drug is probably best avoided in pancreatic and islet cell transplant recipients.

Atovaquone 750 mg twice daily by mouth may be used for mild to moderate disease. This drug is only available as an oral suspension and is absorbed best with fatty foods. Aside from its unpleasant taste and some instances of rash, it is well tolerated, but efficacy in active diseases is uncertain and hence should be avoided in more serious cases. Other combinations such as pyrimethamine and sulfadiazine, a macrolide and SMX, and dapsone with trimethoprim have been used as well, but data is limited. Echinocandins do have activity in pneumocystis but are not effective when used. We do not recommend their use for treatment of PJP.

Resistance Issues

Resistance to TMP/SMX is rare but of concern. Widespread exposure to the drug may cause selective pressure for resistant isolates. These can then be transmitted between individuals such that prior exposure to TMP/SMX is not necessary for a resistant isolate to be present in a given patient. Assessing for drug resistance is a challenging issue in *Pneumocystis* owing to the absence of culture systems. Mutations in genes coding for dihydrofolate reductase (DHFR) and dihydropteroate synthase (DHPS), the targets of trimethoprim and sulfa, respectively, have been speculated to cause resistance to TMP/SMX. The clinical significance of such mutations is unclear. In one study, presence of such mutations was associated with longer duration of mechanical ventilation, but not mortality [96]. It appears that DHPS mutations represent a low-level resistance that can be overcome by higher doses of TMP-SMX [8]. Mutations in the gene coding for mitochondrial cytochrome b, which is the target of atovaquone, have been associated with resistance to that drug and have been linked to failure of prophylaxis.

Steroids

As a general rule, immunosuppression should be reduced in patients with PJP, although this is not always straightforward with corticosteroids. Clearly the pathway leading to PJP includes immunosuppression, and corticosteroids are often directly implicated. However, once infection has developed, particularly when it is severe, the immune response is a double-edged sword. Sometimes infection only becomes manifest when

high doses of corticosteroids are being tapered. Similarly, experience from HIV has shown that hypoxemia can actually worsen with treatment due to an overexuberant inflammatory response and that corticosteroids are necessary to avoid further respiratory decline. How this experience translates to non-HIV patients is a matter of ongoing debate. Recent data in non-HIV patients, some of which were transplant recipients, found no advantage in routine steroid use [97].

Published guidelines are somewhat conflicting. Guidelines from the European Conference on Infections in Leukemia (ECIL) recommend against routine adjunctive steroids and state that the decision in those with PJP and respiratory failure be made on an individual basis [94]. The American Society of Transplantation (AST) guidelines on the other hand recommend that patients with severe disease (i.e., hypoxemia; pAO2 $<$ 70 mmHg on room air) received adjunctive corticosteroids, ideally within 72 h of initiating antimicrobial therapy [28]. The recommended dose is 40–60 mg of prednisone twice daily for 5–7 days followed by a 7- to 14-day taper. With respect to those patients that have been on steroids prior to onset of PJP, it is unclear whether the appropriate approach is to maintain the current dose, escalate it, or even taper off. The approach typically has to be individualized.

Response to Therapy

Patients with PJP do not always improve right away. In cases of empiric therapy, it is tempting to abandon the diagnosis if the patient does not respond immediately. It should be expected that patients may take up to a week to respond, and sometimes there is clinical decline in the first few days. Conversely, an immediate response to therapy should not necessarily be interpreted as proof of the accuracy of the diagnosis as the improvement may be due to co-administration of corticosteroids. In cases of proven infection, a lack of response or worsening after a week of therapy should raise concern. The differential diagnosis includes coinfection due to an additional pathogen (e.g., CMV, other fungal organisms, bacteria), complication of PJP such as pneumothorax, pleural effusion or extensive pulmonary injury, noninfectious etiologies such as pulmonary edema due to fluid overload, and possibly treatment failure related to the anti-pneumocystis regimen selected. Resistance to TMP/SMX has been described as detailed above. However, this phenomenon is uncommon. The decision to replace TMP/SMX, which is the frontline treatment for pneumocystis, in favor of second-line agents with less proven efficacy and more potential toxicity (e.g., clindamycin/primaquine or IV pentamidine) should not be taken lightly (Fig. 2).

Conclusion

PJP is at once a classic infection of immunocompromised patients and an emerging infection in transplant patients. In the past two decades, there has been a major shift in the epidemiology away from it being a disease predominantly associated with

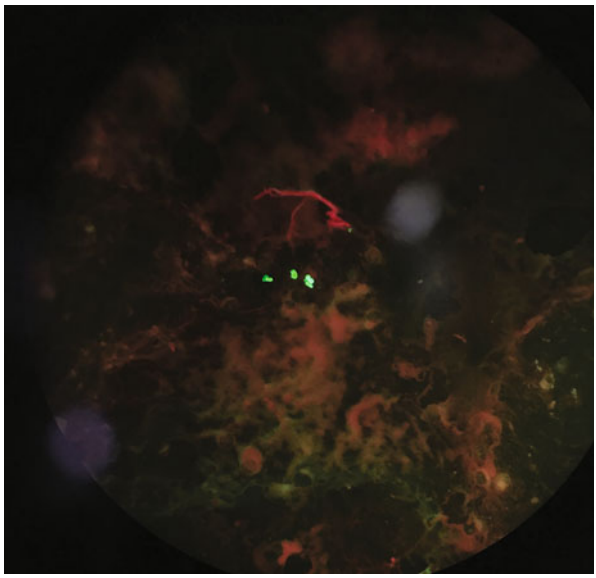

Fig. 2 PJP immunofluorescent staining (From Eunice L. Rogaishio, Melis Anahtar, and Camille N. Kotton, with permission)

HIV to one increasingly seen in non-HIV patients, including solid and bone marrow transplant recipients. It is important for clinicians to be aware of this shift in epidemiology, understand which patients are at particular risk, and how PJP presents in transplant recipients. Such knowledge is important in determining who should receive prophylaxis, where to place PJP on the differential diagnosis, and how to interpret results of diagnostic tests.

Key Points

- *Highest-risk periods*: The first 6–12 months after transplant and during times of intensification of immunosuppression for rejection of GVHD (e.g., with lymphocyte-depleting agents and corticosteroids at $\geq$20 mg prednisone equivalent/day $\geq$2 weeks).
- *Prevention*: Patients falling into the high-risk categories above should receive prophylaxis, ideally with TMP/SMX.
- *Diagnosis*: Stains of induced sputum or bronchoalveolar lavage fluid are helpful if positive. However, a negative stain does not rule out PJP in a transplant recipient with compatible symptoms. PCR has high sensitivity, especially if obtained from BAL. Serum beta glucan can be useful and may obviate need for more invasive procedure such as bronchoscopy but is nonspecific.
- *Treatment*: TMP/SMX is the mainstay of therapy with clindamycin/primaquine and IV pentamidine as alternative options. Adjunctive corticosteroids may have a role in severe disease, but evidence for their use is not as clear cut as in HIV.

areas, donors and recipients can bring transplant-related coccidioidomycosis to transplant programs in non-endemic areas. In this chapter, we will discuss the epidemiology, clinical manifestations, diagnostics, prophylaxis, and treatment strategies in those undergoing or who have undergone solid organ transplantation. We will also briefly discuss the limited available data pertaining to coccidioidomycosis in stem cell transplant patients.

Coccidioidomycosis in Solid Organ and Hematologic Stem Cell Transplantation

Epidemiology

Coccidioidomycosis is caused by the dimorphic soil fungi *Coccidioides immitis* and *C. posadasii*. These infections occur predominantly in the southwestern USA, adjacent northern Mexico, and parts of Central and South America, but cases of infections have also occurred in Northern California, Oregon [1], and Washington state [2], areas that are not normally considered to be regions endemic for *Coccidioides*. Primary pulmonary coccidioidomycosis is colloquially referred to as "valley fever" because of its original descriptions of clinical manifestations among patients in the San Joaquin Valley in California [3]. For years, nearly two-thirds of all reported symptomatic coccidioidomycosis occurred in Arizona, while roughly one-third of cases occurred in California [1, 4]. Recently, however, the numbers from Arizona and California are becoming similar. In 2018, Arizona reported 7626 cases [5] (approximately 111 per 100,000), and in 2017, California reported 7466 cases [6] (approximately 19 per 100,000).

Among the general population, those at risk for acquiring infection include those who reside or travel to *Coccidioides*-endemic areas. Within that population, persons who spend large amounts of time outdoors either for work or recreation, especially in the presence of soil disruption, have increased risk for acquiring coccidioidomycosis [7]. Risk factors for severe pulmonary infections and *Coccidioides*-related hospitalizations include age >65 years, male sex [8, 9], Black race and Hispanic ethnicity [8, 9], older ages [9], diabetes mellitus [8], tobacco use [8], and immunosuppressed states [8]. In one study of coccidioidomycosis-related hospitalizations, nearly half were for pulmonary disease, and the other half occurred in patients with a wide array of extrapulmonary manifestations [9]. Immunosuppression in a wide variety of forms (including individuals with HIV and CD4 counts <250 cells/ml, those receiving tumor necrosis factor-α (TNF-α) inhibition, persons with hematologic malignancies, those receiving high-dose steroids, or those receiving immunosuppressants for solid organ transplantation) substantially increases the likelihood of symptomatic coccidioidal infection in individuals residing in endemic areas [10, 11]. The presence of malignant solid tumors does not appear to increase risk for coccidioidal infection [12].

Extrathoracic infections, which most commonly manifest in the skin, lymph nodes and adjacent soft tissues, and musculoskeletal and central nervous systems

(CNS), occur very infrequently (less than 1% of all infections) in the general public [13]. Risk factors for extrathoracic coccidioidomycosis include male sex, infection acquired in the third trimester of pregnancy, various immunosuppressing illnesses and medications (especially those that impair the cellular immune pathway, including antirejection therapies for organ and hematologic stem cell transplantation), and alterations of critical immune pathways such as the interleukin-12/interferon-γ and STAT3 (a mediator of IL12 signaling) axes [14]. Additionally, extrathoracic infection is thought to be more common in individuals of Filipino and African American descent for reasons that are not clear [15], but perhaps related to inherited defects in immunity [16]. Risk factors for coccidioidomycosis-related death in the general population reflect the same risk factors for severe or extrapulmonary infection. Advanced age, especially individuals greater than 75 years of age, is at high risk of mortality [17].

Individuals who have undergone solid organ transplant are at increased risk for symptomatic coccidioidal infection if they live within or frequently travel to a *Coccidioides*-endemic area [10, 18–20]. Inexplicably, however, while positive coccidioidal serology at the time of transplantation is a risk factor for coccidioidomycosis following transplantation, the presence of old granuloma on chest imaging is not [21]. Coccidioidomycosis in transplant recipients can manifest as a result of reactivation of infection acquired prior to transplantation, infection acquired through the donor organ, or de novo acquisition following transplantation. Prior to the programmatic institution of routine screening and antifungal prophylaxis, coccidioidal infection among transplant recipients was seen in 4–9% of such patients within the endemic area [19, 20]. Since the initiation of screening and prophylaxis programs in these areas, rates of coccidioidal infections have improved (2–3%) [11].

Mycology and Immunity

Outside of an animal host, *Coccidioides* lives as mycelia in the top layers of desert soil. When the soil is disrupted, arthroconidia are released into the air, acting as spores. Once inhaled, arthroconidia morph in the lung microenvironment into mature spherules, containing thousands of endospores which, when released after spherule rupture, are capable of continuing local coccidioidal infection or disseminating disease outside the thorax. Released endospores beget mature spherules and can extend the infection [22]. Once an arthroconidium is inhaled, a complex cascade of immune activity is activated to control infection and includes both innate and adaptive immunities.

When the innate immune system is activated, polymorphonuclear leukocytes are recruited to ingest arthroconidia, followed by the influx of natural killer cells [23]. Human macrophages are recruited to phagocytose and kill *Coccidioides*, a function that depends on IL-12/IFN-γ signaling [14]. Recruited dendritic cells are potent antigen-presenting cells, which then signal and set off the complex cascade of inflammatory cytokines that initiate adaptive immunity. Immunity to

coccidioidomycosis is dependent on the subsequent induction of Th1-related immune responses and establishment of cellular immunity [23]. Controlled and quiescent infection is often associated with the presence of granulomas in the lung or lymphatic tissue. The antifungals used (such as triazoles or amphotericin) to control coccidioidal infections do not appear to be fungicidal for this organism. Therefore, when "old" granulomas are sampled in an immunocompetent host, and cultured in the microbiology laboratory, growth of *Coccidioides* is frequently observed, regardless of whether the patient was previously administered antifungal treatment. Thus, following solid organ or hematopoietic stem cell transplantation (HSCT), with subsequent impairment of cell-mediated immunity, dormant organisms can potentially reactivate from either donor organs or recipients in the absence of antifungal prophylaxis. That cellular immunity maintains control of coccidioidal infection is of critical importance in discussions of transplantation, because antirejection treatments used in transplantation impair the same cellular immune responses that keep coccidioidal infections under control.

Clinical Manifestations

Infections from *Coccidioides immitis* and *Coccidioides posadasii* appear to be clinically indistinguishable. Most individuals (~60%), once exposed to *Coccidioides*, will be asymptomatic. In those infected, 95% of coccidioidal infections are limited to the respiratory system, and the most commonly recognized manifestation is coccidioidal pneumonia, accounting for 15–29% of community-acquired pneumonias in Arizona [24–26]. Symptoms of primary pulmonary coccidioidomycosis can be variable, and include a wide array of nonspecific complaints, but typically include one or more of the following: constitutional symptoms (fever, chills, night sweats, anorexia, headache, malaise, or fatigue), pulmonary symptoms (dyspnea, chest pain or tightness, cough), and often symptoms of hypersensitivity (such as arthralgia, arthritis, and a variety of rashes). Among recently located residents into a *Coccidioides*-endemic area, nearly two-thirds with newly developed coccidioidin skin test (indicative of recent infection) had no symptoms [27].

The primary manifestations of coccidioidomycosis in the transplant recipient predominantly reflect the pulmonary infection, but there is a notably greater propensity toward multi-organ, extrapulmonary infection. The symptoms of such disseminated infection include the same systemic symptoms as noted, and there may or may not be pain resulting from inflammatory lesions or abscesses in the particular area of involvement. Early studies indicated that transplant recipients whose course was complicated by coccidioidomycosis had concurrent pulmonary and extrathoracic infection in 75%, with 63% associated with mortality [28, 29]. More contemporary studies from transplant programs in the endemic area showed that, even with high index of suspicion and early empiric antifungal treatment, patients with new, symptomatic post-transplant coccidioidomycosis still experienced extrathoracic dissemination in 30%, and mortality rates range from 13% to 29% [20, 21, 30–32].

With current screening, treatment, and a 1-year post-transplant universal prophylaxis strategy, one transplant program diagnosed no patients with coccidioidomycosis in the first transplant year [33, 34], and fewer patients overall have contracted coccidioidomycosis. Coccidioidomycosis may still occur after the first post-transplant year, when the level of immunosuppression is lower than the level in the first year, and the first year antifungal prophylaxis has been withdrawn [10]. In a review of 91 solid organ recipients infected with coccidioidomycosis after the first post-transplant year, 56% were asymptomatic (identified by routine serologic screening), while 41% had primary coccidioidal pneumonia. While far fewer patients had severe (22% hospitalized) or disseminated (5.5%) infection, death due to coccidioidomycosis still occurred (1.1%) [10].

Laboratory Diagnosis of Coccidioidomycosis

An important tenant in the recognition of coccidioidomycosis is to think about the diagnosis. To this end, clinical history and exposure status (travel or residence) are important, and there should always be a suspicion of coccidioidomycosis for unidentified febrile illnesses in the transplant patient.

Although early recognition, identification, and treatment are paramount, it can be difficult to assess for active infection with standard lab tests. While 90% of immunocompetent adults with symptomatic coccidioidomycosis have a positive EIA IgG within 4 weeks after infection [35], the routine positivity of these serologic assays in acute infection cannot be assured in those who have suppression of the humoral or cellular immune systems, and the use of multiple methodologies (for diagnosis or screening) is recommended [35]. In a study of 27 transplant recipients with acute symptomatic coccidioidomycosis, initial serology using 3 different methodologies [enzyme immunoassay (EIA) for immunoglobulins IgM and IgG, complement fixation (CF) IgG, and immunodiffusion (ID) IgM and IgG] had a diagnostic sensitivity of 77%, but when repeated, the sensitivity increased to 92% [36]. A complement fixation titer of greater than 1:16 reflects substantial disease burden, but any positive serologic finding indicates the need for continued infection management, follow-up, and monitoring with serial serologies. Cultures of clinical specimens such as respiratory secretions had a sensitivity of approximately 50%, and adjunctive studies were helpful; tissue biopsies, polymerase chain reaction, and cytology had sensitivities of 75%, 60%, and 33%, respectively [36]. Coccidioidal antigen has proven helpful for diagnosis in a small study that included a few transplant recipients [37]. Another non-serologic test of value is the serum (1,3)-beta-D-glucan (sensitivity 43%, specificity 91%; positive and negative predictive values of 82% and 64%, respectively) [38].

Antibodies to coccidioidomycosis develop between 2 weeks and 2 months (or longer) following the onset of coccidioidal infection and are present during active infection. As cell-mediated immunity controls the infection, antibodies wane and eventually disappear over time [39, 40]. Remote infection, completely controlled, is generally not associated with seropositivity [39, 40]. Therefore, antibodies to

coccidioidomycosis are not "once positive, always positive," and the presence of IgG does not imply that infection is controlled and immunity is complete.

Radiographically, acute coccidioidal pneumonia is heterogeneous and appears as a nonspecific consolidation or mass, with or without hilar or mediastinal lymphadenopathy. Miliary, cavitary, and destructive intrapleural forms can be seen. Although there are no set rules as to how pulmonary coccidioidomycosis can manifest, the presence of pneumonia with ipsilateral hilar adenopathy in an endemic area is highly suggestive of coccidioidal infection [41].

Prevention of Coccidioidomycosis in Transplantation

Individuals undergoing heart, lung, kidney, and liver transplant are at increased risk of coccidioidal infection in endemic areas [19–21, 30, 42]. Recipients of other solid organ transplants have not been systematically studied but are presumed to overlap in their risk given the similarities across solid organ transplant immunosuppressive regimens. To this end, there are three modes of coccidioidal infection worth considering in the transplant recipient: [1] recrudescence of old infection in the recent transplant recipient, [2] primary infection after transplant, and [3] donor-derived infection [43]. It is not known whether particular types of solid organ transplants or post-transplant immunosuppressive regimens increase risk of coccidioidal infection relative to others.

Prevention of coccidioidomycosis in transplant recipients begins prior to the transplantation process and starts with identification (screening history and physical examination, chest radiographs, serology) and treatment of patients with active or subclinical infection.

Screening. In one transplant center within the endemic area, all donors and recipients are screened for evidence of active (but not necessarily symptomatic) *Coccidioides* infection prior to (and day of) transplantation to identify and treat subclinical infection prior to initiation of antirejection therapy. Additional screening occurs at regular intervals thereafter (generally 2–3 times in the first post-transplant year and annually thereafter). The recommended screening protocol includes history and physical examination, a chest radiograph, and serologies by EIA for IgM and IgG, complement fixation for IgG, and immunodiffusion for IgM and IgG. The combined sensitivity for detecting subclinical infection for these assays is 95% [21]. Another transplant program in an area of lower *Coccidioides* endemicity screens potential recipients from high endemic areas with the EIA only [44]. A positive screening serologic test implies some level of active infection. Since seropositivity implies recent or current infection, screening for such antibodies is believed to be a point at which intervention can occur by the use of antifungal medications to suppress or treat infections, whether overt or subclinical.

When undertaking serologic screening for coccidioidomycosis, false-positive serologies or serological results of uncertain significance are problematic [45], and if these problematic serologies cannot be adjudicated at the time of history and physical examination, we repeat testing in 1 months' time to assess for evidence of

serologic conversion. Because of low pretest probability in non-endemic areas, it is not necessary (or advisable) to screen for coccidioidal infection unless there has been travel to (or residence within) an endemic area temporally associated with a febrile or respiratory illness or history of coccidioidomycosis [44].

Once screening has identified possible infection, an evaluation by an infectious diseases specialist with knowledge of this infection is recommended to assess the activity of infection and whether treatment of active infection or suppression of subclinical infection is warranted. Computed tomography of the chest is helpful to assess the presence of early findings (such as infiltrate or mass) versus later findings of nodules, cavities, or granulomas.

When screening identifies active coccidioidal infection in recipients or donors, the infections should be treated before transplantation (Table 3) if clinically feasible. Once there has been symptom resolution, marked serologic improvement (our program requires at least 2 dilution lowering of the CF and a titer no higher than 1:2 or 1:4 on 2 occasions), and improved and stable radiographs, patients may proceed to transplant surgery and immunosuppression. Six to 12 months (or more) of antifungal treatment may be required to achieve these clearance goals. Our program requires a minimum of 6-month antifungal treatment for clearance of active infection, even if other clearance goals (i.e., symptoms, radiographs, and serology) have been reached. Following transplantation of these patients, 1 year of full-strength azole (equivalent to 400 mg daily of fluconazole) should be provided, followed by an annual evaluation by an infectious disease specialist to assess candidacy for lowering the dose of antifungal medication to a suppression dose. At the present time, for patients with any serologic evidence of active coccidioidomycosis at the time of transplantation, our program requires antifungal suppression for as long as the patient is receiving an immunosuppressive regimen. Whether there are specific groups who can discontinue antifungal suppression is unknown.

Prevention of primary coccidioidal infection following solid organ transplantation. Table 1 summarizes potential prophylaxis strategies to prevent coccidioidomycosis. Within the first year following transplantation, recipients without prior infection, who are living in the endemic area, appear to benefit from primary anti-coccidioidomycosis prophylaxis strategies. The risk of primary infection after transplant is greatest during the first 6–12 months, and this increased risk is thought to reflect the greater relative immunosuppression during this time [46]. During this time, immunosuppressive strategies aim to deplete T-cell populations and abrogate lymphocyte recruitment through direct and indirect blockade of cytokine-mediated lymphocyte proliferation and trafficking (particularly interleukin-2). This immunosuppressive therapy minimizes the risk of both cellular and humoral forms of rejection but also creates an increased risk for infection (including coccidioidal infection) [46].

With this relative increased risk of post-transplant infection, one transplant program in the *Coccidioides*-endemic area implemented a practice of universal antifungal primary prophylaxis with fluconazole 200 mg daily (or its triazole equivalent) during the first 6–12 months post-transplant in all solid organ recipients. This decision was based on the observation that targeted antifungal prophylaxis did

not eliminate de novo coccidioidomycosis, which occurred most frequently in the first 6–12 months after transplantation [32], and was associated with high morbidity and mortality [46]. Accordingly, there has been a substantial reduction in post-transplant infection [33].

Following the first post-transplant year, most organ recipients no longer require routine or long-term anti-*Coccidioides* prophylaxis. Since antirejection treatment is an additional risk factor for coccidioidomycosis following transplantation [19], some programs prescribe 3 months of fluconazole 200 mg daily (or its equivalent) following antirejection treatment, especially in transplant recipients at high risk for infection. With such prophylaxis, no coccidioidomycosis has been acquired within this time frame following treatment for acute rejection [10].

Prophylaxis of Recipient of Organs from a Coccidioides-Infected Donor

Finally, a recipient may receive an organ from a *Coccidioides*-infected donor and may require prophylaxis even if they do not reside in or travel to the

Table 1 Proposed coccidioidomycosis prophylaxis strategies for transplant recipients

Patient group	Prophylaxis strategy
Strategies for patients within *Coccidioides*-endemic regions	
All patients living in endemic region, who do not fit into a category below	Fluconazole 200 mg daily × 1 year beginning on the day of transplantation For treatment of acute rejection, after primary prophylaxis is completed: Consider fluconazole 200 mg/day × 3 months
Coccidioidomycosis prior to transplant; proceed with transplantation if all criteria met: Symptoms have resolved Cocci CF titer low or negative Radiographs resolved/stable	If seropositive at transplant: Fluconazole 400 mg/day × 1 year post-transplantation After 1 year, continue fluconazole 200 mg/day if seronegative If seronegative at transplant: Fluconazole 200 mg/day × 1 year
Primary coccidioidomycosis after transplantation, after treatment AND Symptoms resolved Serology negative Radiographs stable	Secondary prophylaxis: Fluconazole 200 mg daily for the duration of immunosuppression
Strategies for patients outside the endemic area	
Patients with history of prior residence or travel to endemic area	Screening serology positive at transplant: Fluconazole 400 mg/day × 1 year, then reassess at 1 year for further prophylaxis 200–400 mg/day Screening serology negative: No coccidioidal prophylaxis indicated
Patients without history of prior residence or travel to endemic area No screening serology recommended	No prophylaxis indicated
Post-transplantation relocation to *Coccidioides*-endemic area	Lung: consider fluconazole 200 mg/day Other organs: no prophylaxis indicated

Coccidioides-endemic region. Living donors with exposure to the *Coccidioides*-endemic area should undergo evaluation to assess history of known prior infection or potential infection and then be assessed serologically and radiographically for evidence of coccidioidomycosis [47]. How to best operationalize such assessments for the deceased donor from an endemic area is an unsettled issue [48].

Organ donors from *Coccidioides*-endemic regions may have experienced acute, chronic, asymptomatic, or resolved coccidioidal infection, all of which may harbor live organisms in granulomas, and the potential to transmit infection to the transplant recipient. The risk of transmission likely depends on the organ infected in the donor and the organ received. For example, a lung recipient of a patient with prior pulmonary coccidioidomycosis with residual coccidioidal granulomas in the lung is much more likely to acquire post-transplant coccidioidomycosis [49] than the kidney recipient of the same donor. However, a study of the Organ Procurement and Transplantation Network data identified 6 donors with coccidioidomycosis who donated various organs to 21 recipients, with a transmission rate of 43% and overall mortality of 28% [48]. Among those with preemptive azole treatment, infection was prevented or mitigated, whereas five out of the six recipients who did not receive antifungal prophylaxis died [48].

A number of case reports and case series document the severity of early, donor-derived coccidioidomycosis, which has high mortality [48, 50]. When one recipient is identified, the physicians of the other recipients must be notified, and anti-coccidioidal prophylaxis begun for all recipients of the infected donor. Such prophylaxis is effective in preventing coccidioidomycosis acquired from the donor organs [48, 50]. In the absence of clinical trials, guidance recommendations have been published outlining the approach to such prophylaxis, as summarized in Table 2 [47]. The duration of antifungal prophylaxis for these situations is uncertain, and is often lifelong, especially for lung recipients. Alternatively, in recipients of organs that are less likely to transmit coccidioidal infection, discontinuation of triazole prophylaxis could be considered after the period of highest immunosuppression, if patients are observed closely and understand that the risk of coccidioidal infection after discontinuation of prophylaxis is unknown. All recipients of infected donors should be periodically monitored for evidence of seroconversion.

Effective prophylaxis requires the use of a triazole. If the recipient is already receiving systemic itraconazole, voriconazole, posaconazole, isavuconazole, or amphotericin for prophylaxis or treatment of another fungal agent, additional fluconazole is not needed for prophylaxis of coccidioidomycosis. However, if a recipient is receiving *Aspergillus* prophylaxis with an echinocandin or inhaled amphotericin, additional (or switch) prophylaxis with a triazole will be required [47]. A more complete discussion of issues of prophylaxis for donor-derived coccidioidomycosis has been published [47]. The safety and efficacy of chronic suppressive triazole prophylaxis for endemic fungal infections were studied in 18 organ recipients over a 10-year period; among these, none had reactivated infection, and 1 experienced an adverse drug reaction (itraconazole-related symptomatic bradycardia) requiring medication discontinuation [51].

Table 2 Suggested prophylaxis strategies for organ recipients of a *Coccidioides*-infected donor[a]

Donor with documented coccidioidomycosis		
	Lung recipient	Non-lung recipient
Donor with documented pulmonary coccidioidomycosis but no evidence of extrapulmonary coccidioidomycosis, seropositive, or culture positive	Fluconazole 400 mg daily lifelong	Fluconazole 400 mg daily × 12 months, then 200 mg daily or stop and watch
Donor with documented pulmonary coccidioidomycosis but no evidence of extrapulmonary coccidioidomycosis, seronegative, culture negative	Fluconazole 400 mg daily lifelong	Fluconazole 400 mg daily for 3–6 months, then consider decreased dose 200 mg daily or stop and observe without ongoing prophylaxis
Documented extrapulmonary coccidioidomycosis	Fluconazole 400 mg daily lifelong	Fluconazole 400 mg daily lifelong
Donor with positive serology, but no clear focus of infection	Fluconazole 400 mg daily lifelong	Fluconazole 400 mg daily for 12 months, then consider decreased dose 200 mg daily thereafter

Modified from Singh et al. [47], with permission, endorsed by the American Society of Transplantation Infectious Diseases Community of Practice [60]

[a]All recipients should be monitored periodically for evidence of seroconversion; if discontinuation of prophylaxis is contemplated, regular follow-up clinically, radiographically, and serologically is recommended

Can transplant recipients visit the endemic area, and if so, will they require prophylaxis? The answer to this question is not well-studied. Among the general population in Arizona, the risk of coccidioidomycosis is estimated to be 2–3% per year [52]. Certainly there are published cases of immunosuppressed transplant recipients who have briefly visited the endemic area, and subsequently acquired coccidioidomycosis, some of which had severe manifestations [19]. However, in a small study of 37 liver transplant recipients who relocated to the endemic area, did not receive antifungal prophylaxis, and had at least 1-year follow-up, 1 (2.7%) acquired new coccidioidomycosis [53]. Therefore, we believe the risk of such infection is low, but not zero. When patients are receiving high-level immunosuppression, the risk of symptomatic or disseminated infection is likely higher. However, given drug-drug interactions of triazoles and antirejection treatments such as tacrolimus, there are risks of starting and stopping such prophylaxis. One author suggested the use of such prophylaxis for lung recipients only [42]. Whether prophylaxis should be given for brief visits to the endemic area is an unsettled question.

Non-pharmacologic prevention strategies. Vaccination for the prevention of coccidioidomycosis has been the subject of much study [54]. At the present time, however, there is no vaccine for clinical use. We strongly support current efforts to push this effort forward. In the meantime, avoidance of the endemic area may be possible for some, but not for others, and is not advocated. Theoretically, use of masks to avoid exposure during situations or activities with known or perceived risk

(such as being outside in a dust storm or during digging or landscaping or traversing unpaved roads, etc.) seems logical, but has no proven efficacy.

Treatment of Coccidioidomycosis in Transplantation

Treatment of coccidioidomycosis in transplantation requires the identification of the infection, assessment for the presence of extrathoracic dissemination, and classification of disease severity. An extensive history and physical examination and adjunctive testing will guide this classification.

Recognition of coccidioidomycosis. The symptoms of coccidioidomycosis overlap substantially with community-acquired pneumonia. In addition to respiratory symptoms, patients often complain of significant fatigue, myalgias, and night sweats. Rashes can appear and are highly varied (diffuse macular rash, erythema nodosum, erythema multiforme, or toxic erythema) [55]. Careful attention to symptoms suggesting involvement of the skin, lymph nodes, bones and joints, and/or meninges should help identify extrapulmonary infection.

Antifungal treatment of infection before, during, and after solid organ transplant. As noted above, pre-transplant infection should be treated if possible per standard Infectious Diseases Society of America (IDSA) guidelines (Table 3) [56]. Treatment of de novo, donor-derived, and recrudescent coccidioidal infections is the same as in immunocompetent hosts. Fluconazole and itraconazole are first-line agents, and amphotericin is used (added or substituted) if the infection is rapidly progressing or

Table 3 Initial approach to treatment of coccidioidomycosis [56][a]

Situation	Treatment
Primary pulmonary coccidioidomycosis	Fluconazole 400 mg daily or itraconazole 200 mg BID or TID Lipid-formulated amphotericin if severe or rapidly progressing
Extrapulmonary coccidioidomycosis	
Musculoskeletal Skin/soft tissue Meningitis/CNS	Itraconazole 200 mg BID or TID or fluconazole 400 mg daily Fluconazole 400 mg daily or itraconazole 200 mg BID or TID Fluconazole 800 mg daily
Pregnancy	Triazoles contraindicated, especially in the first trimester Lipid-formulation amphotericin
Other agents for intolerance or salvage	Voriconazole 200–300 mg BID Posaconazole extended release 300 mg daily

Duration of treatment in each case should be individualized, but not less than 12 months. Patients with meningitis/CNS disease should be treated for life

[a]For patients prior to transplantation or following transplantation

BID, twice daily

TID, thrice daily

so unusually severe that management requires the patient to be in the intensive care unit [56]. The level of immunosuppression may need to be decreased to gain control of infection [19].

For patients who do not respond to (or are intolerant of) fluconazole or itraconazole, voriconazole or posaconazole can be used as salvage therapy (Table 4). There is limited experience with isavuconazole in the treatment of coccidioidomycosis [57].

Amphotericin B products (Table 4) have predictable activity versus *Coccidioides* species, and the deoxycholate formulation was used for decades prior to the advent of triazole antifungal agents. However, the amphotericin deoxycholate formulation is fraught with toxicity, including infusional toxicity (fever, rigors, and phlebitis) and acute and chronic kidney injury with nephrogenic losses of potassium and magnesium. The newer lipid formulations of amphotericin have fewer (but still present) toxicities and, although never studied head-to-head with amphotericin deoxycholate, appear to work well in patients who are rapidly deteriorating. Amphotericin formulations are not associated with fetal malformations and are safe for pregnant patients. Intrathecal administration of amphotericin deoxycholate is rarely used anymore, but can be considered for patients with coccidioidal meningitis recalcitrant to triazole therapy (Table 4).

Once the infection is controlled clinically, radiographically, and serologically, secondary suppression is recommended for the duration of immunosuppression. For such suppression (secondary prophylaxis), fluconazole is typically dosed at 200–400 mg daily. Ideally, patients with coccidioidal infection of the central nervous system should not have their triazole dose lowered. Daily azole dosing should not be lowered in patients who have not yet achieved clinical, radiographic, and serologic resolution.

Drug interactions in transplant recipients. Table 4 summarizes selected important drug-drug interactions with azoles in the transplant recipient. Azoles vary in their pharmacologic characteristics, but typically interact with metabolism of tacrolimus and cyclosporine, raising the serum levels of these antirejection medications and risk of related nephrotoxicity. Similarly, azoles variably increase levels and toxicity of sirolimus and, to a lesser extent, everolimus. Therefore, teamwork and close communication with the transplant team are necessary to optimally initiate and discontinue these antifungal regimens.

Follow-up. Depending on the severity of illness in patients with acute coccidioidomycosis, patients may need to be followed closely (e.g., daily while hospitalized and then weekly or monthly as outpatients), but after improvement, follow-up with clinical examination, radiographs, and serology can take place every 2–3 months and then every 3–6 months.

Hematopoietic Stem Cell (Blood and Marrow) Transplantation (HSCT)

Compared to coccidioidomycosis in solid organ transplantation, far less is known about coccidioidal infections in patients who have undertaken HSCT.

Table 4 Antifungal agents for the treatment of coccidioidomycosis in transplant recipients

Agent	Typical dosing in patients with normal kidney function	Notations	Transplantation-relevant drug interactions
First-line agents for coccidioidomycosis			
Fluconazole[b]	400 mg daily for most 800 mg daily for most meningitis	Teratogenic, especially in the first trimester ↑Risk miscarriage	Increases levels of tacrolimus, cyclosporine, and perhaps sirolimus
Itraconazole[b]	200 mg BID or TID	Requires gastric acid for absorption Serum levels required Strong CYP3a inhibitor Teratogenic, especially in the first trimester Black box warning: congestive heart failure and numerous drug interactions	Increased serum levels of tacrolimus, cyclosporine, sirolimus, everolimus
Salvage/second-line agents for coccidioidomycosis			
Voriconazole	200–300 mg BID	Monitor serum trough levels Levels may decline over time Strong CYP3a inhibitor Numerous drug interactions	Increases levels of tacrolimus, cyclosporine, sirolimus, everolimus,
Posaconazole	Liquid formulation: 300 mg BID Extended release capsules: 3 × 100 mg capsules daily	Monitor serum trough levels	Increases levels of tacrolimus, cyclosporine, sirolimus, everolimus,
Agents used in specific circumstances			
Lipid-associated amphotericin products[a]	3–5 mg/kg/day IV for patients with severe/rapidly progressing illness or for control of infection in pregnancy	For patients with severe or rapidly progressing coccidioidomycosis No teratogenicity Nephrotoxicity is less than deoxycholate formulation ↓K, ↓Mg	No drug interactions with any antirejection treatment

(continued)

Table 4 (continued)

Agent	Typical dosing in patients with normal kidney function	Notations	Transplantation-relevant drug interactions
Amphotericin B deoxycholate	Systemic protocol: 0.25–1 mg/kg/day intravenously Intrathecal protocol for recalcitrant meningitis:0.1–1.5 mg/dose IT	For salvage of coccidioidomycosis, if lipid-associated formulations unavailable For salvage of coccidioidal meningitis (IT) No teratogenicity Nephrotoxicity, ↓K, ↓Mg Local and infusional toxicity	No drug interactions with any antirejection treatment

Mg, milligrams
QD, daily
BID, twice daily
TID, thrice daily
IV, intravenous infusion
IT, intrathecal administration
[a]liposomal amphotericin, amphotericin lipid complex, amphotericin B cholesteryl sulfate complex
[b]Will require dosage adjustments in patients with kidney disease

Unlike those undergoing solid organ transplantation, in the absence of relapsed hematologic malignancy or prolonged graft-versus-host disease, the immunosuppression of allogeneic HSCT is more intensive early on, but has a shorter duration than solid organ recipients, and most patients are felt to have normal immunity 2 years following stem cell transplantation. In two back-to-back studies of patients in our HSCT program spanning 20 years (1993–2013), we reviewed the courses of 1318 HSCT patients, of which 439 (33%) were allogeneic HSCT recipients, whose graft-versus-host disease-based immunosuppression was tacrolimus. Among the 439 allogeneic HSCT recipients, 12 (2.7%) had coccidioidomycosis, and 2/12 (16.7%) had extrapulmonary dissemination. Eight of the 12 (66.7%) contracted coccidioidomycosis within 2 years following HSCT, and 6 of these 8 (75%) died with evidence of active coccidioidomycosis [11, 58, 59]. Therefore, we recommend that, for HSCT patients in endemic areas, antifungal prophylaxis with anti-*Coccidioides* activity be continued for 2 years following HSCT.

Conclusion

Organ transplantation can be a successful undertaking within the *Coccidioides*-endemic region. Careful attention to screening and treatment of infection prior to transplantation is important to prevent activation or reactivation following

transplantation. Prophylaxis strategies have undergone study and revision and should target the prevention of coccidioidomycosis in the first post-transplantation year, during acute organ rejection, and in recipients of *Coccidioides*-infected donors. Early recognition and treatment of organ recipients with coccidioidomycosis is key to minimizing morbidity and mortality for patients within and outside the endemic area.

Key Points

- Coccidioidomycosis is an important cause of morbidity in transplant programs in endemic areas.
- Coccidioidomycosis causes infection that ranges from asymptomatic to severe and disseminated infections; among the symptomatic, primary pulmonary infections are most common.
- Immunity, especially cell-mediated immunity, plays an important role in control of coccidioidomycosis in healthy populations. Following transplantation, impaired cellular immunity makes control of infection more difficult.
- Screening potential transplant recipients for active infection prior to transplantation allows treatment and suppression without reactivation following transplantation.
- Post-transplant coccidioidomycosis is complicated by high rates of extra-pulmonary infection and death. A high index of suspicion and early treatment is needed.

Introduction

The endemic fungi are a group of thermally dimorphic fungi that occupy specific defined environmental ranges (Fig. 1). They count *Histoplasma*, *Blastomyces*, *Paracoccidioides*, *Coccidioides*, *Talaromyces*, *Emergomyces*, and *Sporothrix* among their number. In the environment they exist as molds, and at body temperature, they transform into their pathogenic yeast form (or, in the case of coccidioidomycosis, into a specialized structure called a spherule). *Histoplasma*, *Blastomyces*, and *Paracoccidioides* are covered in this chapter. The main form of acquiring these diseases is by inhaling the mold form's conidia, and this frequently happens after the soil or decaying vegetation that houses the fungus is disturbed. After the conidia are inhaled, the fungus undergoes one of three fates. If the host's innate immunity is strong enough, or the inoculum small enough, the conidia and/or yeasts may be killed outright. If this defense fails, the infection may be able to be controlled by the host's T-cell-mediated immunity, often in a quiescent state within granulomas, from which it may subsequently escape if the host's immunity wanes – as, for example, following a transplant. For this reason, disease from one of the endemic mycoses can occur years, sometimes decades, after the patient visited an endemic area. Lastly, if the infection is not able to be sufficiently controlled by the

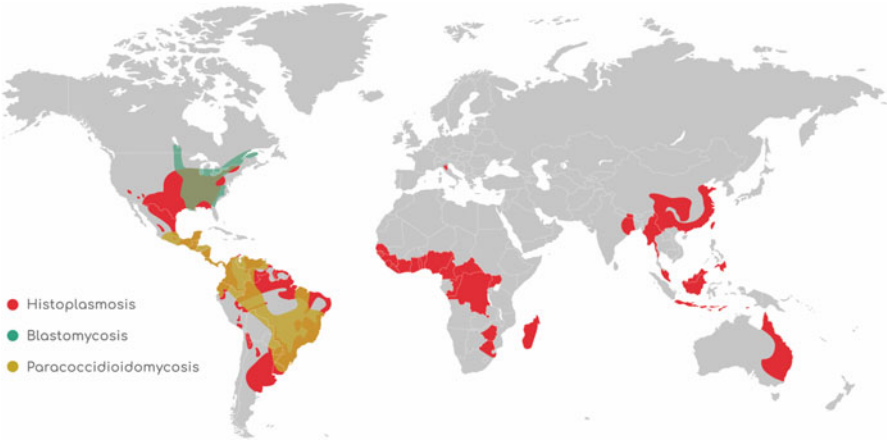

Fig. 1 Approximate areas of endemicity for histoplasmosis, blastomycosis, and paracoccidioidomycosis [6, 86, 87]

patient's immune system initially, symptomatic disease may occur more immediately, either within one organ system (often the lung) or disseminated more broadly.

The microbiologic diagnosis of endemic mycoses is limited by a relative lack of sensitivity of cultures, difficulty in obtaining the most appropriate samples from patients, and the slow growth of the organism in culture. Therefore, non-culture-based methods of diagnosis such as direct microscopic exam of specimens, antigen assays, and antibody tests are used in conjunction with cultures. Antibody assays often have decreased sensitivity in transplant recipients however. Polymerase chain reaction (PCR) assays are an emerging diagnostic modality, albeit one that is often not commercially available or well studied.

The treatments of choice for all the endemic mycoses are liposomal amphotericin B (given up front for severe disease) and the azoles. While the newer azoles such as posaconazole or isavuconazole show some promise, the bulk of the evidence resides with the older azoles, such as itraconazole, fluconazole, and voriconazole, and there are few direct comparisons available by which to dislodge the latter drugs as frontline agents. In general, treatment must be given for a prolonged period (frequently a year or more) in order to prevent a relapse.

Histoplasmosis

Disease Epidemiology

Histoplasmosis is caused by the fungus *Histoplasma capsulatum*. Mycelial growth in histoplasmosis is favored in soil in climates with moderate temperatures (between 15 °C and 40 °C), high relative humidity, and a soil pH >5.5 [1]. Growth and sporulation of *Histoplasma capsulatum* are especially enhanced by the presence of bird and bat guano, which provides a high nitrogen and phosphorus content that can on occasion permit mycelial growth even in the absence of soil [2]. Activities that disturb soil and aerosolize *Histoplasma* spores can place patients at risk of acquiring histoplasmosis. These activities classically include spelunking, digging in soil where there are bird or bat droppings, cleaning bird coops, and renovating or demolishing buildings that have been colonized by bats or birds [1, 3, 4]. However, *Histoplasma* conidia may be carried for miles on air currents, and many patients do not have a history of a specific exposure.

The highest incidence of histoplasmosis worldwide appears to be in North America, in an area surrounding the Ohio and Mississippi River Valleys [5, 6]. However, patches of histoplasmosis endemicity are spread throughout the world. A large number of endemic cases have been reported from Mexico, Central America, and the majority of South American countries (Fig. 1). In areas of Brazil, skin reactivity to histoplasmin antigens (reflecting prior exposure to the fungus) has been reported in nearly 90% of inhabitants tested in some areas of the country [5]. Cases of histoplasmosis have also been identified from the majority of African countries, though the picture is somewhat clouded by the existence of two variants there, with an "African" variant, *Histoplasma capsulatum* var. *duboisii*, prevalent

in the western parts of the continent. *Histoplasma capsulatum* var. *capsulatum*, the variant present elsewhere in the world, is found in Africa's southern parts, and the two variants coexist in the intervening areas [6, 7]. Parts of India and Southeast Asia also appear to be endemic for histoplasmosis, with Malaysia, Thailand, Taiwan, China, and the eastern parts of Australia all reporting endogenously acquired cases and substantial rates of histoplasmin skin hypersensitivity [6]. Histoplasmosis is not generally considered endemic in Europe, with a near 0% rate of positive skin hypersensitivity assays there and reported cases from Europe generally having been imported from endemic areas elsewhere in the world. However, a small number of potentially autochthonous cases have been described from Italy, Germany, and Turkey [8]. This worldwide distribution of histoplasmosis stands in contrast with the much more geographically restricted ranges of other endemic fungi, such as coccidioidomycosis, paracoccidioidomycosis, and blastomycosis. It is possible that naturally infected bats and birds with long-range migrations may be responsible for *Histoplasma capsulatum*'s wide dispersal to disparate regions of the globe [5].

Surveys of histoplasmin skin hypersensitivity that have identified the traditional endemic areas of the world have been performed in only a small minority of countries, and many such maps are now decades old [9]. Factors like climate change and population migration may have changed these areas since the surveys. Indeed, recent evidence suggests that the preferred soil environments in the USA might now include the Missouri River basin, in addition to the Ohio and Mississippi River basins [10]. In addition, soil and climatic conditions that support *Histoplasma* growth likely exist in many "microenvironments" throughout the world, and thus histoplasmosis should be considered in any patient with a compatible clinical picture, even without travel to one of the classic endemic areas [6]. This dictum is all the more important considering that histoplasmosis has been reported to reactivate up to 50 years after initial exposure, which further clouds the association between the disease and a history of exposure to an endemic area [8].

Clinical Impact on Transplant Patients

Histoplasmosis causes the greatest burden of disease of all the endemic fungi seen in immunocompromised hosts. The Transplant-Associated Infection Surveillance Network (TRANSNET) reported 48 histoplasmosis cases in solid organ transplant (SOT) recipients and 4 histoplasmosis cases in in hematopoietic cell transplant (HSCT) recipients, respectively, from 15 surveillance sites over 5 years from 2001 to 2006 [11]. The cumulative incidence in SOT recipients was 0.1% for the 12-month period following their transplants. In a high-volume SOT center in Ohio, incidence of post-SOT histoplasmosis was 1 case per 1000 transplant-person-years (95% confidence interval, 0.6–1.7) [12]. The risk of histoplasmosis is highest in the first year after transplantation, though an increased posttransplant risk is likely to persist indefinitely compared to immunocompetent patients. By way of example, the incidence of histoplasmosis among SOT recipients in Ohio, a known endemic area, was 16 times higher than that of the general population >65 years of age in the same

state [13]. Mortality from histoplasmosis arising after SOT is approximately 10%, with the bulk of deaths occurring within the first month after diagnosis [11, 14]. In the TRANSNET cohort, there were no deaths at 3 months among the four HSCT recipients who developed histoplasmosis.

Pathogenesis

Aerosolized *Histoplasma capsulatum* conidia may be inhaled, and microconidia between the sizes of 2 and 4 micrometers are small enough to reach the alveolar spaces. Microconidia that evade the lung's innate defenses develop into the yeast phase of the organism. Macrophages are initially capable of phagocytosing but not killing the organisms, as it takes approximately 10–14 days for the development of the required CD4 T-lymphocyte-mediated immune response [15]. If this immune response is robust enough, the spread of the organism is arrested. Most immunocompetent patients are thus either asymptomatic or have mild, self-limiting respiratory symptoms [4]. Immunocompromised patients, including SOT and HSCT recipients, may fail to stop the spread of the organism and present with progressive disseminated disease [15].

Even those patients who do control the infection frequently fail to completely eradicate it. Rather, viable *Histoplasma capsulatum* organisms may be walled off inside granulomas within the body. Patients who have had prior histoplasmosis exposure, even decades before, are at risk of suffering a reactivation of the disease if their immunity subsequently declines, whether from SOT, HSCT, immunosuppressant medications, old age, HIV, or other immunosuppressing conditions [15]. In many cases, whether a case of histoplasmosis represents disease reactivation or a new acquisition can be difficult to determine, although some evidence suggests that new acquisition may predominate [13, 16, 17].

SOT recipients may acquire the disease from an infected allograft. To date this method of transmission remains extremely rare, with only a handful of cases in the literature [18, 19].

Clinical Manifestations

Consistent with *Histoplasma capsulatum*'s pulmonary route of acquisition and subsequent engulfment by macrophages, the predominant organs involved are the lungs and the lymphoid-rich tissues. The better the patient's cell-mediated immunity, the greater the chance that disease remains confined to the lungs. Those with a modest exposure to *Histoplasma capsulatum* may develop a subacute or chronic pneumonia or one or more pulmonary nodules that may be incidentally picked up on chest X-ray. Those with a larger exposure can develop an acute pneumonia and acute respiratory distress syndrome. Other less common presentations such as broncholithiasis and fibrosing mediastinitis are also possible [3]. SOT and HSCT recipients may develop any of the above pulmonary syndromes, but disease more

frequently disseminates beyond the lungs; disseminated disease is the rule rather than the exception in these patient subgroups. In the TRANSNET cohort of HSCT and SOT recipients mentioned above, >71% of cases had demonstrable dissemination at the time of diagnosis [11].

Extrapulmonary disease can occur with or without concomitant pulmonary disease in immunocompromised hosts. Commonly infected sites include the liver, spleen, lymph nodes, bone marrow, gastrointestinal tract, and skin (Fig. 2). Systemic symptoms such as fever, loss of weight, anorexia, and fatigue are common. Clinical signs seen with disseminated disease include hepatomegaly, splenomegaly, lymphadenopathy (which may sometimes be massive), and the effects of cytopenias [3]. Hemophagocytic lymphohistiocytosis is also a recognized complication of disseminated histoplasmosis.

Diagnosis

No diagnostic test for histoplasmosis has adequate sensitivity to be used in isolation. Rather, multiple tests should be performed in parallel, guided by the sites of involvement in the individual patient. Urine histoplasma antigen assays have the highest sensitivity of any single diagnostic test in disseminated histoplasmosis, with an estimated sensitivity of ~93% in SOT recipients. Serum antigen testing is somewhat less sensitive (estimated 80% sensitivity). Antigen testing may also be positive in bronchoalveolar lavage (BAL) fluid and cerebrospinal fluid (CSF), when these areas are involved. However, the specificity of the antigen test is limited

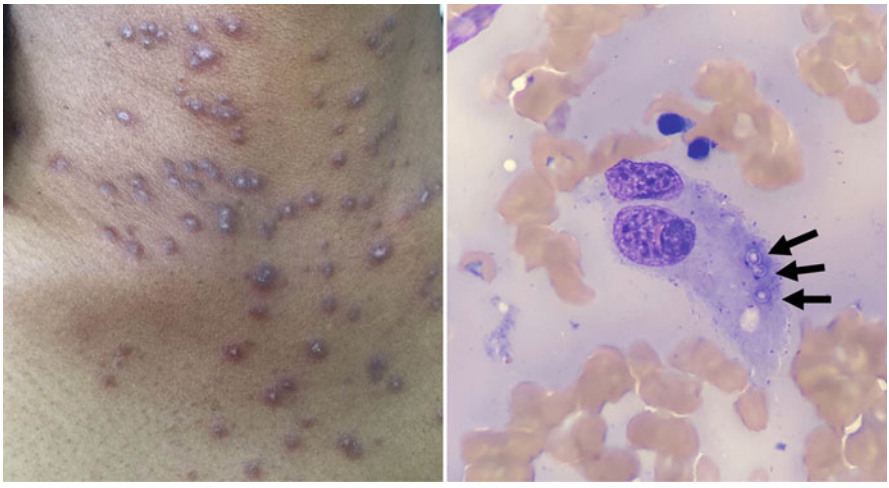

Fig. 2 Histoplasmosis. Left, typical papular rash sometimes seen with disseminated disease. Right, yeast form of histoplasmosis visible on this bone marrow aspirate as small yeasts (arrows) clustered within a macrophage. The pseudocapsule that provides the organism's species name ("capsulatum") is clearly visible but is an artifact of cytoplasmic shrinkage (Wright-Giemsa stain)

Table 1 Role of diagnostic tests in histoplasmosis, blastomycosis, and paracoccidioidomycosis in transplant recipients

	Histoplasmosis	Blastomycosis	Paracoccidioidomycosis
Microscopy	Small (2–4 μm) yeasts clustered within macrophages, with pseudocapsule	Large (10–15 μm) yeasts with thick walls and broad-based budding	Variably sized yeasts (4–60 μm) arranged as a central parent yeast with multiple other yeasts budding off
Cultures	Sensitive but growth typically takes 2–4 weeks	Sensitive but growth typically takes 2–4 weeks	Sensitive but growth typically takes 2–4 weeks
Serology	Limited value – poor sensitivity	Limited value – very poor sensitivity	Moderate sensitivity in transplant patients. Serial measurements can be used to follow treatment response
Antigen test	Urine antigen test has sensitivity >90%. Blood antigen test has sensitivity of ~80%. Some cross-reaction with other fungi	Urine antigen test has sensitivity of 76–93%. Cross-reaction with other fungi seen	Not commercially available

by cross-reaction with similar antigens from other endemic fungi [20]. Cross-reaction with *Aspergillus* antigens has also been reported in solid organ transplant patients [21]. Antibody assays are insensitive in histoplasmosis in general and particularly so in transplant recipients. Cultures from blood and any other infected site (e.g., bronchoalveolar lavage fluid, skin, liver, lymph nodes) are generally positive in >60% of cases [22]. However, the utility of cultures is further limited by the fact that the organism typically takes 2–4 weeks for adequate growth to permit identification [3]. Histologic specimens taken from the lungs, lymph nodes, liver, bone marrow, skin, or other involved organs may reveal typical clusters of small (2–4 μm) yeasts intracellularly within macrophages and other phagocytes (Fig. 2) [23]. This may permit a provisional diagnosis. Polymerase chain reaction (PCR) is a promising emerging diagnostic modality that offers the potential to obtain rapid and highly specific results. However, trials to date have used a variety of methodologies and technologies, with correspondingly varying results, preventing a firm recommendation for the use of PCR-based diagnostics [24–26]. Diagnostic considerations are outlined in Table 1.

Treatment

Transplant recipients with histoplasmosis should generally be considered to have disseminated disease unless proven otherwise. In most cases, amphotericin B is advised for 1–2 weeks initially, followed by itraconazole for at least 12 months [27]. Lipid formulations of amphotericin are preferred over amphotericin B deoxycholate, primarily because of decreased toxicity. In addition, histoplasmosis remains the only condition for which the liposomal form of amphotericin has also been shown to be

more efficacious than the deoxycholate form [28]. Severely ill patients may have attendant acute kidney injury, but this should not dissuade clinicians from using lipid formulations of amphotericin initially in such cases. Indeed, renal dysfunction may improve if the infection is rapidly brought under control with amphotericin.

Following an initial 1–2 weeks of amphotericin therapy, the patient may be transitioned to azole therapy to complete a minimum of 12 months of therapy. Itraconazole is the preferred azole for use in histoplasmosis. In mild to moderate cases of disease, itraconazole alone, without amphotericin, may even be sufficient as therapy [29]. Measuring blood levels of itraconazole is recommended, as its bioavailability may often be impaired by gastric conditions, and itraconazole is also frequently both a cause and target of drug-drug interactions (see section "Common Antifungal Drugs Used to Treat the Endemic Mycoses") [27].

Itraconazole appears superior to fluconazole for the treatment of disseminated histoplasmosis. In vitro data shows a greater potency for the former drug, and acquired immunodeficiency syndrome (AIDS) patients with mild-moderate disseminated disease who were treated with itraconazole had a greater response rate than those treated with fluconazole in a similar trial (85% vs. 70%) [29–31]. The relapse rate with fluconazole was also substantially higher than that seen with itraconazole in these trials, driven by the development of resistance while on therapy [30]. This phenomenon was not seen with itraconazole.

The role of other azoles in the treatment of histoplasmosis has not been well studied. On the basis of in vitro data, posaconazole seems more potent and less prone to developing resistance than voriconazole [32]. Other in vitro data suggest that isavuconazole is an extremely potent drug, and like posaconazole, its potency does not appear to be affected by the development of fluconazole resistance. Furthermore, isavuconazole offers excellent bioavailability that may preclude the need for routinely measured drug levels. However, clinical experience with posaconazole, voriconazole, or isavuconazole in treating histoplasmosis patients is decidedly limited to date, and thus their role is currently relegated to salvage therapy in patients who have failed or are intolerant of itraconazole therapy [27, 33].

Of note, the yeast form of *H. capsulatum* is not susceptible to the echinocandins, which therefore have no role in therapy [34].

Symptoms of histoplasmosis may take several weeks to fully resolve, though some overall clinical improvement is usually seen within a week. Histoplasma antigen levels may be monitored serially to assess response to therapy. A failure of the antigen level to decline on treatment may represent treatment failure. Antigen levels should also be checked for 6–12 months after completing therapy to check for a relapse. In general, antigen levels should be negative at the end of treatment, though some patients with persistent low-level antigenuria without evidence of active disease have had good clinical outcomes when their treatment was stopped [27, 35].

Prophylaxis

SOT or HSCT recipients should avoid activities known to be high risk for acquiring histoplasmosis, such as those mentioned previously. Primary prophylaxis has only been

studied in patients with advanced HIV, where a daily dose of itraconazole more than halved the incidence of histoplasmosis over a median follow-up period of 16 months in an endemic area [36]. Based on expert opinion however, the Infectious Diseases Society of America (IDSA) recommends prophylaxis only in situations where the incidence of histoplasmosis is greater than 10 cases per 100 patient years.

The role of secondary prophylaxis after transplant is also somewhat unclear. Patients with a history of previous histoplasmosis, or radiologic or serologic evidence of past disease, are at risk of reactivation in the posttransplantation period due to their profound immunosuppression. However, the risk of reactivation appears low. Not a single case of histoplasmosis was diagnosed in over 550 HSCT and SOT recipients over a mean follow-up of 16 months in a hyperendemic area. This cohort included patients with radiographic and serologic evidence of past disease. Another important consideration is that the urine histoplasma antigen is a useful screening test for disease reactivation. Thus, instead of itraconazole prophylaxis, an alternative strategy is to measure urine histoplasma antigen levels every 2–3 months during the intensive phase of the patient's immunosuppression regimen [27]. Similarly, patients who develop histoplasmosis for the first time after transplantation probably do not require secondary prophylaxis and should instead have serial urine histoplasma antigen levels mentioned after their treatment course has been completed. Notably, the risk of disease reactivation after appropriate treatment is low, at $<5\%$ [14].

A related problem involves organ donors with a remote history of histoplasmosis. Though little data exists to guide decision-making in this scenario, a suggested approach is outlined in Table 2.

Blastomycosis

Disease Epidemiology

Recent phylogenetic work has revealed that blastomycosis is caused by one of two species, *Blastomyces dermatitidis* and *Blastomyces gilchristii*. The natural habitat of the organism has been far harder to elucidate than that of the other endemic fungi, for two reasons. Firstly, it has proven very difficult to isolate the fungus from environmental sources, and secondly, there are no adequately sensitive and specific serologic tests or skin test reagents [37]. Despite these limitations, autochthonously acquired cases have historically clustered around the Great Lakes area on both the US and Canadian sides, as well as the Ohio, Mississippi, and St Lawrence River basins (Fig. 1) [37]. Indeed, two outbreak studies where *Blastomyces* was ultimately cultured suggest that soil and wooded areas surrounding rivers and lakes may be the organism's favored habitat [38, 39]. The blastomycosis-endemic areas overlap extensively with those for histoplasmosis, though the former are more extensive. Outside of North America, endogenously acquired cases have been reported from India and several African countries [40, 41].

Similar to histoplasmosis, risk factors for acquiring the disease include activities that disturb the soil and thereby aerosolize *Blastomyces* conidia. Known associations

Table 2 Suggested prophylactic regimens for histoplasmosis, blastomycosis, and paracoccidioidomycosis in transplant recipients

	Recipient peri-transplant (primary) prophylaxis	Secondary prophylaxis for recipients after completion of treatment course
Histoplasmosis	Donor with localized pulmonary disease: itraconazole 200 mg once or twice daily for 3–6 months Donor with disseminated disease: itraconazole 200 mg once or twice daily for 12 months [84]	Not routinely indicated. Can monitor urine antigen level every 3 months to determine need. If required, consider itraconazole 200 mg daily [27, 84]
Blastomycosis	Donor with localized pulmonary disease: itraconazole 200 mg once or twice daily for 3–6 months Donor with disseminated disease: itraconazole 200 mg once or twice daily for 12 months	Not routinely indicated. If required, consider itraconazole 200 mg daily [54]
Paracoccidioidomycosis	Itraconazole 200 mg once daily for 12 months [77]. Trimethoprim-sulfamethoxazole may be sufficient if already part of the posttransplant prophylaxis regimen	Not routinely indicated. Can follow with serial serology titers. If required, consider itraconazole 200 mg daily

include camping, forestry work, fishing, cutting trees, or clearing brush in endemic areas [16, 38, 39].

Clinical Impact in Transplant Patients

The TRANSNET surveillance network identified just 9 cases of blastomycosis in transplant recipients (compared to 52 cases of histoplasmosis) over a 5-year period [11]. All nine cases were seen in SOT recipients, though rare cases of blastomycosis in HSCT recipients have been described elsewhere [42]. Similarly to histoplasmosis, the majority of cases occur within the first year after transplantation [11]. Mortality estimates for SOT recipients with blastomycosis have ranged from 0% to 36% [11, 43, 44].

Pathogenesis and Clinical Manifestations

Blastomyces conidia, possibly aerosolized during soil disturbances, are inhaled and reach the alveoli. If they survive destruction by the lung's neutrophils, monocytes, and macrophages, the shift in ambient temperature signals to the conidia to develop

into the yeast form. As with histoplasmosis, this form is harder to kill due to its size (which prevents phagocytosis by neutrophils), its thicker cell wall, and the expression of various virulence factors. In the case of blastomycosis, the latter include BAD-1, which mediates attachment to macrophages and also shifts the cell-mediated immune response away from the Th1 response that is required to eliminate the infection [45]. If the patient's immune response is not adequate to contain the organism within the lungs, disseminated infection may occur. In addition, the organism may be held in check in a dormant state by the patient's immune system, allowing reactivation should the patient's immune competency decline, such as what occurs in SOT or HSCT recipients. Remote reactivation as long as 40 years after initial infection has been described [46]. No cases of graft-derived blastomycosis have been reported to date.

As with all the endemic fungi, clinical manifestations depend on the interplay between host immunity and the inoculum size. Patients with a robust immune response may clear the organism before any symptoms develop. Indeed, approximately half of immunocompetent patients are asymptomatic. However, transplant recipients are more likely to develop symptomatic pulmonary disease – the lungs are involved in 80–100% of cases [43, 44]. Transplant recipients also seem predisposed to have a more severe pulmonary course than immunocompetent patients. Rates of acute respiratory distress syndrome (ARDS) and early mortality are higher, and patients who do recover may have substantial residual lung damage [11, 43, 44].

Transplant patients may also have greater rates of disseminated disease [43]. When the disease spreads beyond the lungs, the next most commonly involved site is the skin, though multiple pustules or ulcers are more common than the classic verrucous lesions seen in immunocompetent patients (Fig. 3) [47]. Other clinical manifestations include lytic bone lesions, prostatitis, epididymitis, meningitis, or cerebral abscesses. Interestingly, CNS disease with blastomycosis appears to be far less common among SOT recipients than it is among patients with AIDS [48]. Importantly, at the time when extrapulmonary symptoms appear, pulmonary findings can be minimal or even absent [49].

Diagnosis

Blastomycosis is often not considered in a patient's differential diagnosis. In one study in Mississippi, USA, only 5% of patients with blastomycosis were correctly diagnosed at presentation, and 43% had a delay in diagnosis of over 1 month, despite the fact that Mississippi is a hyperendemic area [50].

Blastomyces grows readily in appropriate culture media, though, like all dimorphic fungi, it may take up to 4–6 weeks of incubation before it shows adequate growth to permit a diagnosis [49]. The yield from pulmonary specimens is often excellent, with sputum and bronchoalveolar lavage fluid cultures having a sensitivity of approximately 75% and 92%, respectively [51]. Cultures from the skin and other involved areas are also frequently positive.

Direct examination of culture or biopsies taken from the lung, skin, bone, and other sites is less sensitive but when positive allows for a rapid diagnosis. *Blastomyces* has a characteristic appearance, namely, that of a large yeast (10–15 μ) with thick "double-contoured" walls and distinctive broad-based budding (Fig. 3) [23].

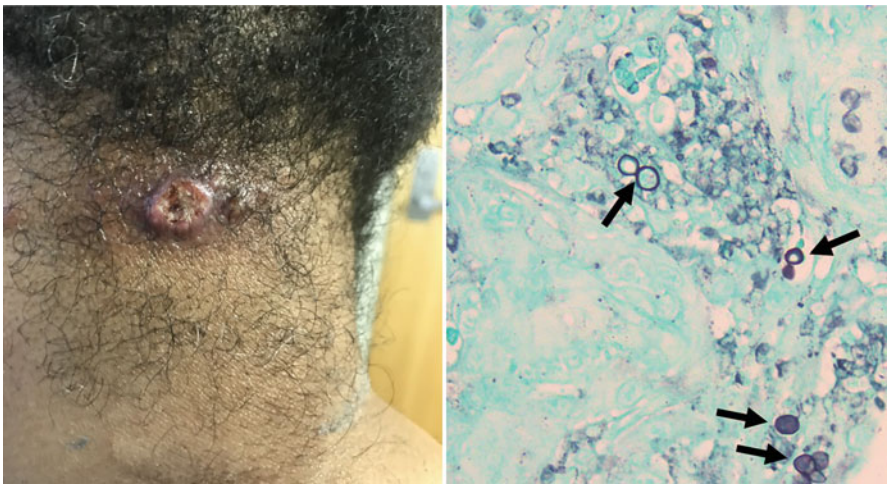

Fig. 3 Blastomycosis. Left, typical skin lesions of disseminated blastomycosis, with ulcerating nodules and papules. Right, histopathologic image of the same skin lesion, showing large yeasts with broad-based budding (arrows) (Grocott-Gomori methenamine silver stain)

A urinary antigen test for blastomycosis is available and has a reported sensitivity of 76–93%. In contrast to histoplasmosis, the test may be more sensitive for pulmonary (83–100%) than disseminated disease (67–89%) [52, 53]. However, because they share similar galactomannans, this assay may significantly cross-react in the presence of other endemic dimorphic fungi [52]. For this reason, simultaneously performing the blastomycosis urinary antigen in conjunction with the histoplasma antigen may be useful [23].

Serology in blastomycosis is of extremely limited value, owing to very poor sensitivity of both the complement fixation and immunodiffusion assays (as low as 9% and 28%, respectively). Enzyme immunoassays (EIAs) have better diagnostic accuracy but are not commercially available [23].

PCR offers some promise, but the technique has not been studied in large-scale trials, and so its place in the diagnostic algorithm for blastomycosis remains unclear.

Treatment

While itraconazole therapy alone may be sufficient to treat mild disease in patients with normal immunity, initial therapy with amphotericin B is recommended for all immunocompromised patients [54]. Lipid amphotericin formulations are preferred over the deoxycholate form due to the former's better side-effect profile, though unlike histoplasmosis there is no evidence that any of them are more efficacious.

Following 1–2 weeks of amphotericin and once the patient has demonstrated clinical improvement, the treatment regimen can be switched to an azole. Itraconazole is the preferred azole in most circumstances. No head-to-head

comparison trials have been done within this class of drugs, but clinical trials using itraconazole to treat blastomycosis have generally shown better treatment responses than trials using fluconazole or ketoconazole [54, 55]. If fluconazole has to be used, it should be at doses of 400–800 mg/day, as outcomes appear significantly better than if a dose of 200–400 mg/day is prescribed [56]. *Blastomyces* is susceptible to voriconazole, and the drug has been used successfully in small numbers of blastomycosis cases, often when there has been CNS involvement since, like fluconazole, voriconazole can achieve therapeutic concentrations within the brain [57]. Both posaconazole and isavuconazole also have activity against *Blastomyces*, but in vitro data and clinical experience are too limited for either drug to be recommended for anything beyond salvage therapy [33, 58]. Extrapolating from data in AIDS patients with histoplasmosis, it is recommended that transplant recipients with blastomycosis should receive azole therapy for at least 12 months. The extent of the patient's immunosuppression is also an important factor to consider when deciding when to discontinue therapy [54]. The role of serial urine antigen titers is less well established for blastomycosis than for histoplasmosis, but clearance of the urinary antigen does appear to be correlated with treatment success [59].

Central nervous system involvement by *Blastomyces* is not common in transplant recipients. When it does occur, the optimal treatment strategy is unknown. Current recommendations are to give lipid formulations of amphotericin B for a prolonged period initially (4–6 weeks) and then to follow this with either itraconazole, fluconazole, or voriconazole [54]. While itraconazole is the azole of choice in general, its CNS penetration is far less than either fluconazole or voriconazole. The lack of head-to-head data thus means that the optimal azole to choose with CNS blastomycosis is unclear.

Prophylaxis

There is limited data to guide decisions regarding prophylaxis in transplant recipients with a history of blastomycosis. Secondary prophylaxis may be reasonable in cases where the patients' immunosuppression regimen renders the patient profoundly immunosuppressed.

There is equally little information regarding the optimal therapy for recipients of organs from donors with a history of blastomycosis. Active disease in the donor is generally a contraindication to organ donation. Remote disease is not, however, and a suggested approach is outlined in Table 2.

Paracoccidioidomycosis

Disease Epidemiology

Paracoccidioidomycosis is caused by one of five species: the *Paracoccidioides lutzii* and the *P. brasiliensis* species complex, consisting of species 1 (S1) and phylogenetic species 2, 3, and 4 (PS2, PS3, PS4) [60]. The disease is limited

to Central and South America, and within this region, it is the most common of the endemic mycoses. Brazil accounts for >80% of cases, but the disease is also known to many other countries in the region from Mexico to Argentina (Fig. 1) [61]. Sensitivity surveys using intradermal paracoccidioidin antigen showed a median exposure rate of approximately 25–35% in Brazil, rising as high as 50–75% among adults in highly endemic areas [61, 62]. *Paracoccidioides* has not often been cultured from environmental sources, but its favored environment appears to be tropical and subtropical rainforest areas, in regions with mild temperatures and good annual precipitation. These conditions also favor crops such as tobacco or coffee, and agricultural work in endemic regions is a known risk factor for acquiring the disease [61].

Clinical Impact in Transplant Patients

A study of pretransplant serologies of liver transplant recipients in an endemic area of Brazil revealed that 0.8% were seropositive for *P. brasiliensis* [63]. There are very few actual cases in the literature of paracoccidioidomycosis in SOT recipients however. A recent review counted a total of just ten, nine of which were in renal transplant recipients [64]. Furthermore, no case of paracoccidioidomycosis has ever been described in a HSCT recipient. The low burden of this disease in transplant recipients is surprising and could reflect a combination of underdiagnosis, relatively limited access to transplants in endemic areas, and the use of trimethoprim-sulfamethoxazole, a drug with known activity against *Paracoccidioides*, as part of routine posttransplant prophylaxis regimens. For a similar reason, most cases of paracoccidioidomycosis reported in SOT recipients have occurred after the first year of transplant, when trimethoprim-sulfamethoxazole prophylaxis is withdrawn [64]. Mortality in SOT recipients is hard to define given the small numbers involved, but the mortality rate seen to date (44%) appears to be far higher than the 5–8% mortality seen in the general population [65]. This would comport with what is known about paracoccidioidomycosis in human immunodeficiency virus (HIV)-infected patients, in whom fungal burden, relapse rate, and overall mortality were all significantly greater than in patients without HIV coinfection [64].

Pathogenesis and Clinical Manifestations

In common with the other endemic mycoses, exposure occurs when the fungus' conidia are inhaled. Within the lung, those conidia that escape destruction by the local immune defenses develop into the organism's yeast form. As few as 2% of patients may develop symptomatic disease overall, reflecting the fact that host immunity is usually sufficient to quickly eliminate the infection [62]. A T-helper cell 1 (Th1) response seems necessary for this, with granulomas being the histological correlates of disease control [66]. By contrast, those patients who develop symptomatic disease may have an overtly Th2 immunologic profile, manifested by nonreactive paracoccidioidin skin tests but detectable antibodies,

or an immunologically intermediate state lying between a Th1 and Th2 response [66].

When symptomatic disease does occur, it occurs as one of two syndromes. An **acute/subacute form** may develop within the first few weeks to months after exposure and is seen almost exclusively in children, adolescents, and adults <30 years old (hence its other name, "juvenile paracoccidioidomycosis"). This form is characterized by disseminated disease that predominantly involves the reticuloendothelial system, with lymphadenopathy, fever, anorexia, and weight loss being the most prominent symptoms. The lymph nodes are often massively enlarged, and the condition must be distinguished from lymphomas and disseminated tuberculosis. Anemia, hypergammaglobulinemia, and eosinophilia are also common, and hepatosplenomegaly occurs in just over one third of cases [67]. Unlike the chronic form, symptomatic pulmonary disease is very uncommon, despite the lungs being the route of entry and respiratory cultures often being positive.

The **chronic form** is much more common, accounting for 90% of symptomatic disease [62]. This represents a reactivation of previously controlled disease that can occur up to decades after the exposure [65]. There is a striking male predominance in the chronic form, with a male-female ratio as high as 22:1. This is possibly explained by the fact that β-estradiol inhibits the conversion of the *Paracoccidioides* conidia into the yeast form [62]. Although disease dissemination is also evident in the chronic form, the lungs are usually the chief focus. The most common symptoms are nonproductive cough and dyspnea, but the underlying pulmonary process is highly destructive over the long term, often leaving the patients with long-term pulmonary insufficiency. Despite this, symptoms and signs may be deceptively minimal. Chest X-ray or CT shows nodular and alveolar infiltrates, with a predilection for involvement of the mid- and lower zones [65]. The oral mucosa is also commonly affected, manifesting as painful ulcers that are most prominently seen around the gingiva and palate. The skin may be seeded by hematogenous dissemination, in which case verrucous or ulcerating papulonodular lesions are seen (Fig. 4). The adrenal glands are involved histologically in approximately 85% of cases, though overt Addison's disease is only seen in roughly 3% [64, 68]. Lytic bone lesions are also sometimes seen, as is lymphadenopathy in a similar manner to the acute/subacute form.

Diagnosis

The yeast form of *Paracoccidioides* has a distinctive microscopic appearance that when visualized allows for a direct diagnosis from sputum, scrapings of skin or mucosal lesions, tissue biopsy specimens, or abscess aspirates [62]. Characteristically, the microscopic appearance is of a central parent cell with multiple other daughter yeasts budding off it [23]. When just two daughter yeasts are present, the complex resembles a "Mickey Mouse head," and when the daughter yeasts surround the parent, a "ship's wheel" appearance is seen (Fig. 4). The yeasts are variably sized, at between 4 and 60 μ [23].

The other principal method by which paracoccidioidomycosis can be diagnosed is by culture. In keeping with the other dimorphic mycoses, a positive result typically

Fig. 4 Paracoccidioidomycosis. Left, typical skin lesions, consisting of nodules with central ulceration. Right, microscopy showing a classic "ship's wheel" configuration with a central yeast, and numerous daughter yeasts budding out circumferentially (methenamine silver stain). (Image credit: CDC/Dr. Martins Castro, Dr. Lucille K. Georg)

takes several weeks. Serology can also assist with the diagnosis. Quantitative immunodiffusion testing is the most widely used assay. Compared with many other types of *Paracoccidioides* serologic tests, this method has a lower rate of cross-reactivity with other organisms such as *Histoplasma*, *Aspergillus*, and *Leishmania* [69]. However, its sensitivity for *P. lutzii* is far lower than that for *P. brasiliensis* [70]. In addition, the sensitivity of serologic tests in general is also lower in immunosuppressed patients. This phenomenon has been documented in patients with paracoccidioidomycosis who were coinfected with HIV and may be expected in transplant recipients as well [64]. Serologic titers usually decline with successful treatment to levels of 1:2 or below, and thus following the titers sequentially is a useful adjunct to monitor treatment response [69].

Antigen tests targeting specific *Paracoccidioides* glycoproteins have been developed for use on serum, BAL fluid, and CSF, and these show great promise. In one diagnostic accuracy study that used the gp43 antigen, the test was 95% sensitive and 97% specific [71]. Unfortunately, these antigen tests are not yet commercially available. PCR assays have been developed but are similarly restricted to research rather than clinical settings [72].

Treatment

Paracoccidioides is susceptible to a wider range of drugs than any of the other dimorphic fungi. In addition to the azoles and polyenes, the sulfonamides and even terbinafine have substantial activity. Equally remarkably, no cases of resistance to

any of the antifungals have yet been documented [69]. The choice of antifungal agent is therefore based on what clinical experience exists in the literature, taking into account the side-effect profiles and pharmacokinetic considerations of the various therapeutic options.

For mild to moderate disease, itraconazole is recommended [69]. The drug has been widely used and demonstrates good efficacy [73, 74]. For severe disease, initial treatment with amphotericin B is recommended, with a transition to itraconazole once the patient's clinical condition has begun to improve (usually after 2–4 weeks) [69]. Lipid formulations of amphotericin are preferred due to their lower nephrotoxicity. The duration of treatment is not well established and should be guided by improvement in clinical, serological, and radiological criteria. Durations of 9–18 months are typically used in the general population [69]. However, it is probably best to err toward the upper end of this range in transplant recipients, since immunocompromised patients tend to have higher rates of relapse [64].

When the above drugs are unavailable or contraindicated, trimethoprim-sulfamethoxazole (co-trimoxazole) is a second-line option [69]. The drug has excellent bioavailability and an acceptable side-effect profile. There have been no randomized trials comparing this drug to any of the other treatment modalities, but most (though not all) retrospective data show equivalent rates of cure. However, side effects are more frequent, and a longer treatment duration (typically $\geq$2 years) is required to prevent relapse [75, 76]. Trimethoprim-sulfamethoxazole may also be the treatment of choice for paracoccidioidomycosis involving the central nervous system due to superior CNS penetration when compared to itraconazole.

The other azoles, such as fluconazole, posaconazole, voriconazole, and isavuconazole, all have activity against *Paracoccidioides*. In a small randomized trial, voriconazole was shown to be approximately as effective as itraconazole, albeit at the cost of slightly more side effects [74]. Fluconazole has not been adequately studied, though it appears to be significantly less potent in vitro as judged by MIC [74]. Posaconazole and isavuconazole have in vitro activity, though clinical experience is limited. In one trial, 8/10 patients with paracoccidioidomycosis had at least a partially successful outcome when treated with isavuconazole as primary therapy [33]. As for other dimorphic fungi, the echinocandins have no therapeutic role.

Prophylaxis

Recipients should avoid travel to rural areas in *Paracoccidioides* endemic regions and should especially be counseled to avoid contact with agricultural activities there [77]. Potential donors with active disease should be excluded until they have been treated for at least 6 months. So far, there have not been any reported cases of transmission via infected allografts.

Recipients of organs from donors with previously treated disease should receive prophylaxis for 12 months, though this is based on expert opinion rather than clinical trial data [77]. Itraconazole can be used, as per Table 2. However, most patients will receive trimethoprim-sulfamethoxazole as part of their routine posttransplant

prophylaxis, and although there is little data to guide clinicians in this scenario, this drug may be sufficient prophylaxis alone without adding itraconazole.

Given that only a handful of paracoccidioidomycosis cases have ever been described in transplant recipients, it is not clear whether posttreatment secondary prophylaxis is required. Provided the patient's immunosuppressant regimen is not too potent at the time of treatment completion, it may be reasonable to withhold secondary prophylaxis and instead monitor the patient both clinically and with serial serology titers, keeping in mind that serology likely has a lower sensitivity in transplant recipients.

Common Antifungal Drugs Used to Treat the Endemic Mycoses

Itraconazole

Itraconazole belongs to the azole family and comes in two forms, as a solution and as capsules. The solution form is preferred due to its better bioavailability and should be taken on an empty stomach. However, this form of the drug is associated with greater gastrointestinal side effects than the capsule. In addition to poorer bioavailability, the capsule also requires an acidic stomach pH for optimal drug absorption, precluding administration of proton pump inhibitors, histamine-2 blockers, and antacids for several hours on either side of taking the capsule [78]. Furthermore, the capsule should be taken with food, rather than without food like the solution, and with an acidic beverage (e.g., soft drinks, or orange juice) to aid absorption [78, 79]. If the solution is used, a lower dose of itraconazole is required, due to its much greater bioavailability.

Side effects include gastrointestinal upset and occasionally transaminitis. Itraconazole also has negative inotropic effects and in rare instances can cause heart failure, especially at high doses. Particular care should be taken in patients with underlying ventricular dysfunction. Despite poor CSF penetration, the drug has proven efficacy in CSF disease. Lastly, itraconazole is a both potent inhibitor and a substrate of the important CYP3A4 enzyme, meaning that it can be the cause or effect of multiple drug-drug interactions [80]. The enzymatic inhibition reaches its peak approximately 1 week after commencing itraconazole, and the effects can last up to a month after stopping the drug [81]. Therefore, any drugs whose levels are affected by itraconazole (e.g., the calcineurin inhibitors) should have their dosages adjusted and/or their levels checked around these times (Table 3).

The usual dose of itraconazole is 200 mg three times a day for 2 days, followed by 200 mg twice daily thereafter. However, care should be taken to make allowances for any drug-drug interactions. Checking drug levels is strongly recommended once the drug is at steady state (after 5–7 days).

Fluconazole

Fluconazole is an azole that is available in both intravenous and oral formulations. The oral form has excellent bioavailability (~90%), and its absorption is not

Table 3 Drug-drug interactions between antifungal drugs and common immunosuppressants and suggested dose immunosuppressant dose modifications

Drug	Tacrolimus dose adjustment	Cyclosporine dose adjustment	Mycophenolate dose adjustment	Sirolimus dose adjustment	Prednisone dose adjustment
Liposomal amphotericin B	No significant change	No significant change	No significant change	No significant change	No significant change
Fluconazole	Tacrolimus levels increased. Decrease dose by 50%	Cyclosporine levels increased. Decrease dose by 50%	No significant change required	No significant change	No significant change
Itraconazole	Tacrolimus levels increased. Monitor level	Cyclosporine level increased. Monitor level	No significant change required	Sirolimus level increased. Monitor level	Unclear; monitor for side effects
Voriconazole	Tacrolimus levels increased. Decrease dose by 66%	Cyclosporine levels increased. Decrease dose by 50%	No significant change	*Coadministration contraindicated*	Unclear; monitor for side effects
Posaconazole	Tacrolimus levels increased. Decrease dose by 66%	Cyclosporine levels increased. Decrease dose by 25%	No significant change	*Coadministration contraindicated* [85]	Unclear; monitor for side effects
Isavuconazole	Tacrolimus levels increased. Decrease dose 25%	Cyclosporine levels increased slightly. Monitor levels	Mycophenolate levels increased mildly. Monitor for clinical effects	Sirolimus levels increased. Decrease dose by 50% and monitor level	No significant change

significantly affected by food or gastric pH. It is generally well-tolerated, with gastrointestinal side effects and occasional transaminitis being the chief complaints.

Fluconazole is a potent inhibitor of CYP2C9 and CYP2C19. However, it is only a moderate inhibitor of the important CYP3A4 isoenzyme, which means that drug-drug effects are often less troublesome than is seen with other azoles [80]. Nonetheless, like itraconazole, the same warnings apply with regard to drugs whose levels are affected by fluconazole (Table 3). Fluconazole is also a substrate of CYP3A4. CSF penetration is good (>50%), which sometimes results in its selection to treat CNS disease despite its relatively weaker potency in most of the endemic mycoses.

The usual dose of fluconazole is 400 mg daily. Because the drug is reliably well absorbed, drug levels do not need to be routinely checked.

Amphotericin B

Amphotericin B belongs to the polyene family and is only available as an intravenous drug. It comes in three formulations – a "conventional" deoxycholate form and two lipid formulations (liposomal amphotericin B and amphotericin B lipid complex). Nephrotoxicity is a major adverse effect of amphotericin, though the lipid forms are substantially less nephrotic than the deoxycholate formulation [82]. Amphotericin also commonly causes hypokalemia, hypomagnesemia, anemia, and phlebitis. A febrile infusion reaction is sometimes noted, especially if the drug is administered more quickly than recommended. This is not a true allergic reaction, and the patient can continue with subsequent doses of the regimen. However, slowing the infusion rate and administering acetaminophen, ibuprofen, hydrocortisone, or diphenhydramine prior to the infusion can help prevent subsequent similar febrile reactions [83]. Resistance to amphotericin B is exceptionally rare among the endemic fungi.

The usual doses of amphotericin vary by preparation. For liposomal amphotericin B, the conventional dose is 3–5 mg/kg, whereas for amphotericin B lipid complex, it is 5 mg/kg. "Conventional" (deoxycholate) amphotericin is administered at the lower dose of 1 mg/kg.

Conclusions

Histoplasmosis, blastomycosis, and paracoccidioidomycosis are important threats to transplant recipients. The risk for these infections is primarily determined by geographic exposure. Diagnosis is made by combining various diagnostic modalities, with tissue biopsy often being needed for confirmation.

Treatment usually includes polyenes and azoles for prolonged treatment durations.

Key Points

- Endemic mycoses are restricted geographically.
- Transplant recipients are at increased risk for dissemination of endemic mycoses.
- Diagnosis of histoplasmosis, blastomycosis, and paracoccidioidomycosis is difficult, and often delayed.
- Combining various diagnostic modalities is often needed for accurate diagnosis of endemic mycoses.
- Treatment of severe disease should start with an intravenous polyene preparation.
- Azoles are the primary choice for maintenance regimens.

Introduction

Toxoplasmosis is a zoonosis infecting humans and warm-blooded animals worldwide, with variable prevalence and clinical burden according to geographical areas [1]. After primary infection, it can disseminate to all organs, as it can infect virtually all nucleated cells. *Toxoplasma gondii* has the capacity to interfere with host immune response, which allows it to persist lifelong within dormant tissue cysts, as long as the host is immunocompetent. Transmission to humans mainly occurs by ingestion of food or water contaminated with oocysts present in feces of infected felids (i.e., the cat family) or by undercooked meat containing cysts [2]. Although largely asymptomatic in adults, toxoplasmosis is a life-threatening opportunistic infection in immunocompromised patients, whether from primary acquisition or due to cyst reactivation. In developed countries, toxoplasmosis is more frequently seen in patients receiving immunosuppressive therapy than in HIV-infected patients, as observed with *Pneumocystis* pneumonia [3, 4]. Indeed, the growing number of grafts makes transplant patients an increasing population at risk, not only because immunosuppressive therapy can reactivate quiescent cysts but also because the parasite can be transmitted through cyst-containing organs from a seropositive donor [5]. In immunocompromised patients, reactivation infection often results in cerebral toxoplasmosis or disseminated toxoplasmosis and leads to death in the absence of treatment. Although prevention measures can be implemented to prevent severe toxoplasmosis, they are not applied in all countries, due to a lack of consensus. This chapter will review the burden of toxoplasmosis according to graft type and the diagnostic methods and discuss prevention measures and treatment.

Burden of Toxoplasmosis in Transplant Patients

In contrast to HIV-infected patients, the incidence of toxoplasmosis in transplant recipients is poorly documented. Published studies reporting patient series are scarce [6–11], and literature mostly consists of case reports [2, 12–14]. Overall, the incidence of toxoplasmosis in a given transplantation center or region depends on many factors: the *Toxoplasma* seroprevalence in the general population, the number of transplant procedures, the immunosuppressive protocols used, the serologic screening guidelines for donor and recipient, the chemoprophylaxis protocol, the diagnostic follow-up (serial PCR and/or serology) after transplantation, and other contributory factors.

The risk for reactivation of chronic infection varies according to the depth of immune suppression induced by immunosuppressive protocol, thus according to the type of graft, with allogeneic hematopoietic stem cell transplant (allo-HSCT) recipients being the most at-risk patients [15]. By contrast, the risk of acquiring infection through transplantation is virtually solely due to solid organ transplantation (SOT), usually due to an organ from a seropositive donor to a seronegative recipient (D+/R-, i.e., “Toxo- mismatch”), and risk depends on organ type (Table 1).

Table 1 Patient management according to organ type and *Toxoplasma* serology

Type of transplant	Risk	Hygienic prevention measures	Chemoprophylaxis	Follow-up
HSCT				
Toxo+	High risk of reactivation	NA	Necessary (preferably 12 months) or according to CD4+ counts	Periodic blood PCR recommended
Toxo-	No graft-related risk[a] Risk of foodborne infection	Recommended	Recommended (6 months) as for *Pneumocystis* prevention	
Heart				
Toxo+	Moderate risk of reactivation	NA	Recommended (3–6 months)	Serology (2/yr)
Toxo-	High risk of organ-related infection if D + Risk of foodborne infection	Recommended	Necessary (6–12 months)	Serology (2/yr) + PCR (1/wk., first month if D+/R-)
Liver				
Toxo+	Low risk of reactivation	NA	3-6 months as for *Pneumocystis* prevention, recommended if organ rejection	None
Toxo-	High risk of organ-related infection if D + Risk of foodborne infection	Recommended	Necessary (6–12 months)	Optional
Kidney				
Toxo+	Low risk of reactivation	NA	3-6 months as for *Pneumocystis* prevention, recommended if organ rejection	None
Toxo-	High risk of organ-related infection if D + Risk of foodborne infection	Recommended	Necessary 6 months	Optional

NA: not applicable

[a]Provided that donor serologic screening is performed and preventive measures applied

Toxoplasmosis in HSCT Transplant Patients

The contamination of HSCT with *Toxoplasma* tachyzoites is theoretically possible, in the setting of acute infection in the donor at the time of sampling. The bone marrow and the blood are not sites for parasite encystation; thus, chronically infected people are not a source for parasite transmission. Cord blood cells could also be a vector of toxoplasmosis if they contain replicating parasites, i.e., when the newborn has been congenitally infected. In both instances, serologic screening of the donor is an efficient barrier to prevent HSCT-acquired infection (see below) [16]. Therefore, in HSCT patients, toxoplasmosis results primarily from reactivation of latent tissue *Toxoplasma* cysts in the *Toxoplasma*-seropositive recipient (R+). Most cases are observed in pretransplant R+ who are grafted with a HSCT from a *Toxoplasma*-seronegative donor (D-) [11, 17]. It is intuitively explained by the loss of memory T-cell repertoire following immunosuppressive chemotherapy and the lack of protection conferred by acquired T cells from the D-. Toxoplasmosis onset mainly occurs early, within the first 6 months after transplantation [11, 15, 17, 18], although it can be observed up to 1 year or more [3, 11, 19]. In a recent French series of 419 HSCT recipients, 17 (4%) cases were reported, of which 7 occurred within the first 30 days, before the prophylaxis was started [20]; these cases of early reactivation have a higher mortality rate. Later onset of toxoplasmosis can be associated with etanercept, usually introduced during steroid-refractory graft-versus-host disease (GVHD) when immunosuppressive regimen intensification is needed [18]. In the study by Conrad et al. [18], the origin of the HSCT (bone marrow, peripheral blood, or cord blood) had no clear impact on the onset of toxoplasmosis, as no significant differences were observed between cases and controls, but in view of the low number of patients included (23 cases et 46 controls), this question should be further explored.

Data on toxoplasmosis incidence are scarce and greatly vary according to the geographical area [21], but also on the diagnostic tools used. The incidence also greatly differs according to the care management practices and guidelines, as shown in a recent European study, where it ranged from 0 to 92.3 cases per 1000 grafts over a 5-year period [11].

Toxoplasmosis in SOT Transplant Patients

Due to the preferential localization of *Toxoplasma* in muscles, the incidence of *Toxoplasma* transmission via the graft is highest in heart transplant compared with other SOT. D+/R- heart recipients have a 57–75% risk of early posttransplant toxoplasmosis unless they receive prophylaxis [22, 23].

The incidence of toxoplasmosis was reported to be 0.08% in kidney and liver transplant patients, thus much less frequent by comparison to that observed in heart transplant patients (0.61%, $p < 0.001$), in a Spanish study including 7709 renal, 4872 liver, and 1979 heart transplant patients, respectively [6]. About half (10/22) cases occurred in kidney or liver transplant patients; the remaining 12

cases were heart transplant patients. No cases were diagnosed in the 1240 pancreas, lung, or small bowel recipients. All but two patients with toxoplasmosis who had documented serologic results before transplantation (20/22) were seronegative.

The overall incidence of toxoplasmosis in non-heart SOT patients is assumed to be below 1% [24], and the vast majority of cases are reported in D+/R- [6], although D/R serologic status is not always known in published reports [2].

Although kidneys are organs at low risk for parasite transmission, the very high number of transplantation procedures explains that the number of toxoplasmosis cases reported in kidney transplant patients is similar to that reported in liver recipients. By contrast, the liver is a frequent site for parasite encystation [25] and thus carries a high risk for the recipient in case of toxoplasmosis mismatch.

Unlike allo-HSCT, SOT (and particularly non-heart SOT) patients seem to be at low risk of reactivation toxoplasmosis well after transplant (>12 months), in the absence of rejection or unusual immunosuppression [24, 26] (Table 1). The Spanish case-control study [6] showed that a negative serostatus prior to transplantation was the only independent risk factor for toxoplasmosis in SOT patients, confirming that primary infection is more frequently observed than reactivation in these patients.

Clinical Signs

Common clinical manifestations may include neurological signs, which can be pleomorphic (such as headache, seizures, confusion, vertigo, language disorders, vision alteration, paralysis, coma), pulmonary signs (from moderate interstitial pneumonitis to acute respiratory distress), myocarditis, and ocular signs, but other organs can be involved in case of disseminated toxoplasmosis (including skin, kidney, and liver). Pulmonary toxoplasmosis is the result of disseminated toxoplasmosis, as no transmission of toxoplasmosis has been reported after lung transplantation, meaning that *Toxoplasma* cysts are virtually absent from this organ; thus, it cannot be the primary site of reactivation. In a recent European study, cerebral, disseminated, and pulmonary toxoplasmosis accounted for 19%, 17%, and 10% of cases, respectively, whereas in a French multicenter study, cerebral and disseminated toxoplasmosis were observed in 19% and 42%, respectively [3]. The overall survival is usually around 50% or lower, except when infection is limited to the eye compartment [11]. However, among transplant patients, HSCT have a poorer survival rate than SOT patients, regardless of chemoprophylaxis, probably because of deeper immune suppression [11]. In the study by Schmidt et al. [17], the mortality rate associated with disseminated toxoplasmosis was 69% in allo-HSCT, thus much higher than in HIV-infected patients (17%), underlining the need for rapid diagnosis and treatment in these patients. Additionally, data obtained from 13 French centers showed that frequency of disseminated toxoplasmosis was higher in transplant patients than in HIV-infected patients [3] (Fig. 1); this observation could be due to the more rapid evolution in transplant recipients or delay of diagnosis.

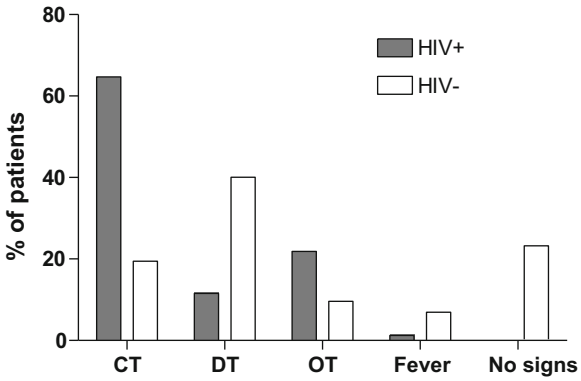

Fig. 1 Frequency of clinical setting of toxoplasmosis, according to a French multicenter study [3]. CT, cerebral toxoplasmosis; DT, disseminated toxoplasmosis; OT, ocular toxoplasmosis

Diagnosis of toxoplasmosis is sometimes difficult in HSCT recipients and may be delayed or missed, as clinical signs can be limited to fever or nearly absent at onset of reactivation, as observed in 65% (30/58), 65% (11/17), and 39% (28/72) of cases in three recent studies [3, 11, 20]. These cases are mostly reported in France, where follow-up by serial PCR after transplantation is common practice (see below), thus allowing early diagnosis.

Although nonspecific, hemophagocytic syndrome (HPS) can be associated with acute toxoplasmosis in SOT patients [27]. Therefore, diagnostic investigations targeting toxoplasmosis should be included in the workup following HPS diagnosis.

Furthermore, toxoplasmosis has been described in the setting of immune reconstitution inflammatory syndrome (IRIS) in a HSCT [28]. Although previously described in HIV-infected patients, HPS- and IRIS-associated toxoplasmosis in transplant recipients could be observed more frequently, due to the increasing number of transplantation procedures [27, 29–32].

Diagnosis of Toxoplasmosis in Transplant Patients

Although prophylaxis significantly reduces the risk of developing toxoplasmosis, the efficacy of such drugs can be hampered by pharmacokinetic issues as gastrointestinal intolerance or impaired gut absorption due to GVHD or due to the early interruption because of myelotoxicity. Patient compliance must be always queried. Therefore, toxoplasmosis should not be excluded on the sole knowledge that trimethoprim-sulfamethoxazole (cotrimoxazole, TMP/SMX) has been prescribed.

Given the potential severity of toxoplasmosis in immunosuppressed patients, urgent diagnosis of a primary *Toxoplasma* infection in a seronegative recipient (R-) or a reactivation in a seropositive recipient (R+) is crucial. This diagnosis remains challenging due to the nonspecificity of clinical and radiological signs, which can delay *Toxoplasma*-specific diagnostic exams, i.e., IgG/IgM serology and parasite detection.

Serology

Serologic techniques are essential to estimate the risk of toxoplasmosis in patients with clinical signs, which can be attributed to any other opportunistic infection. Indeed, if the serology is positive, a *Toxoplasma* reactivation should be considered as a possible etiology. Detection of specific IgM antibodies can result from either a primary infection or from a parasite transmission through the solid organ graft, but it must be confirmed by the rise of specific IgG. If the serology is negative, a primary infection cannot be excluded in a HSCT transplant or a SOT within the first months after the transplant, as antibody synthesis can be attenuated, delayed (SOT), or nearly abolished (HSCT). Thus, when negative results are obtained initially, serologic testing should be performed serially and periodically (every 2–4 weeks) after symptom onset, until at least 3 months before primary infection can be ruled out. Besides, serologic tests may miss a *Toxoplasma* reactivation, especially in HSCT patients in whom the humoral response can be reduced or abolished. The use of adequate serologic technique is required, and several different commercial assays should be performed when there is a low titer of IgG. A recent French study compared the performances of nine marketed immunoenzymatic assays in sera with low or negative IgG titers from immunosuppressed patients, showing the highly variable performances of the assays. They emphasized the need to confirm any results in the gray zone using a confirmation method based on Western blot [33].

Serology can be useful a tool for patient follow-up [34] (see below), but its interpretation should be done with caution in transplant patients, taking into account the pretransplant serologic status and the occurrence of blood transfusions which make the interpretation of anti-*Toxoplasma* antibody levels more complicated. When pretransplant serology is not available, IgG avidity testing can help to distinguish transfusion-acquired IgG (high avidity) from recent infection (low avidity), but is of no use if the patient was seropositive (high avidity) before transplant.

Finally, a significant increase of IgG level is not necessarily associated with a clinical reactivation, and thus, the IgG titer has only an indicative value.

In ocular toxoplasmosis, aqueous humor or vitreous fluid can be sampled to detect a neosynthesis of specific IgG, using Western blot. However, the weak antibody production in patients receiving immunosuppressant agentSerologic techniques usually makes serologic techniques of reduced sensitivity, compared to molecular detection of *Toxoplasma*.

Parasite Detection

While serologic screening is essential to estimate the risk of reactivation, the definitive diagnosis of acute infection is based on the detection of *Toxoplasma* tachyzoites and DNA in various fluids (such as bronchoalveolar lavages (BAL), cerebrospinal fluids (CSF), aqueous humor, blood, or bone marrow) or biopsies, either by microscopic examination or using PCR. Optical immersion microscopy on Giemsa or May-Grünwald-Giemsa-stained smears is a rapid and inexpensive exam but offers low

sensitivity and requires trained operators, given the small size of the parasite. Over the past 20 years, real-time PCRs have been developed and gradually replaced end point PCRs as more sensitive and more specific methods [35–37], with a lower detection limit of approximately one parasite genomes/mL [35]. The most sensitive techniques target the repeated 529 pb sequence (rep529) [38] which has been shown to provide a higher sensitivity than B1 PCR [39, 40].

Most clinical studies assessing the diagnostic performances of PCR in immunocompromised patients focused on HIV-infected patients, reporting sensitivities from 35% to 72% and from 15% to 80%, in CSF and the blood, respectively [41]. Of note, sensitivity on CSF was shown to be higher when cellularity was ≥4 nucleated cells/μL and in patients with multiple brain lesions (≥4) detected with MRI [42]. The delay between the start of curative treatment and CSF sampling also strongly impacted PCR sensitivity; as expected, early sampling after the beginning of anti-*Toxoplasma* therapy (<1 week) led to higher PCR performances [43].

There are very scarce clinical studies assessing PCR for the diagnosis of pulmonary toxoplasmosis in immunocompromised patients [7, 44]. The very low incidence of pulmonary toxoplasmosis (2/336 BAL [7]) did not allow the authors to study the sensitivity of PCR against microscopy. Nevertheless, the value of molecular methods remains indisputable for pulmonary toxoplasmosis, as PCR provided the diagnosis in 9/10 pulmonary cases versus only 1/10 by microscopy, as described in a recent European cohort [11].

PCR on peripheral blood has been evaluated in the diagnosis of ocular toxoplasmosis, but its sensitivity was shown to be lower than in ocular samples (25% and 36%, in blood and ocular specimens, respectively) [45]. Overall, PCR has a better sensitivity in ocular samples from immunocompromised patients than from immunocompetent patients, especially when it is performed early after the onset of symptoms [46, 47], and on vitreous fluid rather than on aqueous humor puncture [48]. PCR sensitivity in ocular samples also varies according to the size of lesions and is higher in case of large atypical foci of retinitis, as commonly observed in immunocompromised patients [49, 50]. Overall, when possible, combining both PCR and IgG testing in ocular samples will yield better performances.

PCR in peripheral blood is part of the diagnostic algorithm in transplant patients with any symptoms suggestive of systemic infection of unknown etiology, as an alternative or in complement to invasive sampling, although with lower sensitivity [3].

Finally, quantitative PCRs can also be of interest to monitor treatment efficacy, as parasite loads are expected to decrease rapidly in the blood, BAL, or CSF within the 3 first weeks of treatment [51, 52]. Given the lack of standardization of such testing, it would be important to use the same sample type and diagnostic platform so as to be able to trend and compare results over time.

Histopathologic Examination

Given the small size (7 μm × 2 μm) of tachyzoites, the parasite stage associated with acute disease progression histopathologic examination is difficult. It may

be contributive, albeit mainly used for postmortem diagnosis. Parasites can be seen in tissue sections after staining with hematoxylin-eosin-safran (HES) or May-Grünwald-Giemsa (MGG), provided that slides are observed by a trained microscopist. Immunoperoxidase staining can be also used. Parasite multiplication can be associated with cell lysis or necrosis, but such observation is nonspecific, and tissue reaction can be modified by immunosuppression. Infrequently, tachyzoites can be spotted in brain or heart biopsies, but qPCR has far better sensitivity.

Imaging

Radiographic imaging provides substantial diagnostic input, although with variable sensitivity depending on the clinical toxoplasmosis form, ranging from 92% (12/13), 70% (7/10), and 42% (8/19), respectively, in cerebral, pulmonary, and disseminated toxoplasmosis [11]. Clinical presentation guides selection of imaging. A cerebral computed tomography (CT) scan or a magnetic resonance imagery (MRI) should be performed if there is evidence of any neurological signs, best done with contrast. Imaging generally reveals solitary or multiple brain abscesses, of variable size, homogeneously nodular, or with a typical peripheral enhancement surrounding a central necrosis zone. The "asymmetric target sign" is another feature suggestive of toxoplasmosis; it is a small eccentric nodule along the wall of the enhancing ring, reflecting a vein thrombosis [53]. Edema is often present and can induce a deviation of the midline. Most lesions are observed in the white matter, followed by peripheral location (cortex and corticomedullary junction) and basal ganglia but also in the posterior fossa, thalamus, and brainstem [54]. These features are suggestive of toxoplasmosis but are not specific and may differ according to the type of immunosuppression. Atypical imaging can be observed in HSCT recipients, without any contrast enhancement and even any significant lesion, related to leukopenia and the missing inflammatory response [55, 56]. In this context, MRI should be preferentially performed as it can demonstrate additional abnormalities in gray matter or hemorrhagic lesions [55].

In pulmonary toxoplasmosis, chest x-ray or thoracic CT scan usually shows a diffuse interstitial pneumonitis with nonspecific alveolar condensations or ground-glass opacities [57].

Ultrasound scan can evidence an organ involvement as myocarditis, hepatitis, etc.

Funduscopic examination should be performed with any ocular symptoms. The eye fundus enables the diagnosis of toxoplasmosis in 50% of cases, when hyperpigmented old scars residual from previous retinochoroiditis foci are present. Typical acute lesions are intensely white with overlying vitreous inflammatory infiltrates, retinal vasculitis, and hemorrhages [58]. When observed in a *Toxoplasma*-seropositive patient, this type of lesions may be sufficient to ensure the diagnosis, but atypical lesions are frequently observed in immunosuppressed patients, and further diagnostics may be indicated (see above).

Patient Management

The European group for Blood and Marrow Transplantation Infectious Diseases Working Party (EBMT-IDWP) [59] has proposed a classification of toxoplasmosis according to clinical signs and diagnostic workup as follows:

Toxoplasma infection is defined as a posttransplant seroconversion in R- or a significant increase of IgG titer in R+ or a positive *Toxoplasma* PCR in the blood, without any evidence of organ involvement. *Toxoplasma* disease requires demonstration of organ involvement and can be further classified as possible (radiological + clinical signs consistent with organ involvement), probable (radiological + clinical signs + detectable *T. gondii* DNA in any type of sample), and definite (microscopic evidence for tachyzoites in tissue or body fluids) [24, 59].

Probable and definite toxoplasmosis will require curative treatment, but it is sometimes less clear for *Toxoplasma* infection, when a positive PCR result or a seroconversion is found in a patient with no apparent clinical signs or with only fever. As it can lead to *Toxoplasma* disease in about one third of HSCT patients [59], leaving a patient untreated would be risky. In this setting, patients are usually given chemoprophylaxis if they had none previously, or are switched from TMP/SMX prophylaxis to curative therapy, as observed in recent reports [20].

Therefore, we propose diagnostic algorithms (Figs. 2 and 3) according to the patient background, clinical signs, imaging, and diagnostic findings. Overall, the diagnostic workup must be guided by clinical signs and adapted to various parameters, e.g., the pretransplant serologic status, and whether chemoprophylaxis has been administered.

In a previously seronegative recipient presenting with suggestive symptoms (Fig. 2), chemoprophylaxis should be checked, to verify the patient compliance to and/or correct absorption of TMP/SMX, and plasma levels of the drug should be measured when needed. In parallel, a specific serology should be performed. The detection of specific IgM antibodies and/or IgG is usually the result of primary infection (provided that the patient received no recent transfusions, see above) and needs specific treatment if transplant is <1 year, as well as further diagnostics according to clinical signs and symptoms (Fig. 2). If the time from transplant to diagnosis is >1 year, the decision to treat will depend on the PCR results, the graft type, the severity of clinical signs, and/or the diagnosis of organ rejection or GVHD. Even if the serology remains negative, any positive PCR result (in blood or other body fluids) can be suggestive of recently acquired toxoplasmosis and should prompt treatment. Conversely, if there is no evidence of *Toxoplasma* infection, the patient should be closely followed, through careful clinical, serologic, and molecular monitoring, without excluding the diagnosis of other opportunistic infections (Fig. 2).

The diagnostic interpretation of a symptomatic seropositive recipient will be different (Fig. 3). A positive PCR in the blood or in any other sample usually signals reactivation and requires starting a curative treatment. If both imaging and PCR are uninformative, serologic testing could help characterize a possible reactivation (significant increase of IgG level $\pm$ IgM recurrence). If antibody titers are steady, the interpretation of the results may differ according to the time post transplantation

and the type of graft (HSCT, SOT), keeping in mind that SOT patients with organ rejection and HSCT patients with GVHD are prone to reactivation events even when >1 year after transplant. Besides, serologic tests may miss a *Toxoplasma* reactivation, especially in HSCT patients in whom the humoral response is highly reduced. Therefore, the decision to treatment must take into account all these parameters, and other options, such as restarting chemoprophylaxis, can be considered (Fig. 3).

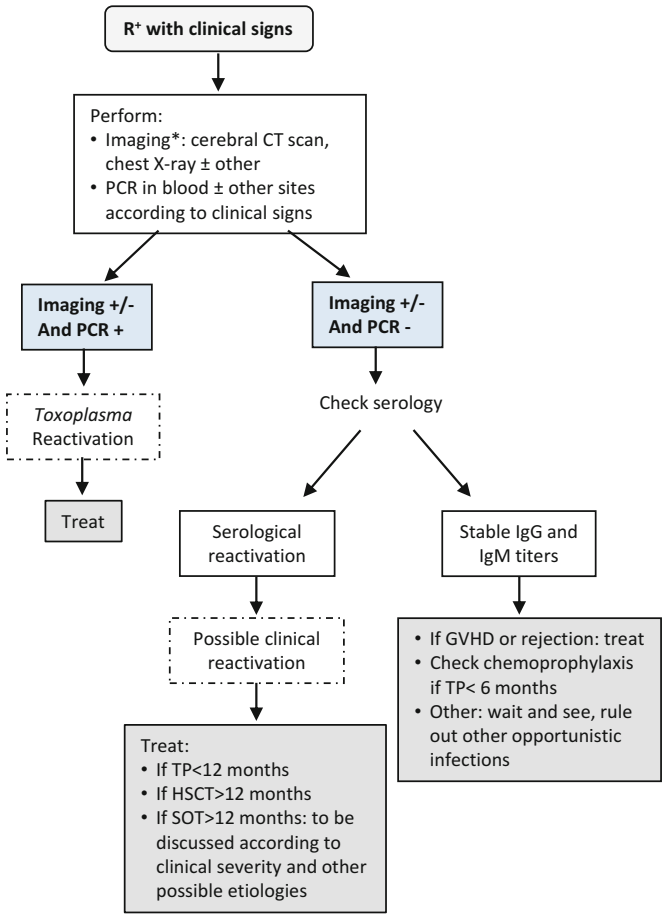

Fig. 3 Management of clinical and diagnostic explorations in *Toxoplasma*-seronegative recipients with clinical signs

Treatment

The severity of toxoplasmosis in immunocompromised hosts requires prompt initiation of effective therapy, including choices with effective penetration through the blood-brain barrier, as the delayed initiation can result in a poorer outcome [60]. It is particularly crucial in HSCT patients in whom toxoplasmosis-related mortality remains extremely high, from 38% to 67%, despite treatment [15]. In patients at high risk (HSCT R+, D+/R- SOT), either because chemoprophylaxis had been stopped or because of organ rejection or GVHD, empiric curative therapy should

be started without waiting for diagnostic confirmation and stopped in absence of improvement or if another etiology was subsequently documented.

In the absence of therapeutic guidelines based on comparative trials including transplant patients, the current treatment protocols follow recommendations established for HIV-infected patients. The therapeutic arsenal for toxoplasmosis is poor and relies on a few molecules [61, 62], as depicted in Table 2. Effective drugs interfere with parasite replication, i.e., on tachyzoites responsible for disease manifestation, but they do not act on cysts, which contain quiescent forms.

The standard protocol for toxoplasmosis curative treatment relies on combination therapy with two drugs for at least a 6-week induction period, i.e., until clinical and radiological improvement, and is followed by maintenance therapy. According to HIV American and European guidelines for toxoplasma encephalitis [63, 64], the recommended first-line treatment relies on the combination of pyrimethamine-sulfadiazine (PYR/SDZ), a synergistic association which offers the highest rapidity of action, starting with a loading dose on day 1 (Table 2). PYR displays an efficient penetration in the brain parenchyma, even in the absence of inflammation. Folic acid should be added to decrease the myelotoxicity attributed to PYR. Alternative regimen for patients who do not tolerate sulfonamides or who fail to respond to first-line therapy is PYR combined with clindamycin (CLD) [65, 66] or trimethoprim-sulfamethoxazole [67]. A marginally better survival with PYR-SDZ has been reported in a retrospective analysis of toxoplasmosis in HSCT, but other factors impacting on mortality such as underlying disease or delay between onset of symptoms and therapy were not introduced in the analysis [68]. Clinical reports raise the possible use of other combinations, including atovaquone (AVQ) combined with PYR or SDZ [69] and azithromycin (AZT) with PYR [70, 71]. Side effects, but also price and availability of those molecules, guide the choice of therapy. PYR is not available and affordable in many countries, thus explaining the preferential use of TMP/SMX in these areas [72, 73].

For severe cases, particularly in HSCT patients with reactivation, the addition of a third drug has been suggested, e.g., CLD combined with PYR-SDZ or TMP-SMX [61, 68].

In the specific context of cerebral toxoplasmosis, brain edema can be reduced through the use of a short course of high-dose corticosteroid. However, the risk of worsening the immune suppression should be considered carefully, as it has been sometimes shown to be detrimental [74].

For ocular toxoplasmosis, the adjunction of corticosteroids [75, 76] a few days after initiation of systemic anti-*Toxoplasma* therapy [77, 78] is recommended and usually continued for about 1 month with gradual tapering [62]. Despite the lack of clinical trials in immunocompromised patients, the classic PYR/SDZ regimen associated with corticosteroids is considered the treatment of choice [75, 77, 79]. As extensively reviewed by Dunay et al. [62], other regimens have been proposed for their potential efficacy in ocular toxoplasmosis in immunocompetent patients: TMP/SMX, intravitreal CLD, and more anecdotally AZT [80], or atovaquone alone or combined with PYR, but data supporting their use in immunocompromised patients are lacking.

Table 2 Main drugs used in curative treatment of toxoplasmosis in transplant recipients

Drug	Plasma half-life time/diffusion	Dose regimen[a]	Route	Combination	IDSA recommendations[b] (grade)	Other possible associations
Pyrimethamine (PYR)	Long (4 days) Brain diffusion ++	200 mg on day 1, then 75 mg/day if ≥60 kg, or 50 mg/day if <60 kg	PO	**PYR-SDZ**[c] or **PYR-CLD**[c] PYR-AVQ[c,d] PYR-AZT[c–e]	**First line (AI)** **Alternative to PYR-SDZ (AI)** BII CII	PYR/ SDZ + CLD [68]
Sulfadiazine (SDZ)	Intermediate (13 h)	2 × 3 g/day if ≥60 kg or 2 × 2 g/day if ≥60 kg	IV, PO	**PYR-SDZ**	**First line (AI)**	PYR/ SDZ + CLD [68]
Sulfamethoxazole (SMX)	Intermediate (9–11 h)	2 × 25 mg/kg/day	IV, PO	SMX/TMP[c]	Second line (BI)	SMX/TMP-CLD [68]
Trimethoprim (TMP)	Intermediate (10–12 h)	2 × 5 mg/kg/day				
Azithromycin (AZT)	Long (2–4 days) Brain and ocular diffusion ++	900–1200 mg/day	PO	AZT-PYR[c,d,e]	CII	

Clindamycin (CLD)	Short (2.5 h) Tissue diffusion ++	4 × 600–900 mg/day	IV, PO, IVT	**PYR-CLD**[c]	**Alternative to PYR-SDZ (AI)**	CLD (IVT)[f]
Atovaquone (AVQ)	Long (2–3 days)	2 × 750–1500 mg/day (with food)	PO	AVQ + PYR[c,d] or AVQ-SDZ[d]	BII	

PO, per os; IV, intravenous; IVT, intravitreal

A: Both strong evidence for efficacy and substantial clinical benefit support recommendation for use. Should always be offered

B: Moderate evidence for efficacy – or strong evidence for efficacy but only limited clinical benefit – supports recommendation for use. Should generally be offered

*C: Evidence for efficacy is insufficient to support a recommendation for or against use. Or evidence for efficacy might not outweigh adverse consequences (*e.g.*, drug toxicity, drug interactions) or cost of the treatment or alternative approaches. Optional*

I-III: Quality of evidence supporting the recommendation. I: At least one properly designed randomized, controlled trial. II: At least one well-designed clinical trial without randomization, from cohort or case-controlled analytic studies (preferably from more than one center), or from multiple time-series studies, or dramatic results from uncontrolled experiments. III: Opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees

[a]Guidelines from the European AIDS Clinical Society [64] on treatment of opportunistic infections in patients living with HIV

[b]IDSA guidelines for curative treatment of *Toxoplasma* encephalitis in HIV patients

[c]Adding folinic acid 10–15 mg/day (po) to prevent myelotoxicity associated with PYR therapy or TMP/SMX

[d]Very limited clinical experience with these therapies, should be used only in the absence of alternatives [62]

[e]In ocular toxoplasmosis good efficacy of AZT combined with PYR; AZT can be used at lower dose (250–500 mg/day) for a better tolerance [62]

[f]Efficacy of intravitreal CLD associated with steroids in ocular toxoplasmosis [62]

In addition, as immune restoration is part of treatment success, clinical improvement in transplant patients can require reduction or discontinuing immunosuppressive therapy, which should be discussed, depending on the type of graft and the risk of rejection or GVHD [60, 81].

The monitoring of treatment efficacy is based on clinical examination, keeping in mind that radiologic improvement can be delayed without suggesting treatment failure, as shown in *Toxoplasma* encephalitis in HIV patients. In patients having a positive *Toxoplasma* blood PCR at diagnosis, the treatment efficacy can be followed through iterative PCRs, which are expected to turn negative in case of successful therapy.

Curative treatment must be followed by secondary prophylaxis/maintenance therapy (see below).

Prevention of Toxoplasmosis in Transplant Patients

Prevention of toxoplasmosis relies on multiple approaches, including serologic screening of donors and recipients, patient education, chemoprophylaxis, and diagnostic follow-up of patients after transplantation.

Pretransplant Serologic Screening for Toxoplasmosis

Serologic screening allows clinicians to target patients most at risk for toxoplasmosis: (i) seropositive HSCT patients, (ii) seronegative SOT patients, and (iii) seropositive heart recipients (Table 1). Systematic donor/recipient *Toxoplasma* serologic screening is not uniformly adopted in all countries, either because the risk of toxoplasmosis is considered negligible or underestimated or because the universal use of TMP/SMX to prevent *Pneumocystis* pneumonia is assumed to protect against toxoplasmosis. However, whether mandatory (healthcare policy) or not, a recent European survey revealed that 24/26, 24/26, 31/35, and 25/26 transplantation centers from 11 countries screened recipients for anti-*Toxoplasma* antibodies before HSCT, liver, kidney, and heart transplantation, respectively [11]. Serologic screening of solid organ donors (heart, kidney, or liver) and HSCT donors was performed in all countries, although screening was reportedly mandatory in only seven countries (France, Greece, Italy, Romania, Slovakia, Switzerland, and Turkey) [11]. The knowledge of both recipient and donor serologic status allows starting primary chemoprophylaxis at the time of transplantation in case of toxoplasmosis mismatch, with particular attention given to heart transplant patients. Interestingly, in this study toxoplasmosis in SOT was due in equal proportions to a mismatch D+/R- or to probable foodborne infection, emphasizing the need for combining targeted primary prophylaxis through donor/recipient screening and hygienic measures.

Accurate interpretation of low-level IgG (even if detected in the gray zone) is crucial in both donor and recipient samples. It is now well established that many immune assays can detect specific IgG with titers below their positive threshold (or

in the gray zone); thus, these samples must be confirmed using a Western blot assay or a dye test [33, 82]. Indeed, misinterpreting serologic results can have serious consequences, particularly if a SOT donor or a HSCT recipient is misdiagnosed as seronegative. If a reliable confirmation method is not available, borderline IgG titers should be considered as positive. If borderline IgG titers are detected in a SOT recipient who is about to receive an organ from a Toxo+ donor, and no confirmation method is available, then it would be reasonable to manage this patient as if he were Toxo- (in other words, assume the higher-risk situation with respect to management of prophylaxis).

Serologic interpretation of IgM detection in donor or recipient serum may be also challenging. The presence of IgM may indicate recently acquired infection and should lead to measurement of IgG avidity to evaluate whether an acute infection is ongoing. In both instances, if acute infection is likely (very low IgG avidity), the (living) donor and recipient should be treated before organ/cells sampling and transplantation procedure, respectively.

Screening of cord blood samples destined to HSCT is an important issue. Cord blood can be contaminated with *Toxoplasma* tachyzoites if the fetus has been congenitally infected and thus can be a high risk for transmission to the recipient. The hallmark of *Toxoplasma* congenital infection is the detection of specific IgM in the cord blood serum, but IgM can be undetectable at delivery, depending on the trimester of maternal infection during pregnancy or on specific anti-*Toxoplasma* therapy of the mother [2, 83]. Therefore, the absence of IgM detection in cord blood cannot be a completely reliable marker to decide whether this sample is free of parasites, and it should be coupled to maternal serology performed on peripheral blood. However, it should be kept in mind that the presence of anti-*Toxoplasma* IgG without IgM doesn't rule out possible maternal infection during pregnancy (and thereby possible congenital toxoplasmosis), as maternal IgM may have disappeared by the time of delivery. For all these reasons, cord blood samples from Toxo+ women should be excluded from HSCT donation in countries where serologic follow-up from the beginning of pregnancy is not implemented [16].

Anti-*Toxoplasma* Chemoprophylaxis

For Which Patients and for How Long?

Prevention of toxoplasmosis is an object of consensus in HIV patients, and guidelines recommend the use of TMP/SMX which also protects patients from *Pneumocystis jirovecii* pneumonia [63]. Despite abundant literature calling for prophylaxis in transplant recipients, there are currently no worldwide consensus nor standardized guidelines. As the risk for *Toxoplasma* varies according to the type of graft, prophylaxis should be adapted accordingly, taking into account the serologic status of both donor and recipient. The American Society of Transplantation has recently published guidelines to prevent infection with protozoa in transplant patients and recommends donors and recipients screening for anti-*Toxoplasma* IgG to tailor chemoprophylaxis [84].

In SOT (heart, kidney, liver) patients, the major focus should be on D+/R- patients. The use of prophylaxis in orthotopic heart transplantation is standard practice in D+/R- recipients, warranting a very low incidence of toxoplasmosis despite high risk [5, 11].

Strikingly, while TMP/SMX was effective in preventing toxoplasmosis, Chehrazi-Raffle et al. reported a lower 5-year survival of D+/R- patients compared to D−/R- patients (60% vs. 87%, P = 0.04) [85]. Meanwhile, they did not find any impact of *Toxoplasma* serologic status of the recipient on the 5-year survival. These results could be explained by the low prevalence of toxoplasmosis in this series where 711/785 (91%) of recipients were seronegative. In a more balanced cohort (258 seronegative, 324 seropositive), van Hellemond et al. [86] also found no impact of *Toxoplasma* serostatus on the 4-year mortality using a multivariate analysis, although seropositivity appeared as a predictor of all-cause mortality in univariate analysis. Barge-Caballero et al. recently confirmed theses observation on a cohort of 4048 heart recipients [26]. Of note, all D+/R- patients received chemoprophylaxis. These data underline that while heart transplantation carries a high risk of organ-transmitted toxoplasmosis, it is well controlled by universal prophylaxis, provided that it is not interrupted too early. In a multicenter Spanish study reporting 22 cases, of which 18 were D+/R-, toxoplasmosis occurred at a median time of 92 days after transplantation, and none of them was diagnosed while on chemoprophylaxis, suggesting that the prophylaxis course was too short (when utilized, they used 3–6 months of prophylaxis) [6]. Therefore, in D+/R- heart TP, a minimum duration of 12 months is recommended, or even lifelong in high-risk patients, as recommended in the new guidelines from the American Society of Transplantation [84]. Similar observations can be found in the literature. Sarchi et al. diagnosed three thoracic transplant patients (D+/R-) around 1 year after transplant [87].

Kidney and liver transplant should also be given careful attention in the setting of Toxo-mismatch, as lack or early interruption of targeted prophylaxis can result in rapid onset of disease and fatal outcome [88–90]. Although there are no universal guidelines, a minimum of a 6-month course is reasonable, as the onset of *Toxoplasma* disease occurs at a time when immunosuppression is lower, thus reducing the severity of clinical symptoms [24, 91] (Table 1).

The necessity of chemoprophylaxis to prevent reactivation in SOT patients is not widely appreciated, based on the low incidence of *Toxoplasma* reactivation. Indeed, of the 22 cases described in the study by Fernandez-Sabé [6], only 2 cases occurred in seropositive patients prior to transplantation, highlighting that reactivation is uncommon if anti-*Pneumocystis* prophylaxis with TMP/SMX is usual practice, as it was described in this chapter. In the era of widespread use of TMP/SMX in this setting, some authors have even questioned the interest of *Toxoplasma* serologic screening of donors and recipients [92], but blind TMP/SMX prophylaxis for 3–6 months doesn't protect efficiently D+/R- heart transplant patients, as said above.

Furthermore, *Toxoplasma* reactivation should not be neglected if anti-*Pneumocystis* prophylaxis relies on aerosolized pentamidine or if TMP/SMX is withdrawn, as toxoplasmosis can occur very shortly thereafter [13, 51, 93–96]. Again the optimal duration is debatable, but several reactivation infections were

reported after 3 months of transplantation without prophylaxis, thus supporting the use of 3–6 months of prophylaxis in SOT seropositive patients. However, a recent systematic review suggests that reactivation of *Toxoplasma* disease is uncommon unless associated with recent rejection [24]. Therefore, the authors propose targeting prophylaxis to seropositive recipients with recent rejection or unusual immunosuppression for 3–6 months (Table 1).

In HSCT seropositive patients, the risk of *Toxoplasma* reactivation is generally well appreciated but diversely taken into account among countries, often according to the seroprevalence in the general population. D−/R+ allo-HSCT patients are the population at highest risk, but given the potential severity of disease, prophylaxis is justified in all patients. TMP/SMX prophylaxis tends to be the rule in Europe, aiming at providing protection against both *Toxoplasma* and *Pneumocystis* [11]. This universal practice is indeed efficacious, as Conrad et al. [18] showed in a case-control study that the absence of effective anti-*Toxoplasma* prophylaxis was an important risk factor (odds ratio 11.95; 95% CI 3.04–46.88; $p < 0.001$). However, there are two significant drawbacks associated with TMP/SMX, in that its myelosuppressive effect often leads to a delayed start of prophylaxis in allo-HSCT patients and that breakthrough infections have been described, possibly associated with suboptimal dosages or regimens, noncompliance, or inadequate oral absorption due to gastrointestinal intolerance [15]. The decision to postpone prophylaxis onset until HSCT engraftment (usually around 1 month after the transplant) is difficult to handle, as a fair proportion of cases occur within the first month (30% of patients in the series of Conrad et al.). In the systematic review of Gajurel et al. [15], 11% and 32% of patients developed *Toxoplasma* disease and *Toxoplasma* infection, respectively, before day 30. Hence, prophylaxis should ideally be initiated upon transplantation whenever feasible. Patients for whom prophylaxis is delayed should benefit from a close follow-up with blood PCR (see below).

Despite frequent concern about myelotoxicity, Fontanet et al. [97] found no effect of TMP/SMX on the speed of myeloid and platelet engraftment when comparing patients who underwent continued prophylaxis with those had interrupted prophylaxis from the day of stem cell infusion until day 30.

Prophylaxis Protocols

In a systematic review and meta-analysis, Gajurel et al. [15] showed that in allo-HSCT, TMP/SMX prophylaxis was more efficacious in preventing reactivation toxoplasmosis when given at a dose of 160 mg/800 mg at least three times a week. Indeed, 57% of breakthrough infections have been observed when given two times a week even at higher dosages. The preferred duration should be of 6 months or more and guided by CD4+ T cell monitoring [15]. Overall, this protocol is the most frequently applied in Europe [11, 98].

In SOT, the same regimen is commonly used (160 mg/800 mg × 3/week) for heart recipient, but 80/400 mg daily is another efficient regimen widely applied for kidney or liver recipients to reduce hepatic and renal toxicity [11, 24] and allow for ease of daily medication dosing. Prophylaxis with a regimen of dapsone 50 mg daily, plus pyrimethamine 50 mg weekly, plus folinic acid 10 mg weekly can be considered

in sulfa-allergic patients after checking for glucose-6-phosphate dehydrogenase deficiency [84].

Following a reactivation episode, secondary prophylaxis is required for at least 6–12 months, but data on the duration and drug regimen are scarce. Trimethoprim-sulfamethoxazole [5] or pyrimethamine-sulfadiazine (25 mg/2 g daily or 50 mg/2 g three times a week) [26] have been proposed for maintenance therapy, as used in HIV-infected patients [99, 100].

Patient Counseling and Hygienic Measures

Primary prophylaxis aims to prevent orally acquired *Toxoplasma* infection. Hygienic recommendations should be provided to any seronegative transplant recipient, in order to prevent primary infection, as usually done in counseling of pregnant women [101]. As presented in Table 3, these measures require caution with at-risk foods, e.g., meat, shellfish, and vegetables/fruits, which are consumed under- or uncooked, drinking water, and to respect hand hygiene after manipulating raw meat, gardening, or any contact with soils or cats.

Additionally, any transplant recipient who would travel to South America should be aware of the risk of acquiring more virulent *Toxoplasma* strains, even if he is already immune (R+) [102, 103].

Table 3 Hygienic counseling for prevention of *Toxoplasma* infection

Prevention of foodborne infection	Prevention of cat-related infection	Prevention of environmental transmission
Peel or wash vegetables, fruits, and herbs carefully if eaten raw Drink bottled water Cook meat thoroughly, at safe temperatures (63–74 °C or 145–165 °F) [107]; avoid microwave cooking or freeze meat for 5 days at −20 °C if consumed undercooked Carefully wash hands, dishes, and kitchen tools with soapy water after contact with raw meat or unwashed vegetables/fruits Avoid raw or undercooked seafood (oysters, mussels, etc.) Avoid consumption of crudités outside home Do not drink unpasteurized goat's milk	Wash hands after contact with cat Frequently change the litter box (oocysts become infective 2–5 days after shedding in cat's feces), rinse the box with hot water (>60 °C), and wear gloves and mask to manipulate the litter Feed the cat with dried or canned marketed food	Wear gloves for gardening Carefully wash hands and nails after outside activities in contact with soil or sand that might be contaminated with cat feces Avoid accidental water ingestion when practicing aquatic activities in fresh water

Diagnostic Follow-Up After Transplantation

Serologic follow-up of D+/R- SOT patients was reported to be performed by 40–50% of European centers, depending of the type of graft [11]. Serologic follow-up (on a 2-year basis or more) should be part of the systematic workup implemented in D+/R- SOT patients to document possible seroconversion after prophylaxis ends. Such findings should further prompt questioning of the patients for mild or unnoticed symptoms, clinical examination, and/or imaging to evaluate the clinical impact (Fig. 4).

Monitoring using PCR on the blood has also been proposed to detect early *Toxoplasma* infection in heart D+/R- recipients in the first weeks following transplant and is implemented in some centers [3]. In this setting, Dhakal et al. proposed that SOT patients with positive peripheral blood for *Toxoplasma* DNA be given prophylaxis if not yet implemented or be treated [24]. La Hoz et al. recommend careful monitoring of patients with discontinued prophylaxis and PCR testing [84].

A follow-up by PCR on peripheral blood performed on a weekly or twice-monthly basis has been proposed in allo-HSCT patients in the early weeks/months

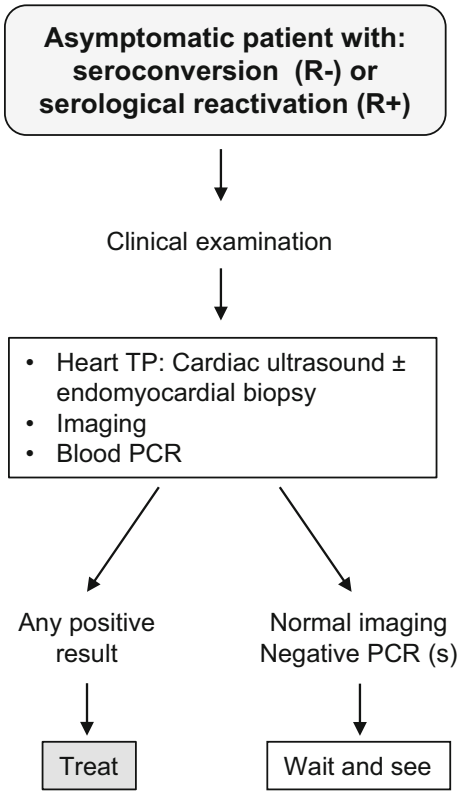

Fig. 4 Management of *Toxoplasma*-seropositive recipients with serologic reactivation or *Toxoplasma*-seronegative recipients at transplantation with seroconversion during follow-up

following transplantation [10, 59, 104], to guide rapid preemptive treatment. However, this practice is not universally applied, mainly because of concern about cost versus benefit or because of systematic TMP/SMX prophylaxis. Some studies have provided arguments in favor of PCR monitoring to improve survival [3, 9, 34, 105, 106]. In most studies, treatment of patients with circulating *Toxoplasma* DNA avoids full-blown infection. In a French study, centers with routine PCR monitoring had better survival rates than centers with no PCR monitoring [3]. Although no randomized study was designed to demonstrate the proficiency of such follow-up, we recommend that patients with delayed TMP/SMX prophylaxis initiation or under other prophylaxis protocols due to intolerance may benefit from PCR monitoring. Serologic follow-up of allo-HSCT patients is of little interest as antibody synthesis is severely impaired for several months and transfusions often complicate the interpretation of results.

Conclusion

Prevention of toxoplasmosis in transplant patients is a crucial but difficult task and relies on a multidisciplinary approach, gathering pretransplant serologic data, patient background, type of graft and chemoprophylaxis in the short term, and clinical and diagnostic follow-up in the long term. As any misdiagnosis can have serious consequences, the accurate interpretation of diagnostic results is of utmost importance to target patients at high risk who should receive chemoprophylaxis or may benefit from immediate curative treatment.

Key Points

- Toxoplasmosis is efficiently preventable by universal pretransplant donor and recipient *Toxoplasma* serology screening and targeted chemoprophylaxis with TMP/SMX.
- D+/R- SOT recipients and D−/R+ HSCT patients are the most at-risk patients for acquired and reactivation toxoplasmosis, respectively, and must be given TMP/SMX.
- *Toxoplasma*-seropositive heart and other SOT patients should be given TMP/SMX for a minimum of 6–12 months, and of 3 months, respectively.
- *Toxoplasma*-seronegative transplant patients should be advised on how to avoid infection.
- The preferred regimen for HSCT patients should be 160 mg/800 mg TMP/SMX × 3/week.
- In patients at high risk with signs and symptoms of disease, or in whom this is otherwise a major concern for disease, curative treatment should be started promptly awaiting first diagnostic results.

Introduction

Strongyloidiasis is an infection caused by the intestinal nematode or roundworm *Strongyloides stercoralis.* This parasite can complete its life cycle in the environment and human host. It also has an auto-infective cycle in the human host that results in persistent infections that can last up to four decades, a feature unique among nematodes [1]. The immune response of the host regulates the extent of autoinfection, while the severity of the disease correlates with the worm burden. The primary reservoir of the parasite is soil contaminated with human feces that harbor *Strongyloides* larvae. The infection cycle begins when human skin is breached by filariform larvae. They penetrate the intact skin and migrate via the venous

circulatory system to the lungs where they penetrate the alveolar space, ascend to the pharynx, and are swallowed. The larvae finally arrive in the duodenal mucosa where they molt twice to become adult female worms. Adult females reproduce asexually by parthenogenesis in the human intestine, laying eggs that become rhabditiform larvae. This stage can be excreted in the stool, thus completing the parasite's life cycle, or transform to filariform larvae while still in the intestines. In the auto-infective cycle, the filariform larvae penetrate the intestinal mucosa or perianal skin where they again gain access to the venous circulatory system. The molting of rhabditiform to filariform larvae is accelerated in the milieu of immunosuppression, allowing a potentially massive number of larvae to proliferate in the intestine. As a result, solid organ and hematopoietic stem cell transplant recipients are at risk for complicated and even life-threatening infections with *Strongyloides stercoralis*.

Epidemiology

*Strongyloide*s is a neglected global public health problem. It was initially estimated that it infects approximately 100 million people worldwide [2]. Accounting for the inaccuracies due to diagnostic techniques and underreporting, a prevalence of 370 million persons is more accurate [3]. The parasite is endemic throughout the tropics and subtropics. A country-specific Bayesian meta-analysis determined that Africa, Asia, and Latin America are disproportionately affected [4]. Societies where fecal contamination of the soil is rare have a low prevalence. Studies in the United States (USA) estimate a prevalence among immigrants of 4–46% depending on the population studied [4–6]. In the USA, *Strongyloides* continues to be endemic to the Appalachian region [7–9]. Solid organ and hematopoietic stem cell transplant (HSCT) programs must consider the epidemiology of this parasite when developing screening protocols for the evaluation of transplant candidates and solid organ transplant (SOT) donors.

Clinical Impact on Transplant

Strongyloidiasis can be a devastating disease in transplant recipients. The mortality rate approaches 50% in hyper-infection syndrome and 70% in disseminated infection [10–12]. A retrospective analysis at MD Anderson between 1971 and 2003 estimated an infection frequency of 1.0 per 10,000 new cancer diagnoses [13]. In this study, hyper-infection syndromes were more frequently observed among HSCT recipients. The reported mortality of HSCT recipients with *Strongyloides* hyper-infection syndrome is about 80% [14, 15]. A retrospective study from Stanford University Medical Center reviewed 185 autopsies of HSCT recipients; 35 patients (19%) had a total of 41 missed infections. Parasitic infections represented 5% of the missed infections. Half of those were due to *Strongyloide*s [16]. The Ad Hoc Disease Transmission Advisory Committee (DTAC) of the Organ Procurement and Transplantation Network (OPTN)

reviewed *Strongyloides* potential donor-derived transmission events from 2008 to 2017 [17]. Organs procured from 15 donors, involved in a *Strongyloides* proven or probable donor derived event, were transplanted to 43 recipients; 19 (44%) developed strongyloidiasis. Five of the 19 recipients (26%) died at 45 days follow-up, with all deaths attributed to *Strongyloides*. These studies should encourage SOT and HSCT programs to be vigilant about ensuring appropriate screening and treatment of transplant candidates and organ donors prior to transplantation.

Diagnosis Including Clinical Presentation and Available/Emerging Diagnostics

Strongyloidiasis in solid organ and hematopoietic stem cell transplant recipients could be the result of de novo acquisition, re-infection, or reactivation of chronic intestinal infection [18–21]. In SOT recipients, it could also be a consequence of donor-derived infection [22]. Reactivation and donor-derived infection occur in the initial months after transplantation when immunosuppression is highest [20, 21]. Case series describe a median time to presentation in HSCT recipients of 21 days (range, 2–64) and for donor-derived strongyloidiasis in SOT recipients of 13 weeks (range, 7–33) [20, 22]. Clinical syndromes include acute infection, chronic infection, hyper-infection syndrome, and disseminated disease. Risk factors for hyper-infection syndrome and disseminated diseases have been linked to the immune status of the host and are mainly related to immunosuppressive medications. Human T-lymphotropic virus type I (HTLV-1) co-infection is also a risk factor for progression to hyper-infection syndrome and disseminated disease [23]. In the hyper-infection syndrome, there is an accelerated proliferation of larvae in the duodenum as a consequence of an increased rate of molting of rhabditiform to filariform larvae during the auto-infective cycle. Larvae migrate through the bowel wall and then travel through the venous system to the lungs and back to the small bowel. In this syndrome, larvae are restricted to the pulmonary and gastrointestinal system. Larvae cause symptoms as they migrate through the host and include fever, dyspnea, wheezing, hemoptysis, acute respiratory distress syndrome, anorexia, nausea, vomiting, abdominal pain, diarrhea, ileus, obstruction, and gastrointestinal bleeding. Common complications of the hyper-infection syndrome include septic shock (50%) and bacteremia (40%) caused by translocation of gut flora from bowel damage by migrating larvae. Disseminated disease is characterized by the spread of the larvae to other organs [10–12, 18]. Meningitis, peritonitis, pancreatitis, cholecystitis, liver abscess, and other complications have been described.

There is a lack of a reference standard for the diagnosis of strongyloidiasis [24]. Although eosinophilia is reported in patients with *Strongyloides* infection, it should not be used as a single criterion to screen or diagnose transplant patients or SOT donors; up to 20–30% of patients with chronic infection and 70–100% of patients with hyper-infection syndrome or disseminated disease have normal eosinophil

counts [10, 11, 25, 26]. Also, transplant recipients and deceased SOT donors often receive corticosteroids that decrease the eosinophil count [27]. The diagnosis of strongyloidiasis is usually made by serological assays or detection of rhabditiform larvae from clinical specimens. A study comparing the performance of five serological assays against a composite reference standard revealed an overall sensitivity of 75–94% and specificity of 94–100% [28]. Because other helminthic infections can cause false positives, local epidemiology is essential when considering the positive predictive value of these assays. False negatives occur in immunocompromised hosts due to the net state of immunosuppression. The reported sensitivity and specificity of serological assays in this population is 43–68% and 89–96%, respectively [29, 30]. Serological assays are mainly used in three scenarios in the field of transplantation: [1] screening transplant candidates; [2] screening deceased and living SOT donors; and [2] diagnosis of strongyloidiasis in transplant patients. Due to the low sensitivity of serological assays in the immunocompromised host, a combination of diagnostic methods is required to establish the diagnosis of strongyloidiasis in transplant recipients.

A definitive diagnosis of strongyloidiasis is achieved by identification of larvae in a clinical specimen. In uncomplicated infections, stool is the preferred sample. However, in patients with hyper-infection syndrome or disseminated disease, larvae can also be found in respiratory secretions, cerebrospinal fluid, peritoneal fluid, urine, pleural fluid, blood, and other tissue specimens. Examination of a single stool sample lacks sensitivity for the diagnosis of chronic strongyloidiasis. In patients with a low burden of infection, larvae are excreted intermittently. The sensitivity is increased to 50% by analyzing three stool samples and can approach 100% if seven serial stool samples are examined [1, 31]. The Agar Plate method is the technique with the highest sensitivity (89%) to identify larvae in the stool [32]. This method is labor intensive and requires that at least three stool samples be tested to achieve adequate performance [7]. Direct examination and formalin-ethyl acetate concentration methods are also used and have a sensitivity of 21 and 49%, respectively.

The performance of the polymerase chain reaction (PCR) to detect *Strongyloides* in stool has varied due to the different techniques used to extract DNA and neutralize inhibitors [24]. The method that obtained the best results included an extra step that involved the incubation of stool samples with glycine-SDS buffer and mechanical disruption before DNA extraction [25]. The sensitivity and specificity of PCR was 62% (42–78%) and 95% (92–97%) in a systematic review and meta-analysis [33]. Although PCR is a promising technique, it is not widely available.

Transplant patients diagnosed with strongyloidiasis should be screened for HTLV-1 by serology, as co-infection is associated with a high risk of relapse and disseminated disease. HTLV-1 downregulates the T-helper type 2 (Th2) immune response (decreasing interleukin-5 production and total immunoglobulin E levels), therefore impairing eosinophil recruitment and helminthic-killing activity [23, 34, 35]. Due to the increased risk of relapse in patients with HTLV-1 co-infection, some experts recommend intermittent treatment during periods of augmentation of immunosuppression [21].

Management Including Emerging Treatment Modalities and Options for Prophylaxis/Prevention

Ivermectin is the preferred anti-parasitic to treat strongyloidiasis (Table 1) and is available in several formulations, including oral, rectal, and subcutaneous [36–39]. The efficacy of ivermectin is restricted to those parasites found in the intestinal stages [40, 41]. A meta-analysis assessing the efficacy and safety of ivermectin versus albendazole for the treatment of chronic strongyloidiasis concluded that more people were cured with ivermectin [36]. The studied doses of ivermectin for the treatment of chronic strongyloidiasis were 200 mcg/kg by mouth daily for 1 or 2 days [37–39]. A multicenter open-label randomized controlled trial compared a single dose of ivermectin 200 mcg/kg to four doses of ivermectin 200 mcg/kg (given on days 1, 2, 15, and 16) for the treatment strongyloidiasis. The primary endpoint (proportion of participants with clearance of infection at 12 months) occurred in 86% of the single-dose group and 85% of the four-dose group ($p = 0.75$). Adverse events were mild albeit more common in the multi-dose group [42]. Immunosuppressed patients were excluded from this study. Therefore, some experts still recommend ivermectin 200 mcg/kg by mouth for 2 days followed by another series 2 weeks later (the duration of one autoinfection cycle) for the treatment of transplant patients [37, 38, 43]. This recommendation balances the devastating effects that *Strongyloides* may have in transplant patients and the tolerability of ivermectin. Immigrants from endemic areas for filarial diseases such as *Loa loa* (West and Central Africa, within the past 3–5 years) should be screened with a blood smear to exclude microfilaremia as the administration of ivermectin in this setting has been associated with an increased risk of encephalopathy [44]. In patients co-infected with filarial parasites, the Mazzotti reaction may occur within 7 days of administration of ivermectin. It is characterized by fever, urticaria, lymphadenopathy, myalgias, tachycardia, and hypotension [45]. Albendazole has a primary cure rate of only 38–68%, relegating it to second-line therapy for chronic strongyloidiasis [36, 46–48].

There is a paucity of information to guide treatment of hyper-infection syndrome and disseminated disease. Recommended interventions include a combination of anti-parasitic therapy, broad-spectrum antimicrobials for Gram-negative bacterial

Table 1 Management of *Strongyloides stercoralis* infection

		Solid organ transplant	Hematopoietic stem cell transplant
Treatment	Chronic strongyloidiasis	200 mcg/kg by mouth for 2 days and repeated 2 weeks later	
	Hyper-infection syndrome	Ivermectin 200 mcg/kg by mouth daily for at least 2 weeks after the last positive stool sample. Ivermectin 200 mcg/kg subcutaneous is recommended for those unable to tolerate oral therapy or with severe ileus. Broad-spectrum antimicrobials for gram-negative sepsis Supportive care Reduction of immunosuppression if feasible	
	Disseminated disease		

sepsis, supportive care during the critical phase of illness, and, if possible, reduction of immunosuppression. If the patient can tolerate oral therapy, ivermectin 200 mcg/kg by mouth daily is recommended for at least 2 weeks after the last positive stool sample to cover a complete autoinfection cycle [21]. Some experts advocate for combination therapy with albendazole until there is evidence of clinical improvement [43]. The optimal treatment route for patients unable to tolerate oral therapy due to ileus, intestinal obstruction, or obtundation is uncertain. Options in this scenario include rectal or subcutaneous ivermectin (200 mcg/kg/daily) [49, 50]. Case reports describe subtherapeutic levels of ivermectin with rectal administration; thus, subcutaneous administration is favored [21, 51, 52]. In the USA, use of the veterinary subcutaneous formulation of ivermectin for treatment of human patients requires an emergency investigational new drug (eIND) approval from the Food and Drug Administration (FDA) Division of Anti-Infective Agents (301-796-1400) [53].

Criteria to define cure have not been established [54]. Because larval stool output may be intermittent, stool examination does not have the necessary sensitivity to determine cure [24, 54]. Eosinophilia, when present, is often slow to resolve. In a case series from a non-endemic area, eosinophilia resolved by 6 months in the majority of patients [26]. Transplant patients on prednisone may not have any eosinophilia. A retrospective single-center study demonstrated that serology titers progressively wane after therapy; a decrease of at least half of the initial optical density (ELISA or LIPS) or reduction of at least two titers (IFAT) after 3 months was suggested as criteria to define clinical cure [55]. Unfortunately, commercial laboratories do not routinely report quantitative results for serology, and the using serology as a test of cure has not been validated in transplant patients. A prospective single-center study from a non-endemic area, which limits confounding from re-infection, assessed the long-term response to ivermectin in 48 patients by PCR. Only 21 patients (67% immunocompromised) adhered to the follow-up (1–4 years). All of them had a positive PCR at follow-up, and 14 (67%) had microbiologic evidence of recurrence by either the agar plate and or direct stool analysis. Three of the seven patients with a positive PCR and negative parasitological studies had a clinical presentation suspicious for recurrence of strongyloidiasis [56]. Although the performance of PCR as a test of cure and to predict the risk of recurrence is unclear, the study emphasizes the need to establish long-term follow-up for transplant candidates and recipients diagnosed with strongyloidiasis to monitor for recurrence.

Patients should be educated to wear closed footwear in endemic areas to reduce the risk of de novo acquisition or re-infection. One of the following strategies should be implemented to decrease the risk of post-transplant reactivation in SOT and HSCT recipients (Table 2). In hyper-endemic areas with limited resources, a proposed approach is to treat all transplant candidates [57]. In endemic areas with available diagnostic tools, the alternative is to implement universal screening. In non-endemic areas, a targeted screening approach based on epidemiological risk factors for strongyloidiasis has been successfully used [58]. Based on the epidemiology of *Strongyloides*, proposed risk factors include patients who were born or lived in tropical or subtropical regions, candidates with unexpected eosinophilia, travel to an endemic area, and patients who were born or lived in American Appalachia. Two

Table 2 Prevention of *Strongyloides stercoralis* infection

		Solid organ transplant	Hematopoietic stem cell transplant
Pre-transplant screening indications[a,b]	Donor	Screening is recommended	Not routinely performed
	Recipient	Screening is recommended	Screening is recommended
Transplant candidate/recipient education		Avoid walking barefoot in endemic areas	

[a]Universal or targeted screening strategy depends on the local epidemiology
[b]Proposed risk factors in the targeted strategy include patients who were born or lived in tropical or subtropical regions, unexplained eosinophilia, travel to an endemic area, and patients who were born or lived in the American Appalachia

approaches have been used to screen transplant patients with epidemiological risk factors for strongyloidiasis: combined serological and microbiologic assays versus serology alone [58, 59]. The former is labor intensive but may overcome the risk of a false-negative serology in immunocompromised transplant candidates.

To minimize the risk of donor-derived strongyloidiasis among SOT recipients, living and deceased SOT donors should be screened for *Strongyloides* (Table 2). The decision as to whether to implement a universal or targeted screening approach should depend on local epidemiology. A universal strategy is favored in endemic areas, whereas a targeted screening strategy is favored in non-endemic areas. Serology is the favored screening test for both living and deceased SOT donors [22, 59, 60]. Testing deceased donors to reduce the incidence of donor-derived strongyloidiasis has proven to be an effective strategy [22]. From 2009 to 2013, the Centers for Disease Control and Prevention investigated seven clusters of donor-derived strongyloidiasis, in which donor screening had not been performed before transplantation. Six of the seven donors involved had epidemiological risk factors for strongyloidiasis. Eleven of the 20 recipients (55%) developed strongyloidiasis, of which 2 (18%) died from complications of the disease. In contrast, LiveOnNY (the organ procurement organization serving the southwest of New York State – formerly New York Organ Donor Network) started a targeted screening strategy in 2010, in which procurement was done without delay due to pending tests results. Once available, results were promptly communicated to transplant centers, and recipients from positive donors were treated. With this approach, there were no reported cases of donor-derived strongyloidiasis during the study period [22]. A 10-year analysis from the OPTN DTAC committee described an increase in the proportion of reports initiated due to a positive result on a deceased donor screening *Strongyloides* test and a decrease in the proportion of cases adjudicated as a proven and probable transmission during the study period. This trend occurred during a time frame of improved donor screening and efficient recipient treatment [17]. Despite this data, a survey in 2016 of all 52 Organ Procurement Organizations in the USA revealed that only 6 (10%) of them were screening deceased donors for *Strongyloides* [61].

Living donors, SOT, and HSCT candidates testing positive for *Strongyloides* should be treated before organ procurement or transplantation, respectively, using

the recommended regimen for chronic strongyloidiasis. We also recommend treating transplant candidates with epidemiological risk factors requiring urgent transplantation in whom testing is not feasible. SOT patients receiving organs from deceased donors testing positive for *Strongyloides* should be treated as soon as the donor screening results become available with ivermectin following the recommendations for chronic strongyloidiasis. Additionally, during the investigation of a potential *Strongyloides* donor-derived event, all recipients should be treated empirically; delaying therapy until the investigation is concluded is highly discouraged [21, 22].

Conclusions

Strongyloides is endemic throughout the tropics and subtropics. Due to immigration patterns, patients born in endemic areas now have access to transplantation or may become organ donors in developed countries. Medical advances in endemic areas are also making transplantation more accessible in these regions. To prevent the consequences of the severe manifestations of strongyloidiasis, solid organ and hematopoietic stem cell transplant programs need to be mindful of the epidemiology of this parasite during the evaluation of transplant candidates and donors in the case of solid organ transplantation.

Key Points

- Due to the low sensitivity of serological assays in the immunocompromised host, a combination of diagnostic methods is required to establish the diagnosis of strongyloidiasis in transplant recipients.
- In patients with hyper-infection syndrome or disseminated disease, to establish a diagnosis, numerous specimens should be tested, including stool, lower respiratory samples, and any other affected body fluids and tissues.
- Screen those transplant candidates and recipients diagnosed with strongyloidiasis for HTLV-1 by serology, as this affects subsequent management.
- Oral ivermectin is the anti-parasitic of choice to treat uncomplicated strongyloidiasis.
- Educate transplant candidates and recipients about the use of closed footwear when in endemic areas so as to minimize the risk of de novo infection or re-infection.
- Screen SOT and HSCT candidates with epidemiological risk factors for *Strongyloides* with serology to minimize the risk of reactivation. Treat those that test positive with ivermectin. Transplant candidates testing positive should not be declined for transplantation based on this criterion alone.
- Screen living SOT donors with epidemiological risk factors for *Strongyloides* with serology to minimize the risk of a donor-derived event. Organs from living

donors testing positive can be procured after the donor is treated with oral ivermectin and adequate consent obtained from the recipient.

- Screen deceased SOT donors with epidemiological risk factors for *Strongyloides* with serology. Organ procurement from donors being screened for *Strongyloides* should not be delayed awaiting results. Transplant centers should be notified of a positive donor test and the results promptly reported. SOT recipients receiving organs from deceased donors should be treated with oral ivermectin without delay. SOT deceased donors undergoing screening for *Strongyloides* or testing positive should not be excluded from donation based on this criterion alone.
- Transplant centers notified of a potential donor-derived event with *Strongyloides* should immediately treat their patients empirically with oral ivermectin. Delaying treatment awaiting the outcome of the investigation is strongly discouraged.

Introduction

Chagas disease (ChD), also known as American trypanosomiasis, is a zoonotic protozoan infection caused by the flagellate parasite *Trypanosoma cruzi* (*T. cruzi*). ChD was first described by the Brazilian sanitary physician Carlos Justiniano Chagas in 1909, more than a century ago. ChD remains an important public health problem classified as a neglected disease by the World Health Organization (WHO). There are an estimated seven to eight million infected people in the world, mostly in Latin American countries where it is endemic [1].

ChD disease has two successive phases, acute and chronic. Acute infection is mostly characterized by asymptomatic high parasitemia that is progressively controlled after a few months without treatment. Untreated infection can progress to a chronic form of ChD characterized by low parasitemia, which may remain asymptomatic for life or progress to cause irreversible cardiac, gastrointestinal, or peripheral nervous system disease. Immunocompromised individuals can also present with reactivation episodes of chronic ChD characterized by high parasitemia and clinical manifestations similar to the acute disease. Transplant physicians in endemic and non-endemic countries should be aware of the risk of *T. cruzi* transmission from donors to recipients as well as the risk of ChD reactivation in previously infected patients receiving immunosuppression posttransplant.

This chapter aims to raise awareness among transplant physicians regarding the risk and clinical management of *T. cruzi* donor-to-recipient transmission and post-transplant ChD reactivation in recipients from both endemic and non-endemic countries by discussing the global burden of ChD and its consequences in the field of transplantation. Prompt diagnosis and timely treatment of ChD in transplant patients is associated with good outcome, whereas lack of initial clinical suspicion resulting in a late diagnosis has been associated with fatal outcomes.

Epidemiology

According to estimates by WHO, more than 70 million people living in Latin American endemic countries are at risk for acquiring ChD; 7–8 million people are infected worldwide; and over 10,000 people die annually from clinical complications of ChD [1, 2]. Global estimates of infected people and the status of vector transmission are presented in Fig. 1. ChD is geographically limited primarily to Central and Southern American countries and Mexico because of the distribution

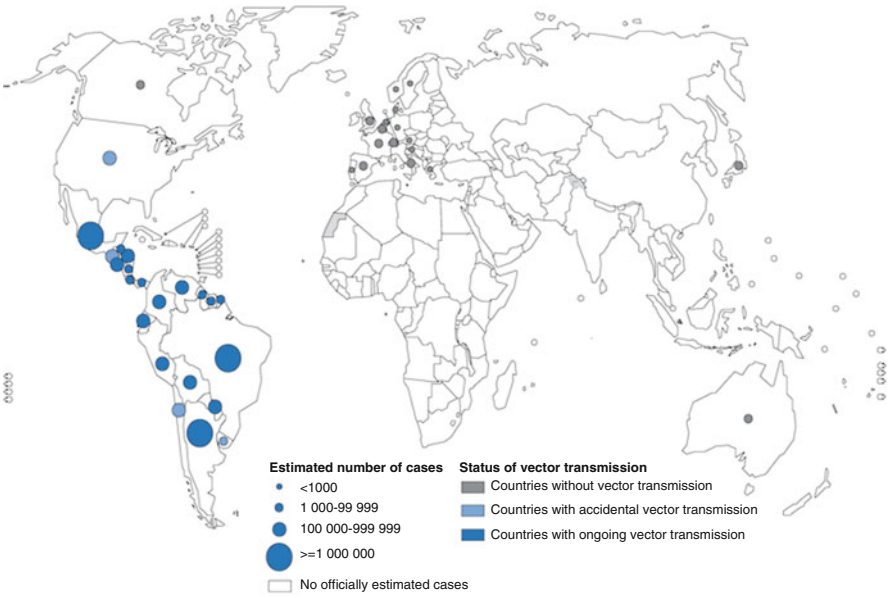

Fig. 1 Distribution of cases of *Trypanosoma cruzi* infection, based on official estimates and status of vector transmission, worldwide, 2006–2009. (Source: Reprinted from WHO [2], Copyright (2010))

of insect vectors responsible for disease transmission. However, since the 1990s, ChD has become a global health problem spreading outside Latin America, a phenomena related to increased international travel and migration flows from endemic to non-endemic areas including Europe, the USA, Canada, and Japan [3].

Modes of Transmission

ChD is transmitted to humans primarily through feces from triatomine insects containing *T. cruzi* parasites. Alternative modes of transmission consist of oral transmission by contaminated beverage and food, vertical transmission (mother to child), transmission via blood transfusion, and tissue and organ transplantation [4].

Vector transmission of ChD is limited to the Americas, involving more than 150 triatomine species (Hemiptera, Family Reduviidae, subfamily Triatominae) known as blood-sucking bugs or "kissing bugs" [5]. The most common triatomine species for *T. cruzi* transmission belong to the genera *Triatoma, Rhodnius*, and *Panstrongylus* [6]. The vector defecates after sucking blood, and the parasites are transmitted to humans through infected feces in contact with disrupted skin as a consequence of the vector bite or other skin lesions or through direct contact of feces with mucous membranes of the eyes or mouth. This zoonosis has involved sylvan or domestic mammals and nonmammal animals (marsupials, Chiroperas,

Rodentia, Edentata, native primates) serving as reservoirs hosts and several domestic and native species of *Triatoma.* Domestic (intra- and peridomicile) triatomine bugs typically live in cracks and holes in walls and roofs of poor housing, in rural and peri-urban areas. This condition is present from the Southern USA and Northern Mexico all the way to Argentina and Chile in the south [7].

Thanks to the intergovernmental Southern Cone Initiative coordinated by the Pan American Health Organization (PAHO)/WHO implemented to eliminate domestic triatomines in 1991, interruption of vector transmission of *T. cruzi* has been achieved in several Southern Cone and Central American countries. PAHO/WHO certifications of virtual or effective interruptions of domestic *T. infestans* populations were issued to Uruguay (1997 and 2012), Chile (1999), Brazil (2006), eastern Paraguay (2008), some parts of Argentina (2001, 2004, 2011, 2012), and southern Peru; and certifications of interruption domestic *R. prolixus* populations were issued to Southern Mexico (2009), Guatemala (2008), Honduras (2010), Nicaragua (2010), El Salvador (2010), and Costa Rica (2011) [8, 9]. Consequently, the number of new cases of infections in Latin America was drastically reduced. On the other hand, *T. cruzi* transmission by ubiquitous native vector populations in natural ecotopes in the Americas continues to occur; however, there is no current evidence of continuous or sustained domestic transmission [10].

An additional aim of the Southern Cone Initiative was the reduction or elimination of transmission via blood transfusions [10]. The reported prevalence of *T. cruzi* infection among blood donors from 1980 to 1989 varied from 1.3% to 51.5%, and the infectivity rate from one unit of infected whole blood was estimated to be around 12–25% [11]. In most Latin American countries, screening for *T. cruzi* infection in blood and organ donors is now compulsory [8]. As a consequence, the prevalence of infected blood samples in the Southern Cone countries has decreased. However, the implementation of serological screening as a control strategy for ChD remains a challenge in many endemic Latin American countries such as Bolivia where approximately 50% of the blood banks do not screen samples [8]. Moreover, there are many differences in the serological procedures and rules regulating the practices of blood screening for ChD.

Therefore, the risk of transfusion-transmitted ChD can present great variability. The residual risk of infection in endemic countries with fully implemented screening strategies is estimated at 1:200,000 units [12]. Transfusion-transmitted ChD has been also reported in non-endemic areas. A systematic review of reported cases in North America and Spain identified a total of seven cases [13]. In the USA, the Food and Drug Administration (FDA) recommends that blood donors should be tested at least one time for antibodies to *T. cruzi* using a licensed test; donors who test negative are qualified to return for repeat donation without further testing. This was implemented after it was realized that donor screening questions were not effective in identifying those at risk for transmission of ChD in non-endemic countries.

Aside from vector- and transfusion-transmitted ChD, transmissions from chronically infected pregnant women to the fetus and through solid-organ transplantation (SOT) or hematopoietic stem cell transplantation (HSCT) are additional modes of *T. cruzi* infection [3], occurring in both endemic and non-endemic countries.

T. cruzi can also be transmitted orally through beverages and food contaminated by infected vector's feces or urine, infected triatomines, or secretions from the anal glands of infected marsupials [6]. Oral transmission of *T. cruzi* has emerged as one of the major forms of ChD transmission in regions such as the Amazon basin and has been responsible for several outbreaks in endemic countries, usually affecting several people simultaneously. It has been related to the consumption of contaminated unpasteurized products such as *açaí* and other fruit juices and sugarcane [14].

The Burden of Disease

Although differences in the estimates of infected individuals in the Americas have been observed reflecting different methods employed to diagnose *T. cruzi* infection, the reported numbers are consistently high, and ChD remains one of the biggest public health problems in the world. Nevertheless, due to several governmental initiatives promoting advances in vector control and quality assurance of blood transfusion in many Latin American countries, the epidemiological measures of ChD in Latin America reported by WHO in 2015 showed a significant reduction compared to the previously reported data [1] (Table 1). The prevalence of *T. cruzi* infection has decreased significantly from an estimate of 30 million in the 1990s to about 7–8 million in the 2010s [7]. The estimated prevalence of *T. cruzi*-infected people in Latin America varies from 0.7% in Mexico to 15% in Bolivia [15] (Table 2). In endemic areas, according to recent estimates based on 2010 data, there are 5,742,167 infected people living in 21 Latin American countries, of which the majority are living in Argentina (1,505,235), Brazil (1,156,821), Mexico (876,458), and Bolivia (607,186) [1].

In the non-endemic areas, ChD is detected among the migrant population from endemic areas. Epidemiological data regarding the burden of ChD in non-endemic areas are limited and mostly acquired by indirect estimates based on the number of migrants from Latin American endemic countries living in non-endemic areas or information from screened blood donations [16–19]. Therefore, the real burden of ChD in non-endemic countries is uncertain, given the underestimation of the number

Table 1 Prevalence and incidence of vector-borne transmission of Chagas disease in 21 endemic countries in Latin America, in the years 1990, 2000, 2006, and 2010

	Estimated numbers			
Parameters	1990	2000	2006	2010
Total population at risk	100,000,000	40,000,000	28,000,000	70,199,360
Number of infected individuals	30,000,000	18,000,000	15,000,000	5,742,167
New cases per year acquired by vector transmission	700,000	200,000	41,2000	29,925

Note: The estimated number of total population of risk is based on official PAHO/WHO data. The higher number of estimated population at risk reported in 2010 compared with previous estimated rates was due to the different criteria used

of migrants and the lack of a surveillance system for ChD in these countries [20, 21]. The estimated prevalence of *T. cruzi* infection in immigrants from endemic areas ranges from 2% in the USA to 5.2% in Spain [15] (Table 2).

The total estimate of ChD cases living in Europe is between 68,318 and 123,078 with most of them living in Spain, Italy, and the UK [20]. The pooled prevalence of chronic ChD among Latin American immigrants living in Europe was 4.2%, ranging from 2.2% to 6.7% [19]. Immigrants from Bolivia had the highest prevalence (18.1%), followed by Paraguay (5.5%), Nicaragua (4.6%), Honduras (4.2%), El Salvador (3.7%), Argentina (2.2%), Mexico (1.5%), and Chile (1.0%) [19]. Prevalence among immigrants from other countries was less than 1% [17–19].

In the USA, from 2007 to 2013, the American Association of Blood Banks reported 1,908 confirmed cases of *T. cruzi* infection through screening of blood donors, and the Centers for Disease Control and Prevention (CDC) approved a total of 422 benznidazole or nifurtimox treatments for ChD during the same period [21]. More recent data estimates 238,091 cases of *T. cruzi* infection are in the USA as of 2012 [22]. Comparing the 2005 and 2012 data, the number of infected

Table 2 Estimated prevalence of *T. cruzi*-infected people living in endemic countries and of the *T. cruzi*-infected immigrants from endemic countries living in non-endemic countries

	Estimated prevalence (year)
T. cruzi-infected people living in endemic countries	
Argentina	8.2% (1990)
Bolivia	15.4% (1990)
Brazil	1.3% (1995)
Chile	2.8% (1990)
Colombia	3.9% (1990)
Costa Rica	4.3% (1990)
Ecuador	1.2% (1990)
El Salvador	6.1% (1990)
Honduras	5.8% (1990)
Guatemala	7.9% (1990)
Mexico	0.7% (1990)
Nicaragua	1.7% (1990)
Panama	9.0% (1990)
Paraguay	9.3% (1990)
Peru	3.0% (1990)
Uruguay	1.2% (1990)
Venezuela	4.0% (1990)
T. cruzi-infected immigrants from endemic countries living in non-endemic countries	
Australia	3.8% (2006)
Canada	3.5% (2006)
Europe (15 countries excluding Spain)	2.9% (1999–2005)
Spain	5.2% (2008)
USA	2.0% (2007)

Source: Adapted from Schmunis and Yadon [15]

immigrants decreased about 20% in the USA. This decrease, however, is probably not accurate, reflecting further the decrease of Latin Americans immigrants observed in the US Census surveys conducted after 2005. In addition, those authors have estimated an additional 109,000 cases of ChD among undocumented immigrants in 2012. The states with higher prevalence of immigrants with ChD (over 10,000 cases) were California, Texas, Florida, and New York, reflecting the distribution of Latin American immigrants in the USA [22].

Based on a systematic review, the risk factors for ChD among immigrants have included older age, living in a rural area, living in a mud/adobe house, having heard about ChD, knowing someone with ChD, having lived in a place with a thatched roof, and having a mother or grandmother born in an endemic country bitten by a triatomine [23].

Natural History and Pathogenesis

The life cycle of the parasite is shown in Fig. 2. *T. cruzi* has two distinct forms in infected humans: flagellate form in the peripheral blood and biological fluids (trypomastigote) and nonflagellated form in the tissues (amastigote) [24].

During a blood meal from an infected host, the triatomine vector ingests trypomastigotes which undergo transformation to epimastigotes (Fig. 2). After 3–4 weeks, infective metacyclic trypomastigotes develop in the triatomine's hindgut and are eliminated in the feces during subsequent blood meals, infecting other individuals [25, 26]. The trypomastigotes invade host cells and transform into intracellular amastigotes, which then multiply by binary fission and transform into blood form trypomastigotes. Afterwards, these trypomastigotes disseminate by infecting adjacent cells, via bloodstream or lymphatic system. Any nucleated mammalian cell can be infected, but *T. cruzi* parasites have a tropism toward cardiovascular, reticuloendothelial, nervous, and muscular systems [26].

ChD is characterized by three well-defined phases of infection or disease: acute, chronic, and reactivation phase (Fig. 3). Acute infection is mostly asymptomatic with high parasitemia. In immunocompetent individuals, infection is usually controlled after a few months even without treatment with trypanocidal drugs, and untreated patients will develop lifelong chronic infection, characterized by low-level parasitemia. The majority of people remain asymptomatic, while infection persists in the indeterminate form, and approximately 30–40% of the patients will progress to irreversible cardiac, gastrointestinal, and/or, more rarely, peripheral nervous system diseases [25, 27]. If untreated, immunosuppressed individuals with chronic infection are at risk of reactivation of ChD, characterized by episodes of high parasitemia and development of clinical and laboratory manifestations.

Vast regional diversity of the course and severity of chronic ChD probably reflects the complex interactions between the genetic variability among *T. cruzi* strains, host immunogenetics, and eco-epidemiological characteristics [28]. *T. cruzi* parasites show high genetic diversity and are classified into six discrete typing units (DTUs), named TcI to TcVI [29]. As an example, TcI has been

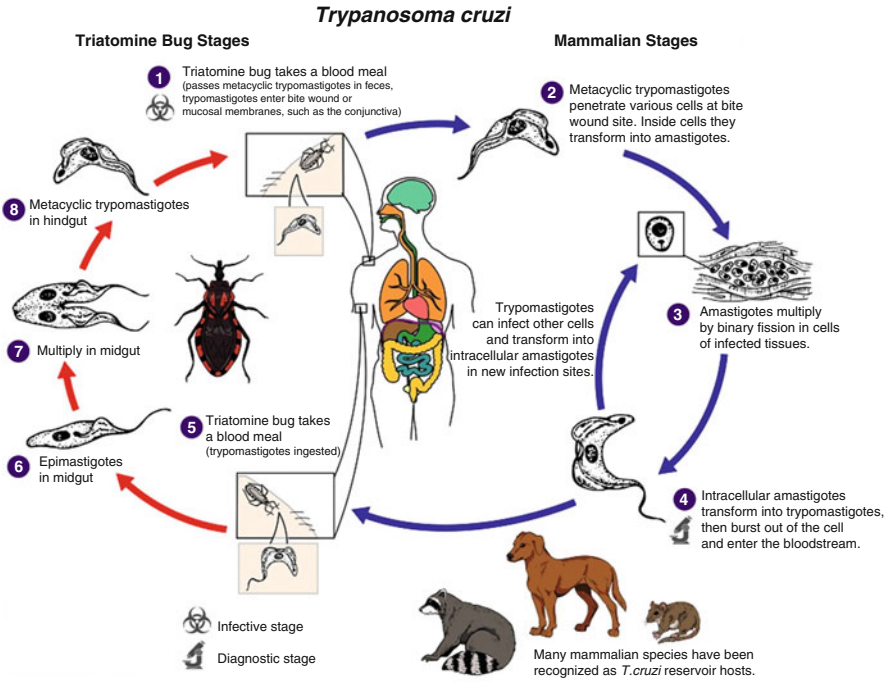

Fig. 2 Life cycle of *Trypanosoma cruzi*. (Source: Parasitic diseases in humans transmitted by vectors [24])

correlated with higher parasitemia and incidence of cardiomyopathy compared to the other *T. cruzi* DTUs [30].

After a variable incubation period, ranging from 7 to 15 days in the case of vector transmission and from 30 to 420 days in the case of transfusion- or transplant-associated transmission, the infected patient develops acute infection characterized by high parasitemia. In immunocompetent individuals, most of the patients are asymptomatic, and infection is usually controlled after a few months even without treatment with trypanocidal drugs. During the acute phase, about 50% of cases are asymptomatic or oligosymptomatic [31, 32]. When present, the main clinical manifestations are Romaña's sign characterized by unilateral painless edema of the eyelids (Fig. 4) and present in about 50% of the patients or inoculation chagoma in the skin characterized by edema at the infection site and present in about 25% of the patients. Other symptoms are fever, malaise, headache, anorexia, myalgia, lymphadenopathy, hepatomegaly, splenomegaly, rash, and diarrhea [27, 33]. Severe disease characterized by acute myocarditis, pericardial effusion, or meningoencephalitis has been reported in less than 5% of patients. The clinical manifestations of acute ChD are similar regardless of whether transmission was by vector, transfusion, HSCT, or SOT, except for the absence of an inoculation chagoma and a longer incubation period in transfusion- or transplant-associated transmission [4, 34].

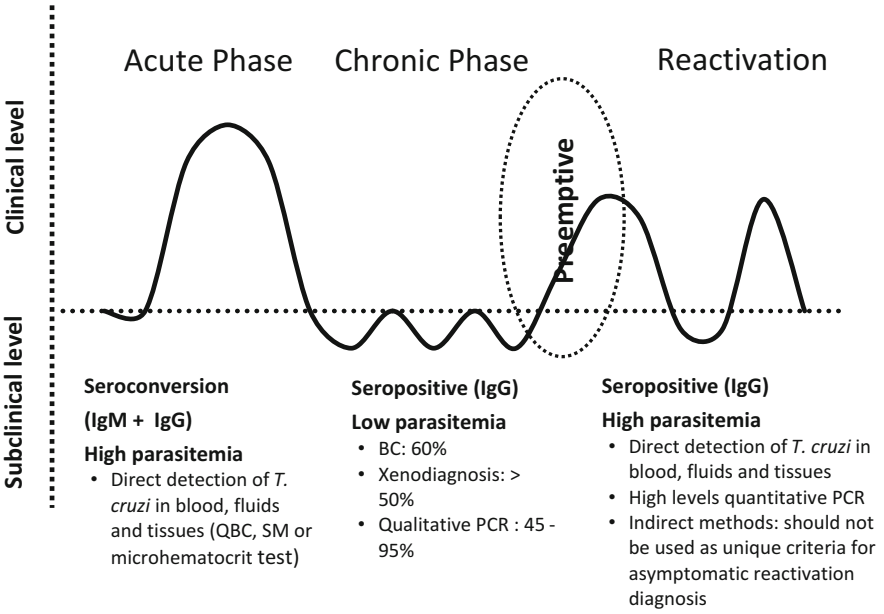

Fig. 3 Natural history of Chagas disease and the diagnostic characteristic in different phases of illness. Ig, immunoglobulin; QBC, quantitative buffy coat; SM, Strout method; BC, blood culture; PCR, polymerase chain reaction

Following parasite dissemination to the lymphatic system and bloodstream, the host's cell-mediated immunity controls parasite replication with a decrease in parasitemia in 1–2 months. Spontaneous resolution of the symptoms then occurs, and infection progresses to the chronic phase without treatment [4]. In this phase, the parasitemia is low and intermittent, and the parasites remain mostly in muscle (cardiac, smooth, and skeletal) and ganglion cells where they undergo further cycles of intracellular multiplication [4].

Approximately 60–70% of patients with chronic infection will evolve to an indeterminate clinical form of ChD characterized by positive serological tests, absence of clinical manifestations, normal electrocardiogram (ECG), and normal radiological examination of the chest [4, 34]. The remaining individuals will develop a determinate form with organ involvement 10–30 years after acute infection, evolving to symptomatic clinical forms related to the involvement of the heart, digestive system, and/or nervous system [27].

Heart involvement is the most serious and frequent form of the chronic ChD occurring in about 20–30% of chronically infected cases [35], and ChD remains the major cause of end-stage cardiomyopathy in endemic regions associated with high mortality [36]. Cardiac disease results from low-intensity continuous focal immune-mediated myocardial injury triggered by persistent *T. cruzi* myocardial infection, therefore resulting in progressive myocardial dysfunction and fibrosis and cardiomegaly (Fig. 5a, b). In addition, autonomic nervous system innervation and

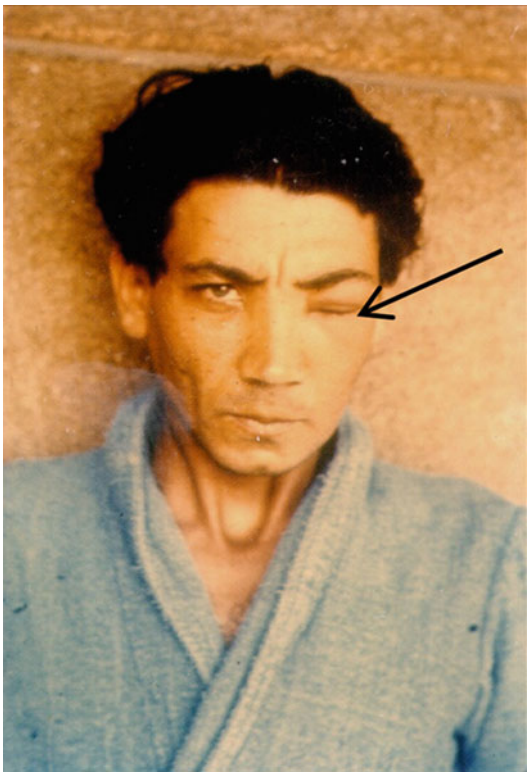

Fig. 4 Acute Chagas disease showing unilateral bipapebral edema in the local of insect bite – Romaña sign (arrow). (Courtesy: Prof. Mário Shiroma, São Paulo, SP – Brazil)

coronary microcirculation disturbances may amplify the pathogenesis of chronic Chagas cardiomyopathy (CCC) [35]. CCC is more frequent among individuals suffering over 30 years of infection and slowly evolves to arrhythmias, congestive heart failure, and thromboembolism [37, 38]. At first, cardiac involvement can be oligosymptomatic with arrhythmias detected only by the ECG or by 24-h Holter monitoring; CCC is essentially an arrhythmogenic disease where any type of atrial and ventricular arrhythmia as well as a wide variety of abnormalities of the conduction system may occur. The most common ECG abnormalities are sinus bradycardia, first-degree atrioventricular block, isolated ventricular extrasystoles, or typical findings such as second-degree and third-degree atrioventricular blocks and right bundle branch block [35, 37]. Congestive heart failure secondary to ventricular dysfunction progresses from mild symptoms of fatigue and dyspnea to more intense symptoms of pulmonary and systemic venous congestion. Pulmonary and systemic embolisms are common manifestations in patients with congestive heart failure [35]. Anatomical changes include thinning of the ventricular walls, biventricular enlargement, apical aneurysms, and mural thrombi [4].

Clinical progression and survival rates are significantly worse in patients with CCC than in those with non-inflammatory forms of dilated cardiomyopathy. The worse prognosis of patients with CCC might be associated with the greater incidence

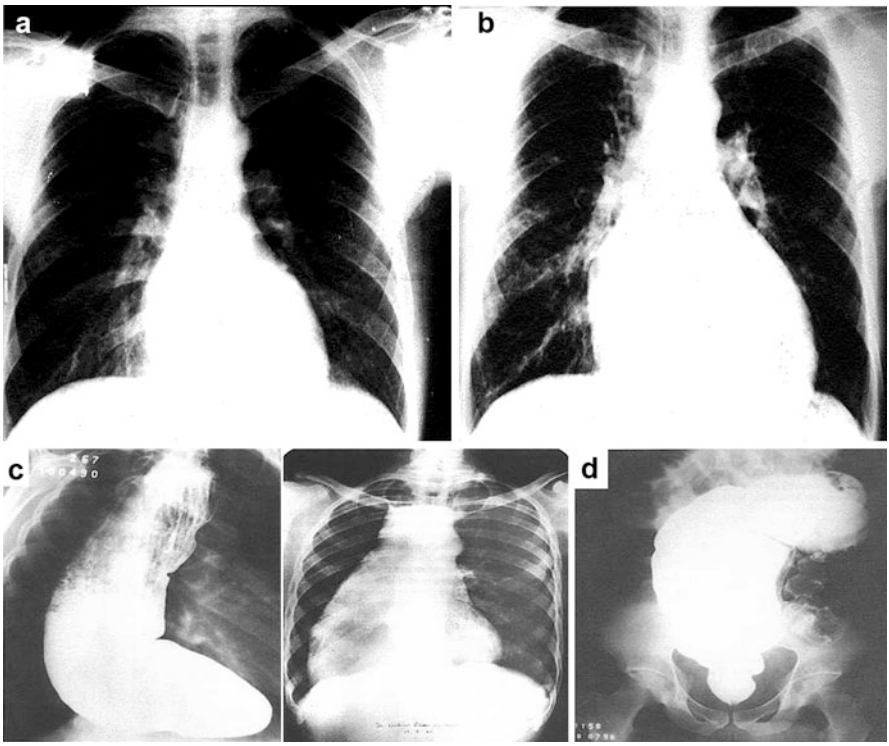

Fig. 5 Chronic ChD complications. (**a**) Patient with normal cardiac area; (**b**) Chronic Chagas cardiomyopathy characterized by the enlarged cardiac area; (**c**) contrasted X-ray of esophagus showing an enlargement of esophagus grade IV (on the right) and simple X-ray showing the shadow of esophagus on paracardiac area (on the left); (**d**) Megacolon in a patient who is 45 days without evacuation. of atrial fibrillation and apical aneurysm observed in these patients in comparison with patients with cardiomyopathy from other etiologies. The most frequent causes of death among CCC patients are sudden cardiac death, accounting for nearly two-thirds of all deaths and usually associated with ventricular tachycardia and fibrillation, followed by refractory heart failure (25–30%) and thromboembolism (10–15%) [4]. Compared to patients with non-chagasic heart failure, the 5-year mortality rate of CCC patients was worse (21.8% vs. 32.8%, $p = 0.046$) [39].

The digestive form of ChD is less common, affecting about 15–20% of chronically infected individuals, occurring mainly in Argentina, Chile, and Bolivia [4]. Gastrointestinal tract disease is caused by injury to the autonomic nervous system throughout the tract, resulting in functional abnormalities of the salivary glands, stomach, extrahepatic ducts, duodenum, and small and large intestines [34]. The functional abnormalities, however, occur mostly in the esophagus and distal colon where denervation leads to loss of motor coordination and achalasia of the

sphincters, followed by difficulty in emptying semisolid material and progressive enlargement of these organs, resulting in the characteristic megaesophagus or megacolon [4, 27].

Concerning megaesophagus (Fig. 5c), the manifestations range from asymptomatic motility disorders, mild achalasia, and esophageal reflux to severe megaesophagus and dolichomegaesophagus. Symptoms include dysphagia, odynophagia, weight loss, aspiration, cough, and regurgitation. Patients with megaesophagus may be at increased risk of esophageal cancer [4].

Megacolon and dolichomegacolon (Fig. 5d) clinical manifestations are characterized by constipation, meteorism, dyskinesia, and, less frequently, abdominal pain. Prolonged constipation can lead to fecaloma, volvulus, and bowel ischemia. The sigmoid and rectum are dilated in nearly all cases of megacolon, whereas dilatation of more proximal colonic segments is rare. Most cases of megacolon are associated with megaesophagus. An increased risk of colorectal cancer has not been found in patients with megacolon [4].

A cardiodigestive form of ChD, combination of heart disease with megaesophagus and/or megacolon, has been also reported, but the real prevalence is unknown. In most patients, the development of megaesophagus precedes the involvement of the heart and colon [4].

Peripheral nervous system involvement by ChD is characterized by a sensorimotor polyneuritis causing paresthesia and hypoesthesia [27]. This form of the disease is much less common than cardiac and digestive manifestation, and it is usually restricted to a reduction or abolition of osteo-tendinous reflex showing destruction of motor neurons and of peripheral sensory nerve fibers at the electromyography examination. The autonomic nervous system can also be involved [27].

During the chronic Chagas infection, the delicate but stable immunological balance between the immune response and the parasite replication control can be broken by immunosuppression and immune deficiency states which lead to reactivation of latent infection characterized by high parasitemia and/or clinical manifestations with the presence of the parasite in fluids and tissues. The reactivation of ChD has been reported in patients with different immunosuppressive states, such as those with human immunodeficiency virus (HIV) infection, malignancies, and systemic autoimmune diseases and those with SOT or HSCT [32, 40, 41].

The risk of reactivation is related to the intensity of immunosuppression and does not depend on the phase of chronic infection whether indeterminate or active organ involvement. Reactivation episodes are usually reported after an intensification of the immunosuppression in chronically infected patients and are characterized by high parasitemia and sometimes atypical clinical manifestations. Moreover, some clinical differences between reactivation episodes among the immunocompromised groups have been observed. Long-lasting fever, cutaneous lesions including panniculitis (Fig. 6a), and myocarditis (Fig. 6b) are common in SOT and HSCT recipients [42, 43], whereas the most common manifestations of ChD reactivation among HIV-infected individuals are meningoencephalitis and central nervous system (CNS) involvement (Fig. 6b, c) [44], conditions rarely reported in transplant recipients [45, 46].

Diagnosis

Methods of Laboratory Diagnosis

The diagnosis of ChD can be confirmed by serological and parasitological tests. Specific comments and indications of each method are summarized in Table 3.

Serological tests are based on both conventional and nonconventional methods. Conventional methods include the high-sensitivity enzyme-linked immunosorbent assay (ELISA) or indirect immunofluorescence assay (IFA) methods and the high-specificity indirect hemagglutination assay (IHA) or recombinant antigen methods [47]. The pooled estimated sensitivity and specificity of 61 *T. cruzi* conventional serologic assays were 90% and 98%, respectively [48]. False-positive serology can occur by cross-reaction with *Leishmania* sp. and *T. rangeli* antibodies. Non-conventional tests, preferably recombinant antigen ELISA and Western blot with trypomastigote excretory-secretory antigen (TESA), have higher sensitivity and specificity and therefore are indicated after inconclusive results in conventional assays. Other serological methods with increased specificity include the complement-mediated lysis, latex agglutination, and radioimmunoprecipitation assay (RIPA). More recently, newer serological tests based on purified, recombinant, or synthetic peptide antigens have been used, and due to its high sensitivity, ELISA has been particularly useful to guarantee the security of blood donations [47]. Parasitologic diagnosis is based on direct and indirect tests. Direct parasitological tests involve direct examination of blood, fluid, and tissue samples for parasites, while indirect parasitological tests detect parasites by culture or xenodiagnosis.

Direct microscopic examination of the parasites based on non-concentration methods (Giemsa stain or thick smear) presents lower sensitivity compared to direct investigation methods of parasite after concentration of the clinical sample by centrifugation (Strout method, microhematocrit, and quantitative buffy coat). For these concentration methods, samples from patients are collected and centrifugated to remove the erythrocyte fraction and concentrate the parasites in the sediment. In the microhematocrit, blood samples are centrifugated in a capillary tube, and the presence of parasite is checked in the layer obtained between plasma and red blood cells (leukocyte cream). For Strout method, after the first centrifugation, the supernatant is separated and centrifugated again, and the presence of parasite is examined in the sediment obtained after the second centrifugation. Buffy coat method combined the concentration techniques with staining of parasite nucleic acids by the fluorochrome called acridine orange.

Xenodiagnosis is based on microscopic examination of the intestinal contents of triatomine nymphs 20, 30, and 60 days after they are fed with blood from a patient with suspected infection. The result is expressed as a percentage of triatomine nymphs infected by *T. cruzi* [49].

Polymerase chain reaction (PCR) assays has been increasingly used in the diagnosis of ChD, albeit with limited research in reference centers and lack of approval by Food and Drug Administration (FDA) [50]. Qualitative PCR results have not provided definitive information since the test can be negative in chronically

Table 3 Diagnostic tests according to ChD manifestation

Diagnostic test	Samples tested	Specific comments	Recommended tests		
			Acute ChD	Chronic ChD	Reactivation ChD
Direct microscopic examination of trypanosomatids	Blood fluids – CSF, cavitary fluids	Quick and easy to perform. Non-concentration methods (Giemsa stain or thick smear) present lower sensitivity compared to concentration methods (SM, microhematocrit, and QBC)	Yes	No	Yes
Xenodiagnosis	Blood	Low sensitivity if low parasitemia, highly specific; labor-intensive and time-consuming (up to 2 weeks or longer). Results can be semiquantitative indicating the percentage of nymphs per assay, useful for monitoring risk of ChD reactivation	No	Yes	No Predictive of ChD reactivation
Blood culture	Blood	Low sensitivity if low parasitemia, highly specific; time-consuming (up to 120 days to get positive results)	No	Yes	No
Polymerase chain reaction	Blood, CSF	High sensitivity and specificity. Not commercially available, performed by only few research/ reference centers, need standardization protocols. Results can be quantitative (IU/ml), useful for monitoring risk of ChD reactivation and monitor therapy response	Yes	Yes, in special situations to confirm inconclusive serological results	Yes Predictive of ChD reactivation Monitor therapy response

infected individuals. Furthermore, positive results are not able to distinguish between acute and reactivation from chronic infection. On the other hand, quantitative PCR (qPCR) tests have demonstrated good accuracy for *T. cruzi* quantification in peripheral blood samples [51, 52]. Parasite load quantification is particularly useful both for monitoring therapeutic response [53] and immunocompromised patients at risk of reactivation [54–56] (see the discussion below). PCR tests are also important for molecular typing of *T. cruzi* and can identify the lineage and genetic diversity of the parasites.

Sensitivity and specificity of noncommercial PCR tests are highly variable due to several technical factors, such as the sample volume, conservation conditions, methods used to extract DNA whether commercial kits or in-house methods, cycling protocols, and the parasite sequences and primers selected [57]. In addition, there is a possible effect of *T. cruzi* DTUs and their respective parasite burden among infected individuals [30]. Therefore, there is an urgent need for PCR tests to follow a standardized protocol. Due to the lack of standardized PCR tests, and the genetic variability of *T. cruzi* strains, currently an isolated positive result cannot be considered accurate enough to confirm or discard cases of acute or chronic ChD, and a combination of two or more PCR assays with different target genes is recommended in order to increase the accuracy [58].

Acute ChD Diagnosis

In the acute phase of infection, parasitemia is high in the peripheral blood, and parasitological examination is the most appropriate. Simultaneous performance of different modalities of direct parasitological examination of the peripheral blood (with or without centrifugation) using microscopy (with or without staining) is recommended [34] (Fig. 7a–c). Fresh examination for parasites is quicker and easier to perform, and it is the preferred diagnostic method in patients with up to 30 days of

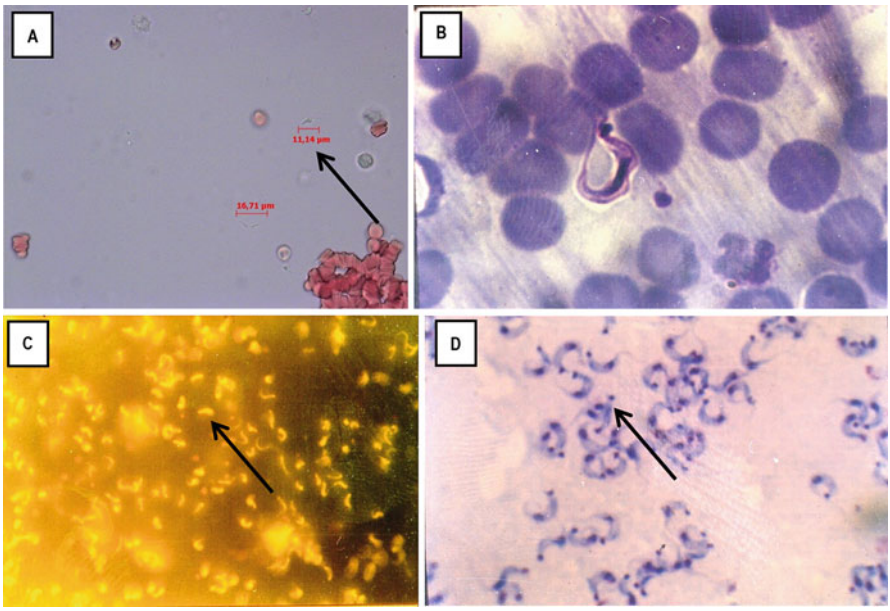

Fig. 7 (**a**–**c**) Parasitemia detection by direct methods in blood samples from a patient with acute Chagas disease. (**a**) Direct visualization of trypomastigote form of *T. cruzi* on peripheral blood smear. (**b**) Trypomastigote form of *T. cruzi* visualized in a Giemsa-stained peripheral blood smear. (**c**) Trypomastigote form of *T. cruzi* detected by quantitative buffy coat (QBC). (**d**) Trypomastigota form of *T. cruzi* visualized in a cerebrospinal fluid. fever. Concentrated methods have a higher sensitivity compared to non-concentrated ones, and they perform better in symptomatic patients with more than 30 days of evolution due to the expected decline in parasitemia. Blood samples should be examined within 24 h due to the risk of parasite lysis that may reduce sensitivity. Whenever the results of fresh examination and concentration methods are negative in the initial sample, additional samples must be tested until ChD suspicion is discarded, symptoms are resolved, or a different diagnosis is confirmed [34].

Parasites have also been observed directly in cerebrospinal fluid (CSF) when neurological signs were present (Fig. 7d) or in biopsied tissues such as the skin, heart, CNS, or any other involved organ when signs of reactivation were present [25, 27].

Indirect parasitological testing like xenodiagnosis and blood culture is time-consuming and laborious, thus are not indicated for the diagnosis of acute infection since treatment must be promptly started. However, positive results are useful to confirm acute ChD given the high specificity of these tests.

Serological tests are complementary and useful in acute ChD diagnosis and should always be performed. When repeated direct examinations are negative as commonly occurs during the late acute infection phase, serological tests are crucial to confirm suspected ChD [34]. Serological diagnosis of acute ChD is based on the

presence of anti-*T. cruzi* IgM antibodies by indirect IFA or the presence anti-*T. cruzi* IgG antibodies by conventional tests where an increase in IgG concentration of at least two IgG titers after a minimum interval of 21 days in preferably paired samples is diagnostic or seroconversion by any of the methods.

Additionally, in cases where a strong clinical and epidemiological suspicion of acute ChD exists, but direct parasitological examination is negative, the diagnosis of *T. cruzi* infection can be confirmed by molecular testing using PCR.

Chronic ChD Diagnosis

To confirm the diagnosis of chronic infection, it is necessary to detect the anti-*T. cruzi* IgG antibodies by two conventional methods with distinct antigenic preparations. Preferably, a high-sensitivity ELISA or IFA test should be performed simultaneously with a high specificity test like IHA or recombinant antigens [47].

Two conventional serological tests provide an accurate diagnosis in more than 95% of samples. Use of three serological tests in parallel can reduced indeterminate results to less than 2% [47]. Samples with indeterminate results (i.e., one negative and one positive result) should be retested. Repeatedly indeterminate results should be further tested by nonconventional tests, preferably using recombinant antigen ELISA and TESA-Western blot.

Chronic phase of ChD is characterized by low parasite burdens and negative results of direct parasitological methods. Low level of parasitemia can be detected intermittently by indirect parasitological methods with highly variable positivity rates, ranging from 25% to 94% for blood cultures [59].

Detection of *T. cruzi* DNA by PCR assays in chronically infected individuals shows a high variability, and therefore a negative result is not sufficiently accurate to rule out a diagnosis of chronic ChD. In a comparative study of different diagnosis methods for ChD, the rates of PCR detection among chronically infected patients with positive, negative, and inconclusive serologies were 83.5%, 47.6%, and 46.2%, respectively [59].

In conclusion, considering the intermittent parasitemia, negative indirect parasitological methods and PCR cannot rule out the diagnosis of chronic ChD. When positive, however, they confirm chronic ChD which is useful particularly in cases where serologic tests present inconclusive results.

Reactivation of ChD Diagnosis

ChD reactivation is defined as increased parasitemia regardless of clinical symptoms. Detection of *T. cruzi* by direct examination is the gold standard for diagnosis of ChD reactivation. In a symptomatic individual, ChD reactivation is confirmed by direct detection of trypomastigotes in the peripheral blood and fluids or intracellular amastigotes in biopsy specimens, including the skin, myocardium, bone marrow, and brain. Once the parasitemia increases, the parasite can be detected by direct methods or even incidentally through the manual differential leucocyte count analysis by visualizing the parasites on blood smear [34].

Asymptomatic reactivation of ChD is characterized by finding the parasite in direct microscopic examination of blood. This condition was first reported in an HIV-infected patient in Brazil [60]. However, direct examination is not usually positive during the early phase of reactivation, thus delaying the diagnosis. Detection of the parasite in blood and tissues by PCR methods is able to confirm the diagnosis of reactivation days to weeks earlier compared to conventional direct methods [55, 61–63]. Studies have reported that parasite DNA is present in blood around 30 days before clinical onset of clinical reactivation [54, 61, 62]. On the other hand, negative parasitemia in patients with clinical suspicion of reactivation does not exclude this diagnosis, and direct parasitological tests must be repeated [49].

Asymptomatic ChD reactivation presenting with subclinical parasitemia, which can only be detected by indirect parasitological methods such as blood culture and xenodiagnosis or by qPCR, must be distinct from the chronic stage of ChD. In chronically infected individuals, positive blood culture or qPCR results do not necessarily imply reactivation, since asymptomatic low-level parasitemia may occur in chronic disease. Therefore, association of quantitative method is recommended to see the increase of parasitemia. Real-time qPCR needs validation and definition of cutoff values to distinguish between reactivation and increased parasitemia in chronic ChD immunocompromised patients [64].

The distinction between chronic parasitemia and reactivation is particularly difficult among immunocompromised patients as these individuals have higher levels of chronic parasitemia compared to immunocompetent individuals. A Brazilian study in patients with chronic *T. cruzi* infection compared parasitemia detected by qualitative and quantitative methods among non-HIV-infected individuals ($n = 57$), coinfected *T. cruzi*-HIV individuals without ChD reactivation ($n = 29$), and coinfected *T. cruzi*-HIV individuals with ChD reactivation ($n = 5$) [64]. The authors showed increased parasitemia across these groups measured by qualitative and qPCR. Qualitative PCR was positive in 50.9%, 89.7%, and 100% individuals, and median parasitemia by real-time qPCR was 0, 1.57, and 1428.90 parasites/ml, respectively.

Semiquantitative xenodiagnosis that indicates the percentage of positive nymphs per assay may predict the occurrence of ChD reactivation. Episodes of reactivation among coinfected HIV-positive patients have been observed in 50% of patients who show >20% positive nymphs per assay in a follow-up period of 5 years [49].

Serology is not useful in the diagnosis of ChD reactivation. Blood culture and nonquantitative xenodiagnoses are time-consuming and do not confirm the diagnosis of ChD reactivation.

ChD in the Transplant Scenario

ChD in transplant recipients may occur in one of the following ways: (i) through the graft from infected donors; (ii) through blood transfusion during the transplant procedure; (iii) by reactivation of a latent infection in chronically infected recipients; and (iv) de novo acquisition posttransplant.

The most experience regarding ChD in the transplant scenario is derived from cardiac [65] and kidney transplantation [42, 66]. There are a few reported cases among liver and lung transplant recipients and among HSCT recipients.

Acute ChD Transmitted Through the Graft from Infected Donors

Acute ChD may occur in *T. cruzi* seronegative recipients of organs or bone marrow from a seropositive donor (D+/R−). The risk of transmission from infected donors to non-infected recipients is probably the same in endemic and non-endemic countries. The lack of systematic screening of donor and recipients in most non-endemic areas, and the fact that affected donors are frequently unaware of their status, probably makes the frequency of unexpected *T. cruzi* transmission higher in non-endemic compared to endemic countries.

Acute ChD Through Solid-Organ Transplantation

There are several reported cases of accidental donor-derived *T. cruzi* infection in SOT recipients in endemic and non-endemic countries [66–72]. Accidental transmission is a challenge especially in non-endemic countries, where systematic serological ChD screening is lacking [66, 73, 74]. Based on a survey study reported in 2011, only 19% of all US organ procurement organizations performed either universal or targeted donor screening for *T. cruzi* infection [50].

The *T. cruzi* transmission rates using kidneys and livers from chronically infected donors range from 10% to 22%, with variable findings across different series, as shown in Table 4. The period between transplantation and detection of infection is

Table 4 Donor-derived *T. cruzi* infection from seropositive donors to seronegative recipients[a]

Organ	Rate of transmission	Prophylaxis	Parasitemia or molecular screening after transplant	Preemptive therapy (number of patients)	Country	Ref
Kidney	3/15	No	Yes	1	Argentina	[42]
Kidney	0/9	Yes	No	–	Brazil	[92]
Kidney	2/15	No	Yes	2	United States	[66]
Kidney	0/6	No	Yes	0	Argentina	[46]
Liver	0/2	Yes	Yes	0	Spain	[77]

Liver	2/10	No	Yes	1	United States	[66]
Liver	0/4	No	Yes	0	Argentina	[94]
Heart	3/4	No	Yes	1	United States	[66]

[a]Each series include at least two patients

variable, ranging from 27 to 203 days [42, 66, 75]. Clinical presentation includes fever, malaise, anorexia, hepatosplenomegaly, acute myocarditis, and pancytopenia [40, 41]; fulminant myocarditis is also reported [66].

Experience with lung transplantation from infected donors is limited to a few case reports; transmission of ChD was reported in three out of four negative lung transplant recipients [63, 66, 76, 77]. Time from lung transplantation to detection of infection ranged from 10 to 61 weeks [63, 66, 76]. The estimated transmission rates from the reported cases, however, are likely lower than the true figures, considering possible publication bias. The rates of ChD transmission after heart transplantation are much higher (75% or more), and reports showed that recipients experience poor outcomes with high mortality rates [66, 78]. There are no reported cases with intestine transplantation.

Acute ChD Through Hematopoietic Stem Cell Transplantation

There is only one case report of ChD transmission in a patient following HSCT in literature. The patient was a *T. cruzi* seronegative marine from Spain who underwent HSCT from a *T. cruzi* seropositive donor originally from Latin America [79]. Ninety-four days after HSCT, the patient was readmitted to the hospital with severe weakness, fever, edema of the face and legs, and hyporeflexia. Trypomastigotes were identified in the blood and probably in the CSF. Despite of treatment with nifurtimox and initial clinical response, the patient developed a bacterial infection with sepsis and died. During this clinical course, the patient received many blood products from potentially infected donors; however, further studies failed to show evidence of positive serologic tests for the HSCT donor or any of the blood donors.

Transfusion-Transmitted ChD Related to the Transplant Procedure

Transmission of ChD by blood transfusion has been recognized since 1952, and the risk is related to disease prevalence in the population as well as systematic blood donor screening [80]. All blood components from infected donors have the potential to transmit *T. cruzi*, but transmission risk has been reported to be higher for platelet transfusion because trypomastigotes are predominantly separated into the platelet fraction during centrifugation [4, 12]. *T. cruzi* can survive in blood components at 4 °C up to 18 days and when stored at room temperature up to 250 days [12]. In addition, platelet leukoreduction or irradiation may reduce but do not eliminate the risk of *T. cruzi* transmission [13]. Finally, although there is evidence of viable parasites in cryopreserved components, there is no clear evidence of transfusion-transmitted ChD through frozen-thawed cellular products [12]. Blood derivatives, such as human albumin solution, clotting factor concentrates, and immunoglobulins, are not infective [12]. Based on a systematic review of transfusion-transmitted *T. cruzi* cases in North America and Spain, the infectivity risk is estimated to be 0–1.5% for red blood cells units, 5.6–25.7% for platelets, and 0–3.7% for frozen plasma or cryoprecipitate units [13]. In all reported cases,

platelets (from both whole blood and apheresis) or whole blood were implicated [13].

In most endemic countries, systematic screening of blood donors for ChD is mandatory. In non-endemic countries, the approach has either been based on the deferral from donations of people at risk of ChD or testing those at risk and accepting them for blood donation if specific laboratory test results are negative [40]. The second approach has been the chosen strategy in countries where there is a substantial Latin American population, such as the USA, Spain, France [81], and more recently Japan [82].

Individuals requiring blood transfusion during the transplantation period are at additional risk of *T. cruzi* acquisition from positive blood donors. Nevertheless, infection can be transmitted to recipients by either transfusion or transplant, and in some cases, the real source of infection cannot be identified.

Fever is the most common symptom, occurring in 80–100% of individuals with transfusion-transmitted ChD, and may be the only symptom. Lymphadenopathy and splenomegaly are also frequent findings [34]. Transplant clinicians should be aware that the incubation period is usually longer than that observed in vector-borne transmission, ranging from 30 to 120 days, although much shorter period of 8 days has been reported [34]. Therefore, ChD must be included in the differential diagnosis in transplant recipients presenting fever of unknown origin, especially if they received a transfusion.

There is no reported case of proved transfusion-transmitted *T. cruzi* infection among SOT recipients. An old report from Chile in 1989 identified ten patients with acute ChD where blood transfusion was suspected as the mechanism of infection in these cases [83].

A fatal case of disseminated *T. cruzi* infection with myocarditis and encephalitis was reported in a 25-year-old male patient with high-risk acute myeloid leukemia who received an unrelated cord blood transplant [84]. The patient developed persistent fever 11 days after transplantation. Trypamastigotes of *T. cruzi* were detected on peripheral blood and bone marrow smears 35 days posttransplantation. Treatment for acute ChD with benznidazole was initiated immediately, but the patient died 2 days later. An infected blood donor was identified retrospectively.

ChD Reactivation Among Chronic *T. cruzi*-Infected Recipients

A possible explanation for ChD reactivation in transplant recipients is that adrenal glands and skeletal muscle may be the reservoirs of *T. cruzi* and the parasites are released into the bloodstream during posttransplant immunosuppression. Parasitemia can thus cause fever and unspecific symptoms, or parasites can invade tissues causing different manifestations, such as myocarditis, encephalitis, and panniculitis [85].

In general, the risk of reactivation in chronically infected recipients is directly related to the intensity of immunosuppression, rather than a specific immunosuppressive protocol; therefore, the risk is higher in the first year after transplantation

and also with subsequent intensifications of immunosuppression (i.e., treatment of rejection). Nevertheless, late reactivation has been reported, and clinicians should be aware of this possibility. Gomez-P et al. reported two fatal reactivations of *T. cruzi* occurring 6 years after kidney and 7 years after heart transplants which were only diagnosed at autopsy [86].

ChD reactivation may remain completely asymptomatic, detected only by direct parasitological testing or qPCR positive results; if symptoms occur, the most common are cutaneous lesions, myocarditis, encephalitis, and other nonspecific manifestations [40, 87]. Reactivation with cutaneous manifestations has been described following kidney, heart, and liver transplantation and HSCT, with similar clinical presentation seen in other immunocompromised patients [88] (Fig. 8a–g).

ChD Reactivation in Non-heart Solid-Organ Transplantation

ChD reactivation among chronically infected recipients after kidney and liver transplantation varies from 10% to 35% [42, 43, 89–93]. The two largest case series of positive recipients were reported by Riarte et al. [42] and Balderramo et al. [94]. Riarte et al. reported 5 (22%) cases of ChD reactivation among 23 chronically infected kidney transplant recipients in Argentina [42]. The patients did not receive prophylaxis and were monitored by direct parasitological and serological tests; reactivations were detected 37 days to 29 months posttransplant. All but one patient were successfully treated before developing symptoms; one patient with asymptomatic parasitemia recovered spontaneously without treatment. Balderramo et al. reported three (33%) asymptomatic cases of ChD reactivation among nine chronically infected liver transplant recipients [94]. Similarly, the patients did not receive prophylaxis and were monitored for *T. cruzi* parasitemia by real-time qPCR. All patients were successfully treated with preemptive therapy based on positive PCR results detected at days 15, 62, and 152 posttransplantation. There are a few case reports of subsequent ChD reactivation after acute infection acquired through the transplant [42, 66].

ChD Reactivation in Heart SOT

ChD cardiomyopathy represents the third leading cause of heart transplantation in Latin America [95], and heart transplant is currently the treatment of choice for chagasic patients with end-stage heart failure. This condition is associated with a worse outcome compared to other causes of heart failure, and it is an independent predictor of waitlist mortality [85]. In a Brazilian cohort, the 100-day waitlist mortality among chagasic patients was 30% compared to 16% for non-chagasic patients with heart failure ($p = 0.002$), despite no difference in the rates of transplantation [96].

Patients with CCC should be screened for megaesophagus before heart transplantation as the presence of severe esophageal dilatation may be a relative contraindication for heart transplant; surgical correction should be considered for eligible patients [85].

After heart transplantation for CCC, a high proportion of patient present with ChD reactivation, with rates of reactivation ranging from 27% to 50% and even

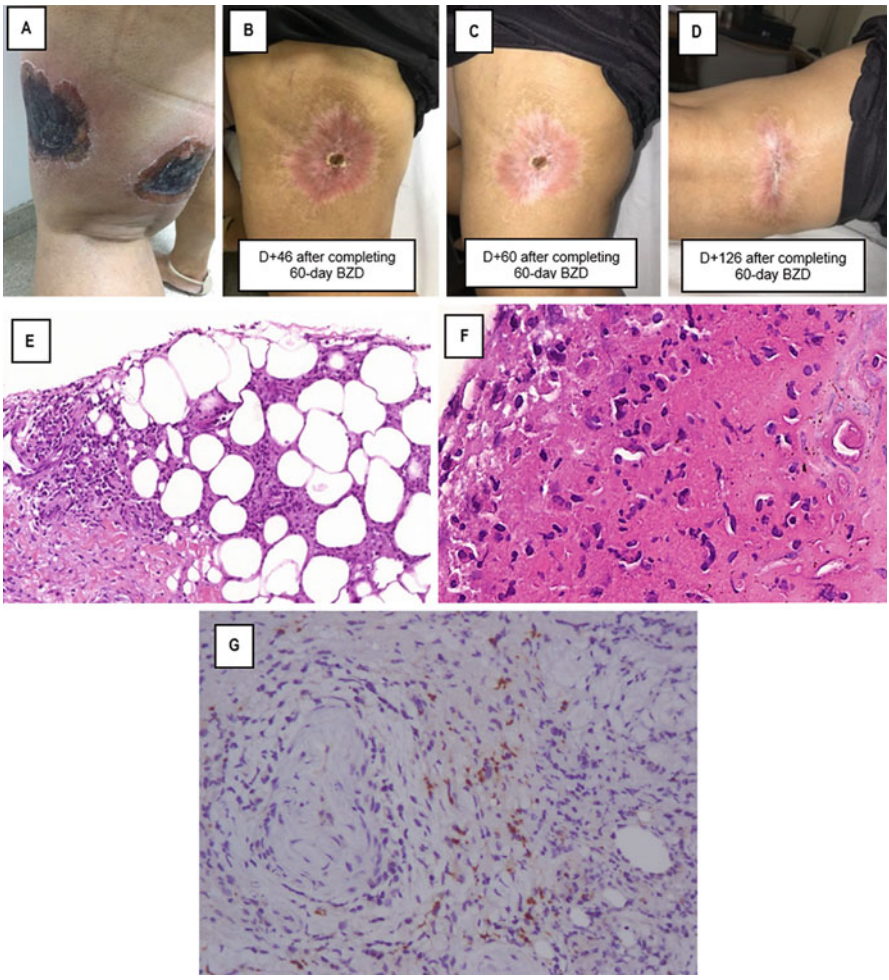

Fig. 8 Chronic chagasic 49-year-old female patient 2 months after kidney transplant. (**a**) Two left thigh eroded crusted lesions with about 4 weeks of evolution. (**b**–**d**) Clinical evolution of cutaneous lesions after completing 60-day BZD and surgical debridement. Maria Irma Seixas Duarte – Pathology Department – Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil)

reported to be as high as 90% [55, 56, 61, 97–101]. These patients frequently present with several episodes of reactivation, ranging from one to eight episodes per patient [98], despite previous correct use of trypanocidal drugs. Nevertheless, reactivation of ChD does not impact the heart transplant outcome. Graft and patient survival rates of chagasic patients are usually similar to those without ChD [102]. The reported mortality rates associated with reactivation ChD are low, at about 0.9% [101].

The most frequent clinical manifestation of ChD among heart transplant recipients is myocarditis given the tropism of the parasite for cardiomyocytes, thus increasing the risk of graft dysfunction [101]. The patients present with symptoms of heart allograft failure similar to acute rejection, including high-degree atrioventricular block and cardiogenic shock in severe cases [103].

Among heart transplant recipients, risk factors associated with higher reactivation rates are rejection, neoplasms, and use of mycophenolate mofetil [99]. Although *T. cruzi* parasites persist in the myocardium of the native heart, and an explanted heart at transplant is usually associated with high-grade myocarditis among chronically infected patients, however, the parasite persistence and parasite load in the myocardium of the native heart explanted are not associated with the risk of ChD reactivation posttransplant [104].

ChD Reactivation in Hematopoietic Stem Cell Transplantation

Immunosuppression secondary to HSCT and treatment for graft versus host disease (GvHD) is usually a trigger for the reactivation of ChD among seropositive patients [43, 105–109]. Table 5 summarizes published case reports and series in the literature.

Altclas J et al. described a cohort of 1,328 HSCT transplant patients (441 allogeneic and 887 autologous HSCT) from 1989 to 2002 from 4 health centers in Argentina [107]. The incidence of ChD in this study was 1.9% (25 *T. cruzi*-infected patients – 12 underwent autologous and 13 allogeneic HSCT). All 25 patients were in the indeterminate phase of ChD. Positive recipients were monitored by Strout and serological methods performed weekly during the first 2 months, every 15 days during the following month, and monthly thereafter. This follow-up took place in the first 2 months after autologous HSCT and throughout the immunosuppressive period after allogeneic HSCT; with any clinical suspicion of reactivation, the protocol returned to a weekly frequency until the etiological cause was diagnosed. During the follow-up period, 6 out of 25 (24%) patients presented with reactivation of ChD characterized by high parasitemia detected by positive Strout method (2 autologous and 4 allogeneic HSCT recipients). One patient presented several skin lesions with *T. cruzi* amastigote forms in tissue.

Dictar et al. followed 28 allogeneic and 206 autologous HSCT recipients from 1989 until 1996; the incidence of ChD was 2% (5 of 234 patients) [105]. Out of five patients, only one presented with reactivation of ChD (20%) during a 7-year period of follow-up, characterized by an asymptomatic positive blood. However, in this study, positive blood culture was considered the only diagnostic criteria for ChD reactivation diagnosis. Given that intermittent and low-level parasitemia is characteristic of chronically infected individuals, a positive blood culture might not mean reactivation; hence, the case reported by Dictar et al. is considered inconclusive. The other four chagasic patients presented no clinical or laboratory evidence of reactivation.

De Novo Infection

After transplantation, de novo acquisition can occur from vector exposure or blood transfusions. Vector exposure represents a risk for patients who reside or travel to

Table 5 Chagas disease reactivation among chronically infected HSCT patients

[a]BC detects low parasitemia and it can be also positive in chronic chagasic patients; positive BC has not been considered a criterion of ChD reactivation

[b]PCR has high sensitivity, so it can also be positive in chronic chagasic patient; positive qualitative PCR has not been considered a criterion of ChD reactivation

endemic regions; these individuals should be counseled to avoid vector exposure through bites or through inadvertent oral intake of contaminated food [87]. If an exposure risk occurs, the transplant patient should be screened for acute infection through direct parasitological examination of blood and other clinical specimens when indicated. Alternatively, serological tests and qPCR should be performed in cases where direct methods examination is negative. If infection is detected, this individual should be treated for acute infection and should be monitored thereafter as a *T. cruzi* chronically infected transplant patient is at risk of reactivation.

Pretransplant Risk Assessment and Management of Donors and Recipients

Pretransplant Risk Assessment

Due to risk of donor-transmitted infection, screening tests to detect chagasic patients should be performed in all potential donors and candidates at risk for this infection. In most endemic areas, pretransplant screening of donors and candidates is mandatory [40, 87]. In non-endemic areas, screening should be considered for those at risk, including individuals who were born in endemic areas or to mothers from endemic areas, individuals who lived for a prolonged time in endemic areas, and those who received unscreened blood in the past [110–113].

Screening is based on commercially available serological tests to detect chronic infection and should follow the current international recommendation for chronic ChD diagnosis. For clinical use, a serological diagnosis is confirmed by at least two positive results with different conventional serological assays using lysates of the epimastigote form of the parasite grown in lipid culture [114]. However, a single highly sensitive test such as ELISA with recombinant antigens is acceptable to certify the suitability of blood donors [47].

In some cases, the impaired humoral immunity eventually present in donors and candidates for transplant may hamper the detection of antibodies by conventional serologic tests [59].

Acceptability Criteria of a Positive Donor

Solid-Organ Transplantation

Based on cumulative successful experience of transplantation using *T. cruzi*-infected donors and considering the shortage of transplantable organs, most of the programs and guidelines have expanded donor criteria to include the use of kidneys and livers, and probably lungs, from chronically infected donors to negative recipients [87, 93, 113, 115]. However, the decision to risk possible infection in seronegative recipients receiving organs from infected donors needs to strike a balance between

the benefits of transplantation and the risk acceptance of the possibility of recipients getting the infection; an informed consent letter by the medial team needs to be acknowledged by the recipients. The decision should take into account the availability of monitoring exams and treatment if infection occurs.

Given that the heart and intestines are potentially chronically infected with a high burden of latent *T. cruzi*, these organs from known infected donors should not be accepted.

Although rare, organs from donors with acute infection should be temporarily deferred, while those from donors who died of acute disease should be not accepted.

Hematopoietic Stem Cell Transplantation

The American Society of Hematology has also published recommendations focusing on prior testing of transplant candidates and on the fact that although a positive serology is not a contraindication for recipients, seropositive HSCT donors are not accepted [115, 116]. In exceptional circumstances, however, when no seronegative donor is available, then a seropositive donor may be considered, and the recipients from this donor should be followed appropriately [107].

Pretransplant Treatment of a Positive Donor

Infected living donors should receive antitrypanosomal treatment for 30–60 days, and donation should take place as soon as possible after completing the treatment [34, 93]. If the transplant procedure needs to take place before completing treatment, the donors should be treated for at least 14 days before the donation [34]. Although the antitrypanosomal treatment response among chronically infected patients is considered minimal, the rationale for this recommendation is to decrease parasitemia and consequently the risk of parasite transmission.

Pretransplant Treatment of a Positive Recipient

Pretransplant treatment of chronically infected recipients is not indicated, given the lack of efficacy of antitrypanosomal drugs on quiescent infections and the risk of drug toxicity. In addition, a recent study in liver transplant recipients with ChD has suggested that pretransplant treatment of parasitemic patients could postpone the reactivation episode to later after transplant [94]. Among two out of nine seropositive candidates with positive parasitemia who received pretransplant treatment, one evolved with relapse of parasitemia at 60 days posttransplant requiring retreatment. In contrast, two out of seven seropositive candidates with negative parasitemia and no pretransplant treatment presented early ChD reactivation (<15 days) posttransplant. The authors suggested that patients with pretransplant *T. cruzi* parasitemia may have a late ChD reactivation and, therefore, they need to have a longer monitoring period.

Posttransplant Management of the Recipients

Posttransplant Surveillance of Negative Recipient from Positive Donor or Positive Recipient

Posttransplant monitoring of seronegative recipients of organs from positive donors or seropositive recipients is mandatory to provide prompt diagnosis of acute or reactivation ChD and timely treatment before the development of clinically significant disease. In both groups of patients, the posttransplant surveillance should be based on both clinical and laboratory monitoring.

Although the current protocols and guidelines may differ a little between the timelines proposed, all of them have highly recommended close monitoring of the patient for the first 3–6 months, until at least 2 years posttransplant; they recommend resuming monitoring if immunosuppression is increased [34, 40, 41, 111, 115]. Laboratory surveillance must be done weekly or every other week for the first months and then monthly until at least 6 months and intensified monitoring if immunosuppression is increased. Surveillance should be based on direct parasitological tests in blood (Strout method, buffy coat) and/or molecular methods. *T. cruzi* DNA analysis by PCR has been proposed as the method of choice, since it is able to detect low parasitemia earlier in reactivation and permit prompt preemptive therapy before development of clinical symptoms, which is more often observed with high parasitemia.

For heart transplant recipients, in addition to the above, parasite monitoring should include routine immunohistochemistry on all endomyocardial biopsies to search for intracellular parasites regardless of indication for biopsy [99].

In Tables 6 and 7, we present a proposal for monitoring SOT and HSCT recipients. Moreover, we recommend additional testing in the setting of intensified immunosuppression, unexplained febrile illness, or episodes of suspected graft rejection when immunosuppression may be intensified.

In transplant recipients with clinical manifestations consistent with acute or reactivation ChD, such as persistent fever for more than 7 days, with at least one or more of the following findings, pancytopenia, panniculitis, meningoencephalitis, or myocarditis, clinicians must consider a diagnosis of ChD if the donor or the recipient is from endemic areas. Histological examination of affected organs can show *T. cruzi* amastigotes. In these cases, serological testing on stored pretransplant serum can confirm the diagnosis of chronic ChD in donor and/or recipients. During the posttransplant period, serological results should be interpreted with caution. Among seronegative individuals under immunosuppression, seroconversion after acute infection may be delayed or never occur. On the other hand, negative seroconversion in chronic ChD patients on immunosuppression during the posttransplant period has been reported. Therefore, in both scenarios, false-negative serological results should be suspected when there is a high clinical probability of ChD [42].

Transplant recipients who become infected through donor-derived *T. cruzi* infection should be treated for acute infection and then managed as chronically infected ChD patients. Since there is no criteria for cure, treated patients remain at risk for further reactivation while on immunosuppression regardless of effective antiparasitic therapy.

Posttransplant Prophylaxis for Seronegative and Seropositive Recipients

Posttransplant Prophylaxis for Seronegative Recipients of Organs from Positive Donors

Data supporting the benefits of prophylaxis for seronegative recipients of organs from infected donors are not uniform. Two published Brazilian studies have shown that the use

of benznidazole prophylaxis 14–60 days posttransplant prevented donor-derived infection in seronegative kidney [92] and liver [117] recipients. However, both studies were carried out on a small number of patients (nine kidney and six liver transplant recipients), and laboratory surveillance to detect *T. cruzi* transmission was not systematically performed according to the current protocol. In fact, parasitemia surveillance was not mentioned in the study of kidney transplant recipients [92]. Other authors have reported successful transplantation of organs from positive donors to negative recipients, without parasite transmission even in the absence of prophylaxis [72, 75].

Therefore, considering the lack of prospective studies supporting posttransplant prophylaxis for seronegative recipients, potential drug toxicity, and interactions in the early posttransplant stages (see discussion in section "ChD Treatment"), in addition to the good outcomes of evidence-based surveillance and preemptive therapy, most guidelines recommend parasite monitoring and treatment if transmission occurs rather than routine prophylaxis [40, 93, 115]. The Brazilian guidelines include two possibilities: start *T. cruzi* prophylaxis for a period of 14–60 days and then proceed with serial clinical and laboratory monitoring or just monitor for *T. cruzi* without prophylaxis [34].

Posttransplant Prophylaxis for Seropositive Recipients

Current knowledge does not support universal prophylaxis for seropositive recipients to prevent ChD reactivation. This scenario has been more evident after heart transplantation where benznidazole treatment for 60 days did not prevent reactivation and treated patients experienced several episodes of reactivation in the posttransplant period [98, 99].

Posttransplant Preemptive Therapy

Preemptive posttransplant treatment for acute or reactivation ChD following laboratory evidence of ChD reactivation during monitoring is associated with good outcomes and is the best approach both for seronegative and seropositive recipients [93, 107, 111, 115].

However, chronically infected patients can have intermittent low-level parasitemia; distinguishing these individuals from those with genuine ChD reactivation based on traditional parasitological tests has been a challenge. Several studies have supported using qPCR assays to systematically monitor parasitemia after transplantation since they are highly sensitive, thus are able to provide earlier diagnosis of acute or reactivation ChD compared to parasitological methods [52, 54, 61, 62, 94].

ChD Treatment

According to current recommendations, trypanocidal treatment is indicated in the following situations: congenital transmission, infected children younger than 18 years, acute infection, laboratory accidents, and reactivation episodes in

immunocompromised individuals [95]. However, evidence supporting the benefit of treatment for chronically infected adult individuals is controversial, and the indication of trypanocidal treatment for these individuals is not at a consensus. A recent meta-analyses have concluded that there is no clear data showing the impact of treatment to avoid, stop, or revert heart pathology among chronically infected individuals [118]. Treatment of ChD beyond the transplant scenario will not be addressed in this chapter. Detailed discussion regarding this topic is available on recent publications [25, 119].

In transplant recipients, ChD treatment is strongly indicated for acute and reactivation disease. There is no data at this moment evaluating the treatment of chronic chagasic transplant patients without evidence of reactivation.

Currently, benznidazole and nifurtimox (developed more than 40 years ago) are the two specific drugs for the treatment of ChD [119]. Benznidazole is currently produced by Brazil and Argentina and largely used in Latin American countries. Nifurtimox is currently not available in many countries in Latin America, and the drug is provided for specific situations (such as suspected of resistance or serious adverse effects associated with benznidazole) through the Pan American Health Organization (PAHO)/WHO. In May 2018, benznidazole was approved by the US FDA for use in children from 2 to 12 years of age and is commercially available. Nifurtimox is not currently FDA approved and is available from the CDC Drug Service for use under an investigational protocol (Table 8).

Benznidazole is better tolerated than nifurtimox, and it has been used for the vast majority of reported cases. Alternative drugs, such as allopurinol and azole antifungals, can be used in immunocompromised patients when traditional drugs are not available, but experience with these drugs is very limited to support any recommendation [120]. Posaconazole has been used to treat chronic asymptomatic ChD, but comparative studies have showed higher treatment failure compared to benznidazole [121, 122]. There is no reported experience using this drug in transplant recipients.

In the chronic indeterminate phase, the cure rates range from 85% to 100% in children and 2% to 40% in adults. The cure rates in the acute phase are estimated to be 80–90% [25, 123].

Nifurtimox

Nifurtimox was the first developed drug against *T. cruzi*, in 1965. The drug is metabolized in the liver via cytochrome P450 and excreted preferentially by the kidneys. The mechanism of action has not been completely clarified. The drug inhibits the trypanothione reductase, a parasite-specific antioxidant defense enzyme; this deficient metabolic detoxification mechanism for oxygen is effective because *T. cruzi* is highly susceptible to oxidation and death [119].

Nifurtimox has shown more toxicity than benznidazole, and adverse effects have been reported in 43–97% of the patients, mostly characterized by anorexia, weight loss, neurological disorders (such as irritability, insomnia, disorientation, mood

Table 8 Specific available drugs to Chagas disease treatment

	Benznidazole	*Nifurtimox*
Formulation	Benznidazole (BZD; *N*-benzyl-2-nitroimidazole acetamide	Nitroheterocyclic compounds nifurtimox (NFX; 3-methyl-4-[59-nitrofurfurylideneamine] tetrahydro-4H-1,4-tiazine-1,1-dioxide)
Presentation	Tablet 100 mg	Tablet 120 mg
Adult dosing	5–7.5 mg/kg/day; recommended maximum dose 300 mg/day Up to 15 mg/kg/day in cases of meningoencephalitis	15 mg/kg/day for children and acute disease 8–10 mg/kg/day
Times per day	Two to three doses	Three to four doses
Administration	Oral	Oral
Adjust for renal function	No need	No need
Adjust for hepatic function	No need	No need
Duration of treatment	Usually 60 days For adults >60 kg, duration of treatment may be prolonged beyond the 60 days	60–90 days
Most important adverse reactions	Rash, polyneuropathy, bone marrow suppression, anorexia, nausea, vomiting	Anorexia, abdominal pain, nausea, vomiting, and weight loss
Laboratory monitoring	Baseline: complete blood cell count, hepatic enzymes, bilirubin, serum creatinine, blood urea nitrogen. While on therapy: complete blood cell count every 2–3 weeks	Baseline: complete blood cell count, hepatic enzymes, bilirubin, serum creatinine, blood urea nitrogen. While on therapy: repeat lab tests every 4–6 weeks
Drug interactions	Risk of disulfiram-like effects with concomitant use of alcohol and should be avoided Concomitant use with aspirin may increase the risk of bleeding The effect of coumarin-derived anticoagulants, such as warfarin, can be potentiated due to inhibition of its enzymatic metabolism	Alcohol increase risk of adverse effects and should be avoid Concomitant use with tacrolimus can increase tacrolimus levels
Contraindications	During pregnancy and for patients with kidney and liver failure If hypersensitivity history to the drug	

Source: Adapted from Pérez-Molina and Molina [25], de Andrade et al. [95], and Chin-Hong et al. [111]

changes, paresthesia, and peripheral neuropathy), digestive manifestation (such as nausea and vomiting), and, occasionally, fever and rash. Treatment is discontinued in up to 75% of the cases [25]. In addition, nifurtimox causes an increase in the tacrolimus levels via cytochrome P450 reductase metabolism, and strict monitoring of tacrolimus levels is recommended when both agents are used simultaneously [111].

Benznidazole

Benznidazole was developed in 1971, and it is currently the first-line treatment of ChD based on the better tolerability profile, tissue penetration, and efficacy. The drug is able to induce prompt remission of parasitemia and avoids severe complications and parasite recrudescence as observed in long-term follow-up studies [25]. The drug acts in different ways, able to induce parasite direct modification, improve phagocytosis, and increase trypanosomal death through interferon-gamma induction and inhibition of NADH-fumarate reductase [119]. Higher doses of benznidazole have been used for transplant recipients with CNS ChD involvement [46, 124].

The most frequent side effect associated with benznidazole is exanthem and urticarial dermatitis, which occur up to 30% of the patients, is not dose-dependent, and usually occurs around the 7th to 9th day of treatment. This usually responds well to antihistamines and low doses of oral corticosteroids, but if fever and lymph node enlargement occur, the drug should be promptly interrupted. Another significant side effect is polyneuropathy, which is dose-dependent and usually occurs after the 5th week of treatment. Other less frequent side effects include pain and/or tingling in the lower limbs, gastrointestinal disorders (such as nausea, vomiting, and diarrhea), and anorexia (usually much less intense that what are observed with nifurtimox). Significant leukopenia and agranulocytosis are rarely observed, but, in their presence, the treatment should be interrupted.

Immunosuppressive Management

Although there is no consensus on optimal immunosuppression during episodes of infection, the intensity of immunosuppression during acute or reactivation ChD may be evaluated and decreased wherever possible. The reported experience with heart transplantation for chagasic patients has supported the administration of lower doses of corticosteroids, adjusted cyclosporine levels (100–150 ng/ml) from the third month posttransplant, and mycophenolate-sparing regimens to reduce the risk of *T. cruzi* reactivation and rejection episodes [125]. The switch to steroid-sparing immunosuppressive regimens is not necessarily indicated.

Monitoring After Treatment and Criteria of Cure

During treatment of acute or reactivation ChD, direct parasitological tests and PCR assays should be performed at least weekly, and the treatment needs to be continued at least until two negative results are obtained [93]. Timely treatment usually has a good response with rapid decrease of parasitemia, and direct tests generally become negative after the first week of parasiticidal treatment. Afterwards, patients should be followed by clinical and laboratory methods for an indefinite period because there is no consensus for cure [95].

Although the current criteria of "definitive cure" is the persistent negative seroconversion by conventional serological tests after treatment, negative seroconversion after treatment usually takes months to several years (10–25 years) to occur, and persistently positive serology does not reveal therapeutic failure with indication of new course of therapy [25, 95, 126]. A reduction in the anti-*T. cruzi* antibody titers by conventional tests has been proposed as indicative of cure in the setting of persistently negative parasitological tests, although this criteria has not been evaluated in immunocompromised patients [95]. Therefore, treated patients remain at risk of repeated episodes of reactivation despite antitrypanosomal treatment, and parasitological tests should be periodically checked to allow early diagnosis of new episode of reactivation [32, 95]. After treatment, parasitological tests should be monitored weekly during the first 2 months, every 2 weeks through 3–6 months, and annually thereafter or at any time if increase of immunosuppression. Repeated negative parasitological assays are insufficient to ensure cure. However, positive direct parasitological tests and/or progressive increase of qPCR are unequivocal evidence of treatment failure, even in the absence of symptoms, indicating a new course of treatment.

New biomarkers including lytic antibody assays and novel serologic tests, host antigens, cytokine production, lymphocytic phenotype, and metabolic molecules are under investigation for use in clinical practice as surrogate cure [127].

Secondary Prophylaxis

Secondary prophylaxis with benznidazole at a dose of 2.5–5 mg/kg/day, orally, three times per week, is currently considered for coinfected HIV patients after standard treatment of a reactivation episode [44, 49]. There are no evidence so far, however, on the efficacy of secondary prophylaxis with benznidazole for transplant recipients, and it is not currently done for transplant recipients after antitrypanosomal treatment.

Prevention

The strategies toward ChD control have been based to promote access to diagnosis and systematic treatment for target populations, in both endemic and non-endemic countries [25]. Prevention of infection in transplant recipients is based on blood and organ donors ChD screening pre-donation [115]. There is no vaccine available for *T. cruzi* transmission prevention; however, the current knowledge about the natural history of ChD favoring the role of parasite persistence in tissues as the main driving mechanism of pathogenesis rather than the autoimmunity theory has supported the efforts to develop a vaccine [128].

Conclusion

ChD, caused by the parasite *T. cruzi*, is endemic in Latin America, and the disease has been increasingly recognized in areas where it had not traditionally occurred, including Europe and the USA. The parasite causes a serious, potentially life-threatening illness because of its ability to cause damage in host tissue. In the transplant scenario, ChD may be a consequence of acute *T. cruzi* transmission in a negative recipient from a seropositive donor or a reactivation of chronic infection in a seropositive recipient. Transmission of ChD occurs in about 10–20% of the recipients of non-heart graft and in 75% or more of the recipients of heart graft from a chronically infected donor. Reactivation of ChD occurs in about 10–35% of the chronically infected kidney and liver transplant recipients and in up to 90% of heart transplant recipients. Transplantation of the heart and intestine from a *T. cruzi*-infected donor is contraindicated; the use of other organs can be considered, and the decision to accept an organ from an infected donor is a balance between urgency of need for the organ and the acceptance of the risk of possible infection in the recipient. Recipients at risk of acute infection or reactivation should be monitored carefully with clinical and parasitological evaluation during the first 6–24 months posttransplant. Early posttransplant detection of *T. cruzi* parasitemia and treatment of acute infection and reactivation with benznidazole are associated with good outcomes in transplanted recipients.

Key Points

- Chagas disease in transplant patients involves acute infection among negative recipients receiving a graft from positive donors and reactivation episodes among positive recipients due to posttransplant immunosuppression.
- Screening should be performed in donor and recipients who were born or have resided in Chagas disease endemic areas through serological testing.
- Transplantation of the heart and intestine from a chronically *T. cruzi*-infected donor is contraindicated; the use of other organs can be considered.
- If transplantation is performed using organ from a chronically infected donor, *T. cruzi* transmission occurs in about 10–22% of kidney and liver transplant recipients and in 75% or more of heart transplant recipients from chronically infected donors.
- Reactivation of Chagas disease among *T. cruzi*-infected recipients occurs in about 10–20% of the liver and kidney and up to 90% of heart transplant recipients who are chronically infected.
- Prospective monitoring and preemptive antitrypanosomal treatment of subclinical parasitemia of the recipients at risk of transmission or reactivation rather than prophylactic treatment of candidates and recipients are indicated.
- Posttransplant monitoring for acute infection or reactivation relies on preferentially direct parasitological tests (e.g., Strout method) and qPCR of blood specimens routinely for at least 6–24 months.

- A positive result by PCR does not prove reactivation, but an increase in parasitic load measured by real-time qPCR can allow an earlier identification of reactivation parasitemia. Additional specimens and histological samples to detect parasite need to be considered in symptomatic patients.
- Treatment is based on standard courses of benznidazole or nifurtimox.
- After treatment of acute infection or reactivation episode, the patient should restart carefully monitoring with clinical and parasitological evaluation indefinite period because there is no consensus for cure. After treatment, parasitological tests should be monitored weekly during the first 2 months, every 2 weeks through 3–6 months, and annually thereafter or at any time if increase of immunosuppression.

Introduction

Leishmaniasis: A General Overview

Leishmania parasites can cause three different clinical presentations: localized cutaneous leishmaniasis (CL), CL with mucosal involvement (MCL), and systemic visceral leishmaniasis (VL), also called Kala-azar (Hindi for black fever) [1]. In general, the disease presentation varies depending on the species and type of host, although it is possible to have multiple combinations that may result in an atypical presentation.

More than 20 *Leishmania* species are known to be present in different endemic areas. Classically, *L. donovani* and *L. infantum* have visceral involvement; *L. tropica*, *L. aethiopica*, and *L. mexicana* complex cause CL; and *L. (Viannia) braziliensis* complex species are mainly associated with CL and MCL [2].

In a geographical context, *Leishmania* species can be divided into Old World species such as *L. major*, *L. infantum*, and *L. tropica* and New World species such as *L. amazonensis*, *L. infantum*, *L. mexicana*, *L. (V.) naiffi*, *L. (V.) braziliensis*, and *L. guyanensis*. Most Old World species commonly lead to self-limiting ulcers, whereas New World species frequently cause CL and MCL disease (which give rise to partial or total destruction of the mucous membranes of the nose, mouth, and throat) and, more rarely, diffuse and disseminated CL [1]. VL is mainly caused by *L. infantum* or *L donovani*; the parasite infects internal organs, such as the liver, spleen, and bone marrow, resulting in life-threatening diseases [3].

In the general population worldwide, the CL or MCL forms are the most prevalent manifestations of the disease comprising 75% of the total cases. It is estimated that between 600,000 and one million new cases of CL occur globally per year. Approximately 95% of CL cases occur in the Americas, the Mediterranean Basin, the Middle East, and Central Asia. On the other hand, over 90% of MCL cases are found in Bolivia, Brazil, Ethiopia, and Peru. Visceral leishmaniasis, which is considered the most serious form of the disease, is endemic in more than 80 countries and highly endemic on the Indian subcontinent and in East Africa. The global number of cases varies from 200,000 to 400,000 new cases each year, of which 90% are reported from six countries: Brazil, Ethiopia, India, Somalia, South Sudan, and Sudan. Without access to treatment, VL is fatal in more than 95% of cases within 2 years after the onset. These numbers may still be underestimated [3].

As described in several studies, contrasting with the classical presentation, some *Leishmania* species are related to more than one disease form. This occurrence points toward the finding of parasite variants linked to atypical disease manifestations and indicates genes that control disease virulence and tropism [4].

In addition, some more recently published studies have described atypical disease manifestations related to *Leishmania* variants [4–10]. In this regard, the association between *Leishmania* species and clinical outcome is an ongoing investigation, but there is evidence pointing to different parasite genotypes in relation to distinct disease forms [4].

Atypical CL presentations are sometimes difficult to diagnose and treat. A Brazilian study found that *L. braziliensis* genetic traits not commonly identified among parasites from CL are plausible risk factors for the manifestation of atypical leishmaniasis [11]. Occasionally, the precise identification of species is important mainly when the disease does not respond to drugs commonly used but readily responds to other treatment options available [11, 52].

Finally, in immunocompromised hosts, such as organ or hematopoietic stem cell transplant recipients, the number of VL cases reported is greater than that of cutaneous forms, and the reason for this difference remains unclear. Notwithstanding, species usually related to CL and MCL can provoke visceral manifestations, and conversely species usually related to VL can cause cutaneous manifestations [12].

This review of leishmaniasis in transplant candidates and recipients aims to present and discuss the most important issues concerning disease management in the transplant setting. Considering that leishmaniasis is a rare disease in the context of transplantation and that the cutaneous form has been reported even less frequently, the main focus of this manuscript will be visceral leishmaniasis.

Visceral Leishmaniasis in Transplant Candidates and Recipients: Diagnosis and Management

Disease Epidemiology

VL is caused by a protozoan from the genus *Leishmania*, which is usually transmitted to human hosts through the bite of female phlebotomine sand flies. The most important *Leishmania* species related to VL are *Leishmania donovani* and *Leishmania infantum (*syn. *L. chagasi* in Latin America), but species that cause CL (e.g., *Leishmania tropica*) can eventually visceralize, particularly in the immunocompromised host [13].

L. donovani and *L. infantum* belong to the *L. donovani* complex, and while closely related, they present some epidemiological differences. *L. donovani* shows an anthroponotic transmission mode (from human to human), while *L. infantum*, on the other hand, is zoonotic. Likewise, *L. donovani* is found only in the Old World (mainly India and East Africa) and *L. infantum* in the Mediterranean region and Latin America. In nonendemic regions, leishmaniasis cases may reflect travel and immigration patterns [3, 13] (Fig. 1).

The incidence of leishmaniasis in the general population has changed over time and is therefore difficult to estimate. According to the World Health Organization (WHO), 25,000 new cases of VL were reported in 2015, although the underreporting rate may be significant. Available data suggest that the real number of cases ranges from 0.2 to 0.4 million cases each year [2, 14].

In both solid-organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients, VL is an uncommon disease even in endemic areas. Nevertheless, transplant patients, like other immunocompromised individuals, are at an increased risk of developing disease, and presumably the frequency varies according

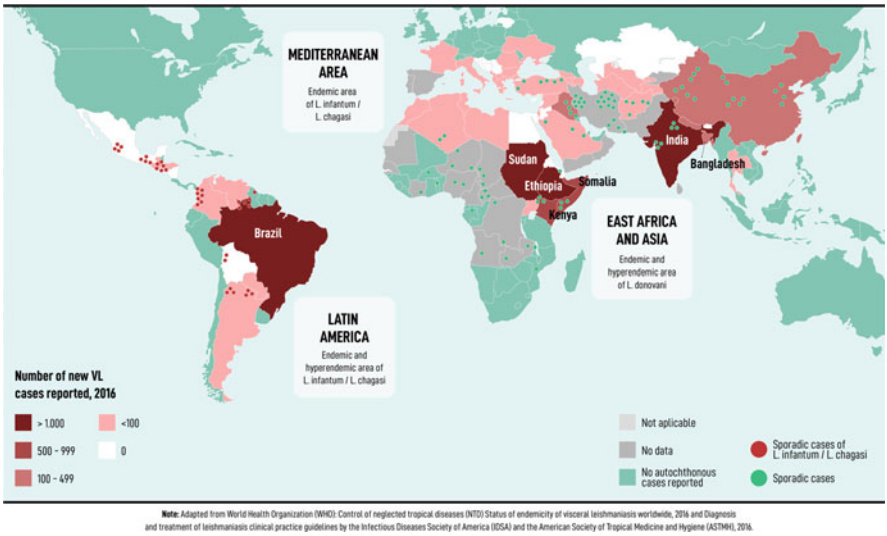

Fig. 1 Visceral leishmaniasis disease endemicity and the geographic distribution of main species

to both the prevalence of VL in the general population and the transplant type. In this scenario, VL can occur after primary infection through a sand fly bite, via transplanted organs, blood products, or consequent to reactivation of a latent infection [15, 16].

Clinical Impact in Transplant (SOT and HSCT)

Typically, VL is characterized by prolonged fever, weight loss, splenomegaly and hepatomegaly, cytopenia, hypergammaglobulinemia, and, less frequently, lymphadenopathy. In contrast, the clinical presentation in SOT recipients can be greatly altered. Fever remains the most common symptom. Unusual manifestations include post-Kala-azar dermal leishmaniasis (PKDL) and gastrointestinal tract manifestations (e.g., digestive bleeding, diarrhea) and can trigger secondary hemophagocytic lymphohistiocytosis, as presented in Table 1 [16–42] and Fig. 2. Although VL predominately affects the organs of the reticuloendothelial system, it can disseminate to other tissues, and cutaneous manifestations can occur before, during, or after VL.

In SOT recipients, the onset of symptoms may occur at any time after transplantation, although the majority of cases are diagnosed in the first 2 years post-transplant. However, this can vary depending on the transplanted organ, earlier after liver transplantation than in kidney transplant recipients, as described by Antinori et al. [43].

There are very few cases of leishmaniasis reported among HSCT recipients [44]. Thus, the limited number of cases precludes further conclusions. A recent review described a series of VL cases in both allogeneic ($N = 9$) and autologous ($N = 2$)

Table 1 Visceral leishmaniasis in transplant recipients: diagnosis, management, and outcome (2009–2018)

Number of cases (SOT or HSCT)	Time after transplant	Country	Clinical manifestation	Diagnosis	Treatment	Mortality	Recurrence	Reference
36 SOT	Median: 11 months	Brazil and Spain	Fever (86%), visceromegaly (81%), and pancytopenia (47%)	Bone marrow microscopy, ~81%; Serology, ~76%	L-AmB (83.3%)	2.8% (1/36)	~26%	Clemente et al. [16]
1 KT and 1 KPT	KT: 2 years KPT: 3 years	Spain	KT: atypical presentation fever + adenopathy; no cytopenia or visceromegaly KPT: fever, pancytopenia, no visceromegaly	Lymph node biopsy and blood PCR	L-AmB (100%)	0	KPT: relapse 3 years after treatment	Sanchez et al. [17]
6 KT and 1 HT	Mean: 1.3 years	Spain	Fever: 6/7 Pancytopenia: 7/7 Splenomegaly: 7/7	Bone marrow microscopy: 7/7 Serology: 3/7	L-AmB (100%)	0	3/7	Carrasco-Antón et al. [18]

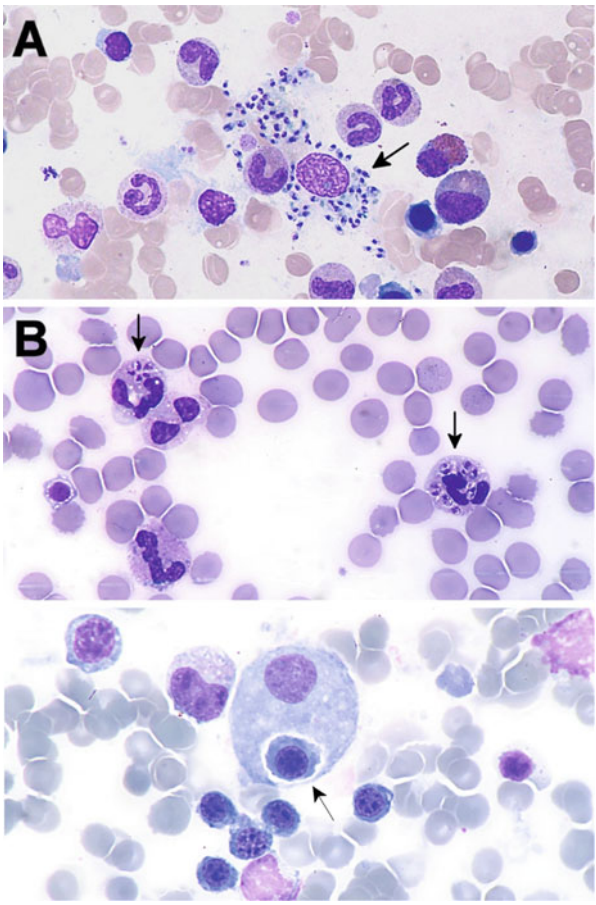

Fig. 2 Peripheral blood and bone marrow aspirate smears. (**a**) Bone marrow aspirate: numerous *Leishmania* amastigotes around the remains of a macrophage. (**b**) Peripheral blood: two neutrophils (arrows) containing phagocytized amastigotes. May-Grünwald-Giemsa stain, original magnification x 800. Hemophagocytosis: one erythroblast engulfed by macrophage (arrow) in bone marrow. Visceral leishmaniasis is one of several conditions that can trigger secondary hemophagocytic lymphohistiocytosis and should be investigate as part of the differential diagnosis in cases presenting with hemophagocytosis. May-Grünwald-Giemsa stain, original magnification x 800

HSCT recipients. The average time of disease onset was 23 weeks (0–240). In this case, relapse was seen in 50% of patients, and the overall mortality was 20% [37].

Reported VL cases in both SOT and HSCT from 2009 to 2018 are presented in Table 1.

Disease Diagnostics and Clinical Evaluation

Diagnostic confirmation is based on the demonstration of *Leishmania* parasites by microscopic examination or culture of sample tissues. A splenic aspirate has the highest sensitivity, exceeding 95%. However, there is a concern about the safety of this procedure, which may lead to life-threatening hemorrhage, particularly if performed by inexperienced personnel. Bone marrow aspirate is considered to be a safer alternative. The sensitivity ranges from 53% to 86% depending on personal expertise. Lymph node aspirates have lower sensitivity (<50%) but may be useful

for patients with lymphadenopathy; however, the frequency of this sign varies in different geographic areas [12, 43, 45]. Peripheral blood smears have poor sensitivity (Fig. 2). In one study [46], thin smear preparations of peripheral whole blood showed sensitivity of only 1.5%. Better results were obtained with buffy coat (19.5%) or peripheral blood mononuclear cell (33.7%) smears. To date, culture isolation of splenic or bone marrow aspirates remains the reference method for parasite identification at the species level. However, culture is time-consuming, is restricted to referral research centers, and has been progressively replaced by molecular techniques [12, 45, 47].

Molecular diagnosis techniques comprise different methods, of which the PCR-based assays are the main molecular tools. Sample sites include the spleen, lymph node, bone marrow aspirates, and peripheral blood [48]. These methods present high sensitivity and specificity with both bone marrow and peripheral blood samples. According to a recent meta-analysis, whole blood PCR presents a sensitivity and specificity of 93.1% and 95.6%, respectively [49]. It is expected that conventional *Leishmania* PCR tests that use blood samples will become negative soon after the beginning of treatment and the reappearance of a positive PCR result can indicate relapse. However, asymptomatically infected individuals may have positive PCR test without any further disease development; thus, a positive PCR result does not always indicate disease [12]. In this regard, quantitative PCR may represent an important tool in early diagnosis and may indicate relapse [50].

Leishmanial antigens can be detected in serum or urine samples with a wide range of sensitivity and specificity. Methods such as the latex agglutination test (KAtex®; urine samples) present good specificity (82–100%) but low to moderate sensitivity (47–95%) [48]. The usefulness of this detection method in the transplant recipient population remains to be determined (Fig. 3).

Serological test sensitivity in SOT recipients appears to be similar to that described for immunocompetent individuals. However, serological assays in HSCT patients generally have a poor diagnostic yield, similar to that observed in HIV/AIDS patients. The most widely used serological techniques are the indirect fluorescent antibody test (IFAT), enzyme-linked immunosorbent assay (ELISA), and rapid tests, such as the immunochromatographic and direct agglutination test (DAT). Sensitivity and specificity vary according to the method, antigens used, and geographical area [12]. A systematic review with meta-analysis showed that rK39, used either in a strip or in ELISA, and the DAT are the best choices for the implementation of rapid and easy VL serodiagnosis [51]. Although rK39 is quite effective in South America and India, its use in East Africa is less satisfactory [45]. Serological limitations include the lack of agreement between methods, the inability to distinguish previous exposure from active infection, and the potential cross-reaction with other protozoa. Diagnosis based on positive serology without confirmation by direct examination should be supported by clinical correlation [12].

As suggested by van Griensven et al. [15] and recommended by a recent guideline from the Infectious Diseases Society of America (IDSA) and the American Society of Tropical Medicine and Hygiene (ASTMH) [52], the diagnostic strategy should be

based on a combination of methods to increase performance, including (when available) microscopy, culture, molecular, and serologic testing (Table 2) [53, 54].

Management

Risk for Donor Transmission

In light of the current knowledge, there are no precise criteria for donor screening or organ deferral [55]. Despite the high prevalence of asymptomatic infection in endemic areas, reaching up to approximately 70% depending on the test used for detection, *Leishmania* transmission through organ grafts has not been conclusively demonstrated [56–58]. A study, performed in Brazil, evaluated the risk of *Leishmania* transmission through blood transfusion. This study followed six previous seronegative patients who received blood components from seropositive donors. Two patients presented seroconversion, and one of them also had a positive PCR after the transfusion of nonleukoreduced packed red blood cells [59]. In this regard, the use of leukodepletion filters (often used with transplant patients) is considered to be an efficient method to reduce the *Leishmania* transmission hazard and may explain the relatively low rates of transfusion-transmitted leishmaniasis (TTL) [60]. According to the Pan American Health Organization (PAHO), blood donors who have had *Leishmania* infections should be permanently deferred [61]. However, compulsory screening for VL in organ donors and the deferral criteria are still not established in current international guidelines, reviews, and protocols, and there is a lack of definitive evidence that serology or molecular methods should be systematically implemented [12, 55, 62].

Table 2 Methods for visceral leishmaniasis laboratory diagnosis

Method	Comments
Direct examination	Bone marrow aspirate sensitivity varies depending on expertise of technician (53–86%) Lymph node aspirates have lower sensitivity (< 50%), and splenic aspirates have the highest sensitivity (>95%) Peripheral blood smear has poor sensitivity, varying with the preparation: peripheral whole blood shows the lowest sensitivity (1.5%) compared with those of buffy coat (19.5%) and peripheral blood mononuclear cell (33.7%) smears
Serology **Should be supported by clinical correlation**	Serological tests in SOT recipients have good performance characteristics (similar to that in immunocompetent individuals). In HSCT patients, serological assays have a poor diagnostic yield (similar to that in individuals with human immunodeficiency virus (HIV)/AIDS) Different serological techniques: indirect fluorescent antibody test (IFAT), enzyme-linked immunosorbent assay (ELISA), and rapid tests (immunochromatographic and direct agglutination test (DAT)) Serology limitations include the potential for lack of agreement between methods, the inability to distinguish previous exposure from active infection, and potential cross-reaction with other protozoa
Molecular diagnosis	Whole blood PCR has a sensitivity and specificity of 93.1% and 95.6%, respectively. However, asymptomatically infected individuals may present a positive PCR test without any further disease development; thus, a positive PCR result does not always indicate disease. Quantitative PCR may represent an important tool in early diagnosis and a tool to monitor relapse
Ag detection	Leishmanial antigens can be detected in serum or urine samples with a wide range of sensitivity and specificity. The usefulness of this detection method in transplant recipient populations remains to be determined

References: [14, 15, 53, 54]
∗If possible, use a combination of methods

For this reason, one should take into consideration that even in areas with a high prevalence of asymptomatic infection, if the screening is considered, the ideal method has not been established. Infection could be recognized by serology or PCR performed on peripheral blood, but these methods may show a poor rate of agreement [56, 60]. The PCR assay presents higher sensitivity and specificity, but nevertheless intermittent parasitemia can lead to a false-negative result. Thus, in the case of a positive serology or antigen test, or if there is a clinical suspicion, a biopsy from liver, spleen, intestine, or skin lesions is recommended [55].

Risk for the Recipient: Infection and Reactivation

Whether an infection remains asymptomatic or progresses toward VL likely results from the complex interaction between genetic susceptibility and the immune response of the host, combined with parasitic, socioeconomic, and demographic

factors. At present, it is not possible to determine among asymptomatic people those who will develop VL disease and when [62–64].

In transplant recipients on immunosuppressive treatment, as well as other immunocompromised hosts, the impaired capability of the immune response to resolve infection allows disease development or reactivation [65]. There is no apparent association between the type of transplant and the risk of developing VL. The number of reported VL cases is greater in kidney transplant recipients than in other organ transplants, but this higher prevalence could be related to the predominance of this type of transplant. Nevertheless, it has been suggested that renal insufficiency and hemodialysis may be factors that contribute to the increased risk [16]. Overall, the major risk factor for VL appears to be related to the prevalence of the disease, as suggested by two studies involving SOT patients from endemic areas [16, 66]. Additionally, in a recent outbreak of leishmaniasis in Spain, the risk of developing VL was 135 times higher in SOT patients than in immunocompetent individuals from the same area [18]. Regarding the immunosuppression (IS) regimen, the risk of VL increases with the use of high-dose steroids [16].

Treatment

VL treatment in transplant recipients requires a systemic approach, and an immunosuppression dose reduction is often advisable. However, such decisions must be made on an individual basis. The choice of therapy depends on various factors, such as patient characteristics (e.g., age, immune status, and renal/liver function), *Leishmania* species, disease extent, drug availability, concomitant infections, and previous treatments.

Currently, liposomal amphotericin B (L-AmB) is considered the drug of choice for VL. The recommended regimen is 4 mg/kg/day IV on days 1–5, 10, 17, 24, 31, and 38 (total dose of 40 mg/kg). Nevertheless, this treatment depends on the patient response, and if necessary, both the dose and duration of treatment may be increased [52]. Other lipid-associated formulations of amphotericin B are less well studied, have not been approved by the FDA for the treatment of VL, and are not generally recommended. Patients who do not respond to initial treatment with L-AmB should be treated with an alternative drug or with a longer course of L-AmB. Higher doses of L-AmB can be applied, but this is usually not necessary. Furthermore, the geographical variability in response to treatment should be considered. Amphotericin resistance has been reported, despite being very uncommon. Notwithstanding, in this situation, pentavalent antimonials or miltefosine might be considered for use alone or in combination, but this has not yet been well studied [52, 67].

Pentavalent antimonials (PAs) have been the first-line drugs for VL in many countries. Overall, they are the second most commonly used drugs for the treatment of VL in transplant patients. These drugs require long courses of administration (up to 30 days). Before treatment, patients should be evaluated for underlying conditions that contraindicate the use of antimonials (such as renal or hepatic insufficiency, arrhythmia, and the use of beta-blockers or antiarrhythmic drugs). Adverse effects include acute pancreatitis, hepatitis, arthropathy, anasarca and oliguria, renal tubular acidosis, bone marrow toxicity and electrocardiographic changes, agranulocytosis, and neurological alterations. Currently, its use is limited in the transplant setting [52, 67].

Miltefosine was approved by the Food and Drug Administration (FDA) for the treatment of leishmaniasis in 2014. It is an oral antileishmanial drug used for the treatment of visceral, mucosal, and cutaneous leishmaniasis. Miltefosine is likely to interact with membrane lipids, inhibit cytochrome c oxidase (mitochondrial function), and cause an apoptosis-like cell response. The drug is administered at 50–100 mg/day for 28 days to treat VL caused by *L. donovani* (for patients over 12 years of age, who weigh at least 30 kg and are not pregnant or breastfeeding, as miltefosine is considered to be teratogenic). Gastrointestinal disorders such as vomiting and diarrhea associated with hepatotoxicity and thrombocytopenia can be seen. There are differences in the therapeutic response based on geographical area and the *Leishmania* species involved; in addition, the evidence for the use of miltefosine for VL caused by *L. infantum* is scarce, and the drug may not be useful for monotherapy in this situation. Some studies have described the development of resistance in India, Bangladesh, and Nepal. Despite the reports of treatment failure, especially for *L. infantum* infection, miltefosine could perhaps become a good option in the future for use in combined alternative therapy or for secondary prophylaxis [52, 67–70] (Table 3).

Secondary Prophylaxis and Follow-Up

The IDSA guidelines do not recommend secondary prophylaxis for initial management in non-HIV immunocompromised patients who have not manifested a relapse (weak, low) [52]. However, the relapse rate can be high, as observed in a series of 36 SOT cases that showed a relapse rate of ~26%. In this study, secondary prophylaxis was provided to 12 patients (34.3%). Relapse was observed in 1 (8.3%) of the 12 patients receiving prophylaxis and in 8 (34.8%) of the 23 patients not receiving prophylaxis (p 0.19, Fisher's exact test). In this series, secondary prophylaxis prevented relapse, but despite decreasing the number of relapse cases, the effect was not statistically significant. This lack of significance may be related to the limited number of patients studied. Moreover, different prophylaxis schemes have been used [67]. Thus, even if secondary prophylaxis is recommended, there is no consensus about the drug or scheme. In the case of secondary prophylaxis, periodic doses of parenteral L-AmB (3–5 mg/kg every 3–4 weeks) are usually prescribed; antimonials and pentamidine are other options [16].

Miltefosine may be a promising drug, but experience with its therapeutic use is limited [67]. As of yet, this issue remains unresolved due to a lack of research [16]. Furthermore, it is possible that patients who have already had recurrence should be under close surveillance or may need suppressive treatment. In this situation, it is reasonable to extend therapy or maintain the patient on secondary prophylaxis for longer periods (3–6 months). In addition, relapse can be related to the intensity of immunosuppression rather than drug failure (if L-AmB is used for primary treatment) [67].

The curative criteria of VL are essentially clinical, and with a favorable clinical evolution, parasitological control is dispensable. The first signs of response are usually nonspecific, such as improvements in appetite and general condition. Frequently, the disappearance of fever occurs between the second and fifth days of

Table 3 Current visceral leishmaniasis treatment in SOT and HSCT recipients

Drug	Mechanism of action	Route of administration	Recommended dosage	Comments
Liposomal amphotericin B (L-AmB)	Alters the parasite's membrane permeability	Intravenous	4 mg/kg/day on days 1 through 5 and 10, 17, 24, 31, and 38 If initial treatment fails, an alternative drug or a longer course of L-AmB should be used	Treatment of choice for VL Amphotericin B lipid complex bioequivalence with L-AmB has not been established
Pentavalent antimonials	Impair cellular energetics and nucleosynthesis	Intravenous (preferred) or intramuscular	[a]20 mg pentavalent antimony/kg/day for 28 days	Severe cardiotoxicity, nephrotoxicity, pancreatitis, and hepatotoxicity Compliance issues (length of treatment and painful intramuscular administration)
Miltefosine	Interacts with lipids (phospholipids and sterols)	Oral	2–2.5 mg/kg/day for 28 days; doses >150 mg/day have not been studied	High cure rates for VL caused by *L. donovani*, not as effective for *L. infantum* Teratogenic: cannot be administered to pregnant or breastfeeding women

References: [67–71]

treatment. Hematological parameters improve after the second week. Weight gain and reduced spleen and liver volume can be seen in the first few weeks, although full regression may take a few months. The process of serum protein normalization occurs slowly and may last for months [67].

Ideally, patients should receive lifelong monitoring, at least for a minimum of 1 year after treatment or until the recovery of the immune response. If there is a clinical suspicion of relapse, this must be confirmed by parasitological methods [52].

Leishmaniasis outcome among transplant recipients depends on early diagnosis and treatment. If left untreated, the disease is fatal, with death being caused by intercurrent infections or bleeding. In a series published in 2008 among 68 transplant patients, death occurred in 22% of the patients, 5 of whom had not received any antileishmanial treatment, and the diagnosis was obtained postmortem [43]. More

recent publications show a lower mortality rate in SOT recipients than that observed in previous studies, likely as a result of accumulated experience.

Conclusion

Visceral leishmaniasis in transplant recipients (SOT and HSCT) is uncommon even in endemic areas, which partially explains the lack of randomized studies that might evaluate treatment and prophylaxis strategies. To date, the current knowledge is based on a few studies, on extrapolations from investigations conducted in the general population or in other immunocompromised conditions, and on expert opinions. Patients usually present with fever and/or cytopenia, and disease should be considered in the differential diagnosis. Visceral leishmaniasis can occur after primary infection through a sand fly bite, via transplanted organs and blood products, or as a consequence of reactivation of a latent infection. At present, diagnostic confirmation is based on the demonstration of *Leishmania* parasites. However, the preferable diagnostic strategy should be based on a combination of methods to increase performance, including molecular and serologic testing when available. L-AmB is still the best choice for treatment and prophylaxis.

Key Points

- Transmission through organ grafts has not been conclusively demonstrated, and there are relatively low rates of transfusion-transmitted leishmaniasis. Despite the potential risk, the best policy for screening and deferral of organs remains unclear.
- The disease presentation can be atypical. In visceral leishmaniasis (VL), fever and cytopenia are the most common symptoms.
- A combination of diagnostic methods is the best approach for investigation.
- L-AmB is the drug of choice and is typically effective and well tolerated.
- Secondary prophylaxis may prevent relapse, but this issue remains unresolved.
- Patients should be monitored for at least 1 year after treatment or until recovery of the immune response.
- If there is a clinical suspicion of relapse, this status must be confirmed by parasitological methods.

Cutaneous Leishmaniasis in Transplant Candidates and Recipients: Diagnosis and Management

Disease Epidemiology

Cutaneous leishmaniasis (CL) is the most common leishmanial syndrome in the general population and presents a worldwide distribution. However, 70–75% of the estimated global incidence is accounted for ten countries, including Brazil,

Colombia, North Sudan, Iran, Afghanistan, Algeria, Syria, Ethiopia, Costa Rica, and Peru. In addition, nearly 90% of MCL cases occur in Bolivia, Brazil, and Peru [3].

The disease usually occurs in people from endemic areas but can affect others, such as travelers, tourists, workers, and military troops, who may also inadvertently carry the disease to nonendemic areas. Anthroponotic CL (in which a disease-causing agent carried by humans is transferred to other animals, here with humans as the major reservoir) is mainly related to *L tropica*, which has a common cluster distribution in urban and peri-urban areas. Typically, in this situation, CL is characterized by large outbreaks, especially in war and conflict zones, in refugee camps, and in settings where there is a large-scale population migration [3].

In the immunocompetent patient, the initial clinical sign of CL is the appearance of small papules and an erythematous nodule, which may be single or multiple, usually located in an exposed region of the skin and progressing to ulcers after a few months. Commonly, the skin lesions have an erythematous base, which is infiltrated and firm in consistency; well-defined, high edges; a reddish background; and coarse granules. The skin lesions of CL are usually painless and chronic and with spontaneous healing as cell-mediated immunity develops as per the usual natural history, accelerated by antileishmanial therapy [1, 52].

Although CL is a self-limited disease, in some cases, it may be severe and lead to mucosal disease or disseminated leishmaniasis. Cutaneous infections caused by *Leishmania* (*Viannia* [*V.*]) *braziliensis* and related species in *Viannia* subgenus, and, less frequently, *L. amazonensis*, in a minority of cases, are associated with concomitant or late MCL, which can cause destructive lesions of the naso-oropharyngeal/laryngeal mucosa [52].

Another form of leishmaniasis with cutaneous presentation is post-Kala-azar dermal leishmaniasis (PKDL). PKDL is a complication of VL related to *Leishmania donovani*, occurring predominantly in Africa and Asia. Typical lesions (hypopigmented or hyperpigmented macules more frequently) present with a perioral distribution, and unlike CL, the lesions are not "volcanic" in shape. They usually appear 0–6 months after VL in Sudan and 2–3 years after VL in India. This form may be neglected and easily misdiagnosed for other skin conditions, and patient history should be reviewed for a prior history of VL [3] (Table 4).

In general, atypical skin lesions may include erythematous volcanic ulcers; diffuse, eczematous, lupoid, verrucous, dry, zosteriform, and nodular lesions; or erysipeloid, sporotrichoid, annular (resembling a ringworm infection), paronychial, palmoplantar, genital chancriform, and psoriatic forms. Leishmaniasis recidivans, characterized by small nodules that develop around a healed scar, has also been reported [72–74].

Clinical Impact in Transplants (SOT and HSCT)

CL or MCL, in addition to being the most common leishmanial syndrome worldwide, is rarely reported in SOT or HSCT recipients [12, 14, 44].

The clinical presentation of CL in immunocompromised patients will often be like that in immunocompetent individuals, and atypical features include parasite

Table 4 Species related to cutaneous leishmaniasis: geographical distribution and clinical manifestations

Species	Geographical region	Clinical manifestations
Old World		
L. aethiopica	Ethiopia, Kenya, Uganda	CL and diffuse forms
L. major	India, Pakistan, Turkey, Middle East, Central Southwest Asia	CL
L. tropica	India, Pakistan, Turkey, Greece, Middle East, Central Southwest Asia, North Africa	CL and VL
L. infantum	Mediterranean, North and sub-Saharan Africa, Balkans, China	VL and localized cutaneous lesions
L. donovani	India, Pakistan, China, North Africa	VL, PKDL, and CL
New World

dissemination with multiple lesions, clinical polymorphism, and visceralization, including in species where dissemination is unlikely to happen. Patients should be evaluated to exclude systemic impairment. Nonhealing skin lesions in patients with history of travel to an endemic region should arise suspicion. Whenever possible, treatment should be based on the species identification, as the treatment varies by parasite species [12], as in Table 5 [87, 95–98].

Disease Diagnostics and Clinical Evaluation

The best diagnostic approach in CL, MCL, and PKLD is the demonstration of the parasite through microscopy or molecular methods. As the clinical spectrum of CL varies and the list of differential diagnoses is long, a biopsy of lesions should be performed to demonstrate the presence of parasites. Biopsy samples should be

[98]

collected based on the type of exam that will be performed, for example, PCR or histology. In CL, *Leishmania* parasites, being quite superficial, are found in the epidermis and upper levels of the dermis. In ulcerative lesions, parasites are more concentrated at the base, although there is more tissue destruction in this location. Given these factors, for PCR and culture, the collection site should be at the base of the ulcer, but for histology, the indurated border of the lesion is recommended [54, 75].

Species identification is valuable, as multiple species can coexist in each area, and the choice of treatment and patient response are species dependent. Thus, parasite isolation through culture is usually required. However, the cultures are not highly sensitive, may be contaminated with skin flora, and may be slow, and the organisms may be nonviable, limiting the use of cultures in clinical practice [1, 75]. Given the low sensitivity of parasite culture, PCR can be particularly useful since it allows species identification [1, 76, 77]. However, there is great variability in the gene targets, performance characteristics, and methods/protocols, as well as a lack of commercial availability that currently limits the routine use of molecular testing for species identification. Recently, a *Leishmania* protein detected by matrix-assisted laser desorption ionization (MALDI) time of flight (TOF) has been used for species identification, which is fast and has lower cost [75], although a positive culture is required.

Histopathological findings depend on the stage of development of the lesion, the species of *Leishmania*, the host response, and the degree of cellular immunity. Immunohistochemical examination is useful as a supplementary tool but presents limitations related to inadequate selection sites for tissue sampling and cross-reactions with other protozoa [78–81]. The Montenegro skin test has limited diagnostic utility considering false positives, as positive results may be obtained in patients without active or cicatricial lesions; furthermore, the test can result in false negatives, especially in the context of anergy [82]. In CL, serological testing is not reliable because infection provokes a poor humoral response, which results in low sensitivity by this method.

Management

The treatment of CL (CL, MCL, and PKDL) for SOT and HSCT patients is not standardized. In general, treatment decisions must be made on an individual basis, and active drugs include amphotericin B, PAs, fluconazole, miltefosine, pentamidine, and paromomycin [15, 54, 62, 83–88]. Topical treatment (cryotherapy, thermotherapy, intralesional antimonials) or surgical excision has been advocated in cases involving a limited number of small lesions. However, taking into account the risk of visceralization, systemic treatment is usually prescribed for transplant patients, and immunosuppressive dose reduction has been recommended [12, 54, 62]. Most reported cases have been successfully treated with a lipid formulation of amphotericin or antimonials.

L-AmB is used for the treatment of CL, extrapolating the efficacy for VL treatment [75]. The majority of studies conducted in the general population

L-AmB demonstrated an overall efficacy of nearly 80–85% [89–92]. Therefore, in transplant patients, L-AmB is still the systemic treatment of choice. It is worth mentioning that patients with cutaneous or mucocutaneous lesions can present with visceral involvement. However, data does not allow further strong evidence-based recommendations.

The second most commonly used drug for CL treatment, including in transplant patients, is an antimonial. However, although antimonial formulations, such as sodium stibogluconate (Pentostam®) and meglumine antimoniate (Glucantime®), are considered the gold standard for the treatment of leishmaniasis for immunocompetent individuals in some countries, they have limitations and substantial toxicity [67, 72].

Miltefosine is an FDA-approved oral option for the treatment of CL due to several *Viannia* subgenera. The susceptibility of cutaneous *Leishmania* species to miltefosine is lower than that of *L. donovani*, and this variable efficacy is related not only to *Leishmania* species but also to geographical heterogeneity within the same species. The treatment of *L. (V.) braziliensis* has varied by geographic region, and the usefulness of this drug has yet to be defined [54, 75]. A recent meta-analysis evaluated the cure rate after miltefosine treatment (>4 weeks) in 324 PKDL patients from South Asia. The results showed an estimated 90% cure rate 1 year after treatment, although nearly 20% of the PKDL patients suffered from side effects. Miltefosine was effective, although its efficacy has been observed to decline. Based on the limited data, longer treatment regimens with miltefosine are not proven to be safe [93]. To date, no trials in transplant recipients have been published, but in a recent small cohort, miltefosine was used in six SOT patients (five kidney transplants and one lung transplant) with VL after previous relapse with L-AmB. In this study, all patients had VL due to *L. infantum*, but one patient also presented with mucocutaneous lesions that responded to miltefosine [94].

Conclusion

CL and MCL in transplant recipients (SOT and HSCT) are a very rare event, and the scarcity of studies and data does not allow further strong evidence-based conclusions. Transplant clinicians should nonetheless be aware of this significant pathogen, which could be transmissed from either the organ donor, blood donor, or stem cell graft donor or be a de novo or reactivation infection in the recipient. At present, diagnostic confirmation is based on the demonstration of *Leishmania* parasites, and species identification should be attempted. Treatment is relatively effective, although may also bring significant toxicity.

Key Points

- Leishmaniasis is a rare disease in both SOT and HSCT, and cutaneous forms are even less frequent.

- Species usually related to CL and MCL in transplant patients can provoke visceral manifestations, and conversely species usually related to VL can cause cutaneous manifestations.
- Biopsy of lesions should always be performed, and species identification must be pursued. If microscopy is negative, PCR could be used, as it has the advantage of species identification.
- Treatment decisions must be made on an individual basis, but liposomal amphotericin (L-AmB) is usually recommended as the treatment of choice.

Introduction

The majority of human malaria cases are caused by four species of *Plasmodium*: *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. *P. knowlesi* also causes disease, although is considered principally a zoonotic malaria. Malaria occurs in tropical and subtropical areas, at altitudes below 1500 m, coinciding with the geographical distribution of the mosquito vector (various species of *Anopheles*). *P. falciparum* is the predominant species worldwide and is distributed mainly in areas of Africa, Southeast Asia, India, South America, and the Caribbean. *P. vivax* is distributed mainly in

Central America, South America, Asia, and the Middle East, while *P. ovale* occurs mainly in West Africa. *P. malariae* is widely distributed in tropical areas worldwide but is less prevalent. *P. knowlesi* is currently limited to areas of Southeast Asia.

Plasmodium species have two main phases in their life cycle: an asexual replicative phase in humans and a phase of sexual replication in the mosquito. The malaria-infected female mosquito inoculates sporozoites during a blood meal. The latter infect hepatocytes and then mature into schizonts which rupture to release merozoites. In the case of *P. vivax* and *P. ovale*, a proportion (hypnozoites) remain dormant inside the hepatocytes, and these forms would be responsible for future relapses.

Symptoms and signs are caused by the asexual erythrocytic stage of *Plasmodium* which involves the invasion of red blood cells by merozoites and replication over 2–3 days, and trophozoites mature into schizonts which rupture with reinvasion of normal erythrocytes by merozoites. Some parasites differentiate into gametocytes (sexual erythrocytic stages), which may be ingested by an Anopheles mosquito, thus completing the life cycle [1].

Increases in travel and migration have contributed to the global emergence of certain geographically restricted parasitic diseases such as malaria. Those at risk for acquiring malaria are people living or traveling in a geographical area where locally acquired malaria cases have occurred in the past 3 years. Special groups at risk include those travelers living in western countries that visit their friends and relatives (VFRs) in endemic areas. Travelers and migrants may import a variety of pathogens, but dissemination in non-endemic areas is usually limited as environmental conditions may be unfavorable and intermediate hosts and vectors may not be present. However, migrants with subclinical malaria may remain asymptomatic up to several years after arrival in the host country [2].

In the context of transplantation, malaria infections may occur as a consequence of a donor-derived infection (transfusion or transplant associated), a relapse of previous *P. vivax* or *P. ovale* infection if the recipient has traveled or lived in endemic areas, or due to newly acquired infection in endemic areas posttransplantation [3]. There is no evidence that the prevalence of arthropod-borne diseases is more common in immunocompromised hosts than in other groups of travelers. Malaria incidence is not increased in immunocompromised patients compared to the healthy population living in endemic areas [4].

See Box 1 for definitions according to the WHO malaria terminology [5].

Clinical Impact

Posttransplant malaria is a rare event, even in endemic areas. One reason may be that areas with greater malaria risk may not have the resources to support large transplant programs [6]. Donor-derived transmission of geographically restricted infections appears to be rare and has been estimated to occur in less than 1% of all transplant procedures [7, 8]; malaria would comprise only a small amount of that.

The incubation period (period between inoculation of malaria parasites and onset of clinical symptoms) ranges from 7 days for *P. falciparum* to 23 days for *P. malariae* malaria. The long incubation period for *P. vivax* and *P. ovale* malaria, from 3 weeks to 1 year, and rarely many years, is due to activation of hypnozoites. Clinicians must bear in mind that the incubation period may be much shorter (depending on the inoculum) in induced infections (produced through transfusion or transplantation from an infected donor). Hypnozoites only develop in vector-borne disease and are not produced in induced *P. vivax or P. ovale* malaria cases although relapses are possible if the liver from a donor infected with these species is transplanted.

Posttransplant malaria can be an insidious disease without the typical periodicity of fever and may be difficult to diagnose if there is no clinical suspicion. A high blood parasitemia, associated with an increased risk of severe malaria (malaria with signs of severe illness and/or evidence of vital organ dysfunction), has been reported in immunosuppressed patients. Severe malaria in SOT patients is mainly produced by *P. falciparum* malaria, but *P. vivax* may result in severe cases [9]. Risk of complicated malaria is significantly higher in patients over the age of 60 years than in younger patients. Respiratory distress with the need for mechanical ventilation is significantly associated with the risk of death [10]. Malaria appears to be associated with more severe outcomes in immunocompromised patients compared with the general population. Severe malaria associated with unfavorable outcomes and increased mortality in SOT recipients has been reported. Malaria can also be more severe in splenectomized patients due to the lack of clearance of intra-erythrocytic parasites. Other concomitant infections may also hamper the outcome [11–13].

Donor-Derived Malaria and Solid Organ Transplantation

Around 50 cases of donor-derived malaria post-solid organ transplantation (SOT) have been published, the majority in renal transplant recipients [8], although in some of the cases, transmission through infected blood products could not be excluded [6]. Transmission from donor products, tissues, or organs (due to infected red blood cells within the transplanted organ or *P. vivax*/*P. ovale* hypnozoites with liver transplantation) may occur, as *Plasmodium* spp. can survive at 4 °C for several days and cold preservation does not necessarily prevent transmission [14].

The first cases of possible donor-derived malaria were reported in the late 1970s/early 1980s [15–17], and the first case of donor-derived multiorgan transmission of malaria was reported in 1985 [18]. At least eight reports of multiorgan transmission of malaria have been published [11, 18–23]. Although rare cases of hospital-acquired malaria may occur, in these reports donor-to-host transmission via the graft may be considered confirmed [24]. Data from these cases are summarized in Table 1. Of note, initial screening of the donors prior to organ procurement was not done or was negative using microscopy in some instances. In some cases, transmission was only documented in some of the recipients, and other organ

Table 1 Cases of donor-derived organ transplant transmission of malaria. Adapted from [23]

Author (year, country of diagnosis) Donor's country of origin/travel *Plasmodium* species Malaria screening in donor	Organ transplant type	Presentation (days posttransplantation) Diagnosis Treatment Outcome
Holzer et al., 1985 (Switzerland) Zaire (recent immigration) *P. vivax* Blood smears negative	Renal transplant	Fever on day 9 Blood smears positive on day 25 Chloroquine Follow-up smears negative (persistent fever due to CMV) Outcome not specified
	Renal transplant	Fever on day 16 Blood smears positive on day 25 Chloroquine Favorable outcome
Babinet et al., 1991 (France) Cameroon (recent immigration) *P. falciparum* Retrospectively: positive serology and antigen	Heart transplant	Fever on day 12 Blood smears positive on day 18 Quinine Died on day 22
	Renal transplant	Died on day 45 due to CMV Retrospectively: weakly positive antigen on day 30
Fischer et al., 1999 (Germany) Cameroon (recent immigration) *P. vivax* Retrospectively: positive serology	Liver transplant	Fever on day 28 Blood smears positive Chloroquine + primaquine Died after 6 months due to progressive liver failure
	Renal transplant	Fever on day 42 Blood smears positive Mefloquine Favorable outcome
	Heart transplant	Asymptomatic Positive serology No treatment Favorable outcome
Chiche et al., 2003 (France) France (recent travel to Togo) *P. falciparum* Retrospectively: positive blood smear and serology	Liver transplant	Fever, coma, cholestasis on day 8 Blood smears positive Quinine + doxycycline Favorable outcome
	Heart transplant	Fever, low consciousness, acute renal failure on day 5 Blood smears positive Treatment not specified Died due to multiorgan failure on day 17
	Renal transplant	Asymptomatic Blood smear positive Treatment not specified Favorable outcome

(continued)

Table 1 (continued)

Author (year, country of diagnosis) Donor's country of origin/travel *Plasmodium* species Malaria screening in donor	Organ transplant type	Presentation (days posttransplantation) Diagnosis Treatment Outcome
Menichetti et al., 2006 (Italy) Ghana (recent travel to Ghana) *P. falciparum* Screening not done	Liver transplant	Fever on day 3 Blood smears positive on day 30 Quinine + doxycycline Favorable outcome
	Renal transplant	Asymptomatic Blood smear positive Mefloquine Favorable outcome
Rodríguez et al., 2007 (Spain) Bolivia (recent immigration from Colombia, treated for malaria 3 years previously) *P. vivax* Thick blood smear negative	Liver transplant	Fever on day 21 Blood smear positive Chloroquine + primaquine Relapse 2 months after treatment successfully treated with chloroquine + double dose primaquine
	Heart transplant	Asymptomatic Blood smear positive Treatment not specified Favorable outcome
	Renal transplant	Asymptomatic Blood smear positive Treatment not specified Favorable outcome
Sabé et al., 2014 (Spain) Mali (recent immigration) *P. falciparum* Blood smears negative Retrospectively: positive serology	Heart transplant	Fever, anemia on day 15 Blood smears positive Quinine + doxycycline changed to artesunate + atovaquone-proguanil Favorable outcome
	Lung transplant	Fever (day not specified) Blood smears positive Quinine + doxycycline Favorable outcome
	Liver transplant	Asymptomatic Positive antigen, blood smears negative Quinine + doxycycline Favorable outcome
Martín-Dávila et al., 2018 (Spain) Equatorial Guinea (recent travel to Equatorial Guinea) *P. malariae* + *P. ovale* Blood smears and rapid diagnostic test negative	Renal transplant	Fever, thrombocytopenia on day 30 Blood smears positive. Rapid diagnostic test negative PCR positive for *P. malariae* + *P. ovale curtisi* Chloroquine Favorable outcome
	Liver transplant	Asymptomatic Blood smears negative Rapid diagnostic test negative PCR positive for *P. malariae* + *P. ovale curtisi* Chloroquine + primaquine Favorable outcome

recipients were apparently not infected and/or received preemptive therapy. Based on previously published cases, the prognosis of posttransplant malaria appears to depend on the type of organ transplanted, the species of *Plasmodium* involved (*P. falciparum* being associated with more severe disease), the immunosuppressive therapy used, and the delay in diagnosis and initiation of adequate antimalarial treatment in the recipient [8].

Malaria and Hematopoietic Stem Cell Transplantation (HSCT)

A retrospective observational survey reported that more than one million of HSCT were performed by transplant centers from 75 countries over five continents. The numbers of HSCT differed by WHO region [25]. Worldwide, more than 70,000 hematopoietic stem cell transplants (HSCTs) are performed each year. Allogeneic bone marrow transplantation (allo-BMT) and allogeneic stem cell transplantation (allo-HSCT) are being increasingly used in countries where malaria is endemic [26–28]. In the setting of HSCT, malaria transmission may occur by natural exposure to infected mosquitoes or as a transmitted disease through contaminated blood products or grafts.

Malaria is an unusual complication after HSCT in non-endemic countries. Few cases of malaria infection in HSCT have been reported, and only approximately ten cases have been published in the medical literature [29–38] **(**Table 2**)**. The first case was reported in 1986 by Dharmasena et al. [29], a case of *P. falciparum* infection during a related allogenic bone marrow transplant in a Nigerian patient. The diagnosis was made on day 6 after transplant, but the patient died before treatment could be administered. Malaria infection was due to *Plasmodium falciparum* in seven cases and *P. vivax* in three cases. Only one case was an autologous BMT; the other cases were allogeneic HSCT (one case unrelated donor, eight cases related donors). The mode of acquisition was donor-derived in six cases, two cases were related with blood transfusions, and two other cases were considered recurrences of previous malaria episodes in the recipients. The median time to symptoms was 10.5 days after transplantation (6–70 days), and the median time to microbiological diagnosis was 14.5 days (6–70 days).

All the donor-derived cases in HLA-matched related allogenic HSCT [5] occurred in recipients born in malaria-endemic areas (Africa, four cases; Asia, one case). Screening for malaria infection in donors was performed with blood smears, and all were negative before stem cell harvesting. A donor-derived *Plasmodium vivax* infection occurred following unrelated bone marrow transplantation; the donor had documented *P. vivax* infection during a travel to Papua New Guinea, was treated, and was asymptomatic 11 months before marrow harvesting [33]. Transfusion-related malaria occurred in two cases, both from Tunisia, a country with no malaria transmission; the authors highlighted the importance of implementing policies for safe blood transfusions [36, 39]. All the cases were treated and cured, except for the first one reported. No recurrences were described after malaria treatment.

Table 2 Published cases of donor-derived malaria in HSCT patients [29–38]

Author, year (country of diagnosis). Reference number *Plasmodium* species	Type of BMT	Donor data Gender, age in years Relationship recipient Country of origin previous malaria infection/screening	Recipient data Gender, age Country of origin Hematology disease Conditioning regimen Previous malaria infection/ screening	Clinical presentation Malaria diagnosis Treatment Outcome	Mode of acquisition
Dharmasena, 1986 UK *P. falciparum*	Related Allo-BMT	Nigeria. Male (brother) Thin and thick blood films negative pretransplant	Female, 27 y-o Nigeria Living in the UK during 5 years Aplastic anemia Visited Nigeria 2 years before BMT Prophylaxis with proguanil chloroquine after travel No malaria screening previous to BMT Needed 2 BMT infusion due to graft failure	Loin pain and hemoglobinuria (after infusion) Graft failure (+26) Reinfused (+29) 2ndTX Fever (day +6) Blood films positive *P. falciparum* No treatment Death	Transplant-related (donor acquired)
Lefrere et al., 1996 France *P. falciparum*	Related allo-BMT	Comorian Islands Male (brother) Living in endemic area until 2 months before BMT Positive malaria serology Previous episodes of acute	Female, 30 y-o Comorian Islands AML Transfused 3 months before Blood smears negative previous to BMT	Fever (day +6) Blood smears + (day +12) (parasitemia 12.5%) Quinine (3d) + halofantrine Parasitemia cleared 3 d Symptoms free 1 y after BMT	Transplant-related (donor acquired)

Mejia et al., 2012 *US* *P. falciparum*	Related Allo-PBSCT	Male (brother) Sierra Leone In the US 3 months prior to donation Thick smears x3 negative pre-transplant Day +17: PCR and PfHRP2 + for *P. falciparum* Atovaquone/proguanil (3 d)	Female, 25 y-o Sierra Leone Sickle cells anemia In US >2 years Conditioning regimen: Alemtuzumab, TBI, sirolimus 5 U ∗RBC exchange, 2 ∗RBC transfusions (∗antimalarial antibodies negative)	Day +13. Routine peripheral blood smear, positive for *P. falciparum* (intracellular parasites (3.5% parasitemia). PCR + for *P. falciparum.* Atovaquone + proguanil (7d) Parasitemia cleared day +3	Transplant-related (donor acquired). ∗Blood donors: antimalarial antibodies negative
Ladeb S. et al., 2018 Tunisia *P. falciparum*	Related allo- BMT	Male. 30 y-o Brother BM negative for malaria	Male, 27 y-o Aplastic anemia Conditioning regimen: ATGAM, CY	Febrile neutropenia, hemolytic anemia, hemophagocytic syndrome (day +12) +26: thick blood film smears (parasitemia 20%) Quinine (20 doses) Fever vanished +28 Parasitemia cleared 3 d FU 1 year after BMT	Transfusion-related (*Plasmodium* PCR + in blood from donor native of endemic area)

ALL acute lymphocytic leukemia, *allo-BMT* allogenic bone marrow transplant, *auto-BMT* autologous bone marrow transplant, *BM* bone marrow, *BMT* bone marrow transplantation, *Bu* busulfan, *CML* chronic myelogenous leukemia, *CY* cyclophosphamide, *FU* follow-up, *MDS* myelodysplastic syndrome; *PCR* polymerase chain reaction, *TBI* total body irradiation, *2ME* 2-mercaptoethanol, *PBSCT* peripheral blood stem cell transplantation, *PfHRP2 P. falciparum* histidine-rich protein 2, *Ph* + Philadelphia chromosome positive, *RBC* red blood cells

Screening and Diagnosis

Diagnosis of malaria is based on microscopy (examination of thick and thin blood films) as the gold standard. If an initial blood smear is negative and the clinical suspicion is high, these should be repeated every 12–24 h on at least three occasions. As an adjunct to diagnosis, rapid diagnostic tests (RDTs) based on the detection of circulating *Plasmodium* antigens may be used. RDTs may detect one or more antigens, depending on the test, such as the histidine-rich protein 2 (HRP-2) which is specific for *P. falciparum*, parasite lactate dehydrogenase (pLDH), or aldolase. Antigenic tests may remain positive more than 1 month after successful treatment as clearance of antigens from the blood stream is slow. False-negative results may occur if parasitemia is very low or very high (prozone effect). In recent years, there have been numerous cases reporting false-negative RDT results linked to an antigenic variant form of *P. falciparum* HRP-2 [40]. PCR-based methods are highly sensitive and specific (with theoretical limits of detection of 0.0002–1 parasites/uL compared with 5–16 parasites/uL by microscopy) and appear to be more sensitive for the detection of mixed parasitemia [41]. PCR results will not generally be available on the same day in the majority of transplant centers, but these may allow early detection of subclinical malaria in donor-derived transmission and will aid in the correct identification of mixed infections with *P. ovale* or *P. vivax* which may need radical treatment of hypnozoites (see section "Treatment" below).

Malaria is recognized as the most significant transfusion-transmitted disease agent worldwide [42, 43] . The high requirements of blood transfusions before and after HSCT mean that the screening of *Plasmodium* infection in blood products must be thorough and utilize the most sensitive techniques. Depending on the risk of malaria infection (endemic or non-endemic areas), hemovigilance methods are defined by each country through their national regulation agencies and safety policies to avoid transfusion-transmitted malaria [44]. Non-endemic countries use several ways to prevent transfusion-malaria transmission, some with questionnaires, excluding or deferring donors who have had malaria, or resided in, or traveled to malarial areas. Other countries check malaria serology to detect malaria antibodies in the donated blood products; this confirms prior donor exposure and may be useful in more endemic regions, but does not specify whether the donor has active disease [45]. In malaria-endemic countries, transplant candidates, recipients, and donors frequently report previous episodes of malaria. Also, blood donors could been exposed to malaria infection many times. Serology-based screening is not useful in this context.

Considering the possibility of malaria transmission as reported here, the monitoring of donors and/or HSCT recipients from endemic areas by both microscopy and molecular tests may represent a safer strategy to prevent graft-transmitted malaria [46, 47].

In non-endemic countries, sensitive techniques like PCR-based tests in addition to malaria serology and peripheral blood and bone marrow smears must be applied to blood and grafts from HSCT donors and candidates with epidemiological risk of *Plasmodium* infection [48]. Molecular techniques could detect asymptomatic, mixed, and low parasitemias [46].

In case of unrelated donors, a detailed travel history and malaria screening in those at risk of malaria infection should be performed also using sensitive diagnostic methods.

For recipients, HSCT guidelines discourage autologous and allogeneic SCTRs from international travel to the developing world for up to ≥2 years after transplant [49].To reduce the risk of malaria infection after HSCT, they should be informed about the risks of international travel and the importance of seeking pre-travel health advice [50, 51].

Treatment

The choice of drug therapy is based on the *Plasmodium species* involved and case severity. If malaria is confirmed without species determination, effective treatment against *P. falciparum* must be initiated without delay. A combination of two or more classes of antimalarial drugs with unrelated mechanisms of action is preferred. Full details on malaria treatment are provided by the WHO [52] and CDC [53].
